Leishmania (Viannia) braziliensis is responsible for the largest number of American tegumentary leishmaniasis (ATL) in Brazil. ATL can present several clinical forms including typical (TL) and atypical (AL) cutaneous and mucocutaneous (ML) lesions. To identify parasite and host factors potentially associated with these diverse clinical manifestations, we first surveyed the expression of two virulence-associated glycoconjugates, lipophosphoglycan (LPG) and the metalloprotease GP63 by a panel of promastigotes of Leishmania braziliensis (L. braziliensis) strains isolated from patients with different clinical manifestations of ATL and from the sandfly vector. We observed a diversity of expression patterns for both LPG and GP63, which may be related to strain-specific polymorphisms. Interestingly, we noted that GP63 activity varies from strain to strain, including the ability to cleave host cell molecules. We next evaluated the ability of promastigotes from these L. braziliensis strains to modulate phagolysosome biogenesis in bone marrow-derived macrophages (BMM), by assessing phagosomal recruitment of the lysosome-associated membrane protein 1 (LAMP-1) and intraphagosomal acidification. Whereas, three out of six L. braziliensis strains impaired the phagosomal recruitment of LAMP-1, only the ML strain inhibited phagosome acidification to the same extent as the L. donovani strain that was used as a positive control. While decreased phagosomal recruitment of LAMP-1 correlated with higher LPG levels, decreased phagosomal acidification correlated with higher GP63 levels. Finally, we observed that the ability to infect and replicate within host cells did not fully correlate with the inhibition of phagosome maturation. Collectively, our results revealed a diversity of strain-specific phenotypes among L. braziliensis isolates, consistent with the high genetic diversity within Leishmania populations.

Keywords: Leishmania braziliensis, virulence, lipophosphoglycan, GP63, macrophage, phagosome, intracellular survival

INTRODUCTION

The various species of the protozoan parasite Leishmania cause a spectrum of human diseases ranging from a relatively confined cutaneous lesion to a progressive and potentially fatal visceral infection (Alvar et al., 2012). Upon delivery in the vertebrate host by an infected sand fly, metacyclic Leishmania promastigotes are engulfed by phagocytes. To avoid destruction, these
parasites have evolved efficient means of disarming the microbialidal functionality of their host cells (Arango Duque and Descoteaux, 2015; Podinovskaia and Descoteaux, 2015; Atayde et al., 2016; Martínez-López et al., 2018). To achieve this, infectious promastigotes rely on a panoply of virulence factors including two abundant components of their surface coat, the glycolipid lipophosphoglycan (LPG) and the GPI-anchored zinc metalloprotease GP63 (Moradin and Descoteaux, 2012; Olivier et al., 2012; Arango Duque and Descoteaux, 2015; Atayde et al., 2016). The use of mutants defective in either LPG or GP63 revealed that these molecules are indeed important for the colonization of phagocytic cells by promastigotes of Leishmania donovani (L. donovani) (Desjardins and Descoteaux, 1997; Lodge et al., 2006), Leishmania major (L. major) (Spáth et al., 2000; Joshi et al., 2002), and Leishmania infantum (L. infantum) (Lázaro-Souza et al., 2018), all of which live in tight individual vacuoles. These virulence factors exert a profound impact on infected cells, altering signaling pathways (Descoteaux et al., 1991; Shibayama et al., 2012), inducing the production of inflammatory cytokines (Arango Duque et al., 2014), activating the inflammasome (de Carvalho et al., 2019), and inhibiting phagolysosomal biogenesis and functionality (Desjardins and Descoteaux, 1997; Spáth et al., 2003; Lodge et al., 2006; Vinet et al., 2009; Matheoud et al., 2013; Matte et al., 2016). Of note, defective synthesis of LPG has no measurable effect on the ability of Leishmania mexicana (L. mexicana), which lives in large communal vacuoles, to replicate in cultured macrophages and cause lesions in mice (Ilg, 2000; Ilg et al., 2001). These findings underline the fact that the relative contribution of a given virulence factor in the ability of promastigotes to colonize mammalian hosts varies among Leishmania species.

Leishmania braziliensis (subgenus Viannia) is responsible for the largest number of American tegumentary leishmaniasis cases in Brazil (ATL) (Alvar et al., 2012; PAHO/WH10, 2017). ATL may exhibit several clinical forms including typical (TL), atypical (AL), and mucocutaneous (ML) lesions. TL can be confined at the bite site or metastasize to the oronasopharyngeal mucosa (Ilg et al., 2001). These lesions do not resemble classical TL lesions (round, ulcerated with elevated borders) and their ambiguous nature hinders correct diagnosis. Whether variations in GP63 and LPG levels are associated to the levels of LPG and GP63 in a panel of L. braziliensis strains and surveyed their ability to interfere with phagosome maturation.

**Materials and Methods**

**Ethics Statement**

This study was carried out in accordance with the recommendations of the Canadian Council on Animal Care on animal handling practices. Protocol #1706-07 was approved by the Comité Institutionnel de Protection des Animaux of the INRS-Institut Armand-Frappier. Leishmania braziliensis field strains were obtained from patients living in the Xakriabá indigenous community located in São João das Missões municipality, Minas Gerais State, Brazil. Isolates from other endemic areas were obtained from the outpatient care facility at Centro de Referência em Leishmanioses—Instituto René Rachou/FioCruz Minas from 1993 to 1998. Patient samples were obtained under informed consent procedures approved by the IRS Research Ethics Committee in Human Research, the National Committee for Research Ethics (Comissão Nacional de Ética em Pesquisa—CONEP) n° 355/2008, and the National Indian Foundation (Fundação Nacional do Índio—FUNAI) n° 149/CCEP/08.

**Cell Culture**

Bone marrow-derived macrophages (BMM) were obtained from the bone marrow of 6–8 week-old female C57BL/6 mice and differentiated in complete DMEM (containing L-glutamine (Life Technologies), 10% v/v heat-inactivated fetal bovine serum (FBS) (Life Technologies), 10 mM HEPES (Biohop) at pH 7.4, and penicillin-streptomycin (Life Technologies)) supplemented with 15% v/v L929 cell-conditioned medium (LCM) as a source of macrophage colony-stimulating factor. To render BMM quiescent prior to experiments, cells were transferred to tissue culture-treated plates containing glass coverslips for 16 h in complete DMEM without LCM (Descoteaux and Matlashewski, 1989). BMM were kept in a humidified 37°C incubator with 5% CO2.

**Promastigotes were grown in Leishmania medium [M199-1X (Sigma) with 10% heat-inactivated FBS, 40 mM HEPES at pH 7.4, 100 µM hypoxanthine, 5 µM hemin, 3 µM biotin, TABLE 1 | Leishmania strains used in this study.

Soares et al., 2002). Particle internalization was assessed via zymography, and detects GP63 proteolysis (Vinet et al., 2009; Arango Duque et al., 2013). Two hours post-internalization, infected macrophages were washed 3X with 1 ml warm DMEM to remove non-internalized promastigotes. Macrophages were either left at 37°C for an extra 22 h, or prepared for confocal microscopy. To assay phagosome acidification, BMM were incubated for 2 h with the acidotropic LysoTracker Red dye (diluted 1:1,000; Molecular Probes) before the 2 h infection. In the case of the 24 h infection, infected macrophages were incubated in diluted LysoTracker for 2 h prior to the infection time point. Cells were then washed and fixed.

For intracellular colonization assays, 6, 24, and 72 h-infected BMM seeded on cover slips were washed with PBS1X, stained with the Hema 3™ Stain Pack (Fisher), briefly washed with deionized water, and air-dried for 10 min. Cover slips were mounted onto a drop of Fluoromount-G and sealed. Images were acquired with a Qimaging camera (Teledyne Technologies International Corp) mounted on a Nikon Eclipse E800 microscope (60X objective). Images were compiled and analyzed with the ImageJ (Rueden et al., 2017) interphase of the Icy image analysis software (de Chaumont et al., 2012). Threshold segmentation was used to differentiate and enumerate BMM and intracellular Leishmania nuclei.

Confocal Immunofluorescence Microscopy
Infected cells on coverslips were fixed with 2% paraformaldehyde (Thermo Scientific) for 20 min and blocked and permeabilized for 17 min with a solution of 0.1% Triton X-100, 1% BSA, 6% non-fat milk, 20% goat serum, and 50% FBS. This was followed by a 2 h incubation with a monoclonal rat antibody to Lysosome-associated membrane protein 1 (LAMP-1) (developed by J. T. August (1D4B) and purchased through the Developmental Studies Hybridoma Bank at the University of Iowa and the National Institute of Child Health and Human Development) diluted 1:200 in PBS1X. Subsequently, cells were incubated for 35 min in a solution containing an anti-rat antibody conjugated to Alexa-488 (diluted 1:500; Molecular Probes) and DAPI (1:40,000; Molecular Probes). Coverslips were washed three times with PBS1X after every step. After the final wash, coverslips were mounted cell-side facing a drop of Fluoromount-G (Southern Biotechnology Associates) that was placed on a glass slide (Fisher); coverslips were sealed with nail polish (Sally Hansen).

Infected macrophages were imaged with the 63X objective of an LSM780 confocal microscope (Carl Zeiss Microimaging) and image processing was done with the ZEN 2012 software. In regards to LysoTracker-treated cells, fixed samples were incubated in diluted DAPI for 35 min prior to mounting. Recruitment was evaluated by scoring the presence of staining on the phagosome membrane (LAMP-1) and/or the phagosome lumen (LysoTracker) (Vinet et al., 2009; Arango Duque et al., 2014). One hundred phagosomes per coverslip were scored for every experimental condition, each done in duplicate.

Electrophoresis, Western Blotting, and Zymography
Before lysis, stationary phase promastigotes, or infected BMM were washed with cold PBS1X containing 1 mM sodium orthovanadate and 5 mM 1,10-phenanthroline (Sigma). Pelleted parasites were resuspended in a lysis buffer containing 1% NP-40, 50 mM Tris-HCl (pH 7.5), 150 mM NaCl, 1 mM EDTA (pH 8), 15 mM 1,10-phenanthroline and protease inhibitors (Roche). Samples were incubated at 4°C, sonicated with 20 s and thereafter centrifuged at 4°C for 15 min to remove insoluble material. After protein quantification, 30 µg of protein (10 µg in the case of promastigote lysate) was boiled (100°C) for 6 min in SDS sample buffer and migrated in SDS-PAGE gels. Proteins were transferred onto PVDF (phosphoglycan blots) or nitrocellulose membranes and thereafter blocked for 2 h in TBS1X-0.1% Tween containing 5% BSA. Membranes were subsequently probed (overnight at 4°C) with a mouse mAb (CA7AE; Cedarlane) that recognizes unbranched Galβ1,4Manα1-PO4 phosphoglycan moieties (Tolson et al., 1989), and detects L. braziliensis LPG (Vieira Td et al., 2019). Membranes were also probed for the presence of GP63 (mouse mAb #235 targeting the membrane-anchored version of L. major GP63) (Button et al., 1993; Macdonald et al., 1995); VAMP8 and syntaxin-5 (Stx5) (rabbit pAbs from Synaptic Systems). Anti-L. donovani aldolase (rabbit pAb, a kind gift from A. Jardim) and β-actin (Sigma) were used as loading controls. After washing, membranes were probed with suitable HRP-conjugated secondary antibodies for 1 h at room temperature, and incubated in ECL (GE Healthcare). Immunodetection was achieved via chemiluminescence (Arango Duque et al., 2014). To assess GP63 proteolysis via zymography, lysates were incubated at 50°C for 5 min in sample buffer without DTT, and then migrated in 10–12% SDS-PAGE gels containing 0.12% gelatin (Sigma) (Hassani et al., 2014; Arango Duque et al., 2019). Gels were incubated for 2 h in the presence of 50 mM Tris pH 7.4, 2.5% Triton X-100, 5 mM CaCl2 and...
1 mM ZnCl$_2$, followed by an overnight incubation at 37°C in a buffer containing 50 mM Tris pH 7.4, 5 mM CaCl$_2$, 1 mM ZnCl$_2$, and 0.01% NaN$_3$. Protease activity was visualized by gradually destaining gels that were incubated in 0.5% Coomassie Brilliant blue (Sigma) for 1 h.

**Statistical Analysis**

Statistical differences in recruitment levels were assessed using one-way ANOVA followed by Bonferroni post-hoc tests. Data were considered statistically significant when $p < 0.05$ and univariate column scatter graphs were constructed using GraphPad Prism 6.0 (GraphPad Software Inc).

**RESULTS**

Expression of LPG and GP63 Varies Among Strains of *L. braziliensis*

The ability of *Leishmania* promastigotes to colonize host cells and impair phagosome maturation and functionality is mediated to a large extent by the virulence factors LPG and GP63 (Chaudhuri et al., 1989; Späth et al., 2003; Moradin and Descoteaux, 2012; Atayde et al., 2016; Matte and Descoteaux, 2016). Here, we sought to determine the relative levels of LPG and GP63 expressed by promastigotes of a panel of *L. braziliensis* strains differing in their origin (Table 1). We included in our analysis *L. major* (NIH Seidman A2) and *L. donovani* (LV9) promastigotes as controls. Western blot analysis performed on promastigote lysates showed notable variations in the levels of LPG among the tested strains (Figure 1). Particularly, whereas the levels of LPG expressed by *L. braziliensis* RR410 were similar to those observed for *L. donovani* LV9, the levels detected in the other *L. braziliensis* strains were lower. In the case of GP63, we observed important differences among the *L. braziliensis* strains (Figure 1). Both *L. braziliensis* strains RR051 and M15991 expressed GP63 at levels comparable to those observed for *L. donovani* LV9. In contrast, GP63 levels were very low in the other strains. Interestingly, when we assessed the proteolytic activity of GP63 present in the *Leishmania* promastigotes lysates, we observed a lack of correlation with the GP63 levels detected by Western blot (Figure 1). Notably, *L. braziliensis* strains with low levels of GP63 (M2903 and RR418) showed high GP63 proteolytic activity, whereas *L. braziliensis* strains expressing higher GP63 levels (RR051 and M15991) showed reduced GP63 activity. These observations clearly demonstrated important intra-specific variations in the levels of detected LPG and GP63 (as well as GP63 activity) expressed by *L. braziliensis* strains isolated from patient with diverse ATL manifestations and from the insect vector.

### Cleavage of GP63 Substrates by *L. braziliensis* Strains

Given the variations in GP63 levels and activity observed among the *L. braziliensis* isolates, we investigated the impact of these differences on the cleavage of phagosomal host cell proteins known to be targeted by GP63 (Matheoud et al., 2013). To this end, we performed Western blot analyses to assess the levels and integrity of the soluble N-ethylmaleimide-sensitive-factor attachment protein receptors (SNAREs) VAMP8 and Stx5, in lysates of BMM infected for 6 h with promastigotes of selected *L. braziliensis* strains (M2903, RR418, M15991, and M8401) and promastigotes of *L. major* NIH A2 as control. As shown in Figure 2, VAMP8 was cleaved to the same extent by all *L. braziliensis* strains and by *L. major* NIH A2, regardless of the levels and activity of GP63 detected in the cell lysates. In contrast, cleavage of the endoplasmic reticulum (ER)- and Golgi-resident SNARE Stx5 was strain-dependent and did not entirely correlate with the levels and activity of GP63 detected in the cell lysates (Figure 2). Collectively, these results indicate that cleavage of host cell GP63 substrates occurs in BMM infected with all *L. braziliensis* strains tested, albeit with some differences in the extent of cleavage. These findings also suggest that sensitivity to GP63 cleavage is substrate-specific.

### *L. braziliensis* Impairs Phagosome Recruitment of LAMP-1 in a Strain-Specific Manner

Given the variations observed among our panel of *L. braziliensis* strains in LPG and GP63 levels and activity, as well as substrate cleavage, we investigated the impact of *L. braziliensis* promastigotes on phagosome maturation. To this end, we incubated BMM with promastigotes from our panel of *L. braziliensis* strains for 2 and 24 h and assessed the
recruitment of the lysosomal marker LAMP-1 to phagosomes. Promastigotes of *L. donovani* (LV9 strain), which efficiently inhibit phagosome maturation and phagosomal recruitment of LAMP-1 (Scianimanico et al., 1999), and zymosan were used as controls. At 2 h after the initiation of phagocytosis, we observed a higher recruitment of LAMP-1 to phagosomes containing *L. braziliensis* strains RR051 and M15991 compared to phagosomes containing *L. donovani* LV9 (Figures 3A,B). As expected, recruitment of LAMP-1 to phagosomes containing zymosan was higher to that observed for phagosomes induced by promastigotes of *L. donovani* LV9 and of those from *L. braziliensis* isolated from an AL lesion (RR410) (Figure 3). At 24 h post-infection, the presence of LAMP-1 on phagosomes harboring *L. donovani* promastigotes LV9 remained very low, as was also the case for phagosomes containing *L. braziliensis* M2903, RR410, and RR418. However, recruitment of LAMP-1 to phagosomes harboring *L. braziliensis* RR051 and M8401 was significantly higher than the levels observed for phagosomes containing the other *L. braziliensis* strains and *L. donovani* LV9 (Figure 3). These results suggest that the ability *L. braziliensis* promastigotes to interfere with phagosome maturation varies among strains.

**Phagosome Acidification Is Differentially Modulated by *L. braziliensis* Strains**

Consistent with their ability to inhibit phagolysosome biogenesis (Desjardins and Descoteaux, 1997), we previously reported that *L. donovani* promastigotes efficiently impair phagosome acidification (Vinet et al., 2009). To further characterize the impact of *L. braziliensis* promastigotes on phagosome maturation, we used the lysotropic dye LysoTracker Red to monitor acidification kinetics of phagosomes harboring the various *L. braziliensis* strains. Consistent with previous studies, at 2 h post-infection, acidification occurred in the majority of zymosan-harboring phagosomes but was hindered in phagosomes containing *L. donovani* LV9 promastigotes (Figures 4A,B). Similar impairment of phagosome acidification was observed for all *L. braziliensis* strains, with the exception of the strain isolated from an AL lesion (RR410) (Figures 4A,B). At 24 h post-infection, most phagosomes harboring *L. donovani* LV9 (80%) and the *L. braziliensis* ML isolate (M15991) (70%) remained negative for LysoTracker Red (Figure 4). In contrast, over 70% of phagosomes containing *L. braziliensis* isolates RR418 and RR410 were positive for LysoTracker Red at 24 h (Figure 4B). These data indicate that most *L. braziliensis* strains in our panel inhibit phagosome acidification during the early phase of macrophage infection. However, at later time points, the capacity to hinder phagosome acidification varies in a strain-specific manner.

**Colonization of Macrophages by *L. braziliensis* Strains Does Not Fully Correlate With the Ability to Inhibit Phagosome Maturation and Acidification**

Previous studies with *L. donovani* and *L. major* (Desjardins and Descoteaux, 1997; Späth et al., 2003; Vinet et al., 2009) revealed a correlation between the ability of these parasites to impair phagosome maturation and the ability to colonize macrophages. To investigate whether such a correlation exists for the *L. braziliensis* strains under study, we incubated BMM for 2 h with promastigotes of selected strains (M2903, RR418, M15991, and M8401) and promastigotes of *L. major* NIHs A2 as control. We then quantified the number of parasites per 100 macrophages and the percentage of infected macrophages at 6, 24, and 72 h post-phagocytosis. As shown in Figure 5, the ability to survive and replicate over time within BMM varied among the *L. braziliensis* strains analyzed. At the exception of strain M2903, which displayed reduced ability to survive in BMM over 72 h, all the other strains persisted and two of them (RR418 and M8401) replicated as was the case for *L. major* NIHs A2. Interestingly, *L. braziliensis* strain M2903, which survived poorly in BMM,

Bars depict the mean ± SEM of % positive phagosomes counted over three independent experiments done in duplicate. *p < 0.05; **p < 0.01; ***p < 0.001; ****p < 0.0001. *Ld*, *L. donovani*; *Lb*, *L. braziliensis*. 
Intracellular survival and replication of *L. braziliensis* parasites. BMM were infected with opsonized stationary phase promastigotes from selected *L. braziliensis* strains, and intracellular survival was quantified in Hema 3-stained cells. (A) Representative images of the 72 h time point. Scale bar = 10 μm. Intracellular survival at 6 (green dots), 24 (blue dots), and 72 h (red dots) post-infection was assessed via the quantification of internalized parasites in 100 macrophages (B) and the percentage of infected cells (C). In both (B,C), bars depict the mean ± SEM of two independent experiments done in triplicate coverslips. **p < 0.01; ***p < 0.001. *Lm*, *L. major*; *Lb*, *L. braziliensis*.
was among the most efficient strains at inhibiting phagosome maturation (Figures 3, 4). For strains RR418 and M8401, their ability to replicate in BMM correlated with their capacity to impair the phagosomal recruitment of LAMP-1 and acidification during the early phases of infection (Figures 3, 4). These data are consistent with the notion that factor(s) other than the capacity to impair phagosome maturation are required for colonization of host cells by *L. braziliensis*.

**DISCUSSION**

The *Leishmania* virulence factors LPG and GP63 contribute to the ability of promastigotes to colonize phagocytic cells by targeting key host cell host defense mechanisms, including the biogenesis of microbicidal phagolysosomes. In the present study, we sought to examine the levels of LPG and GP63 expressed by promastigotes of *L. braziliensis* (subgenus Viannia) strains isolated from patients exhibiting various clinical manifestations of ATL and from the insect vector. We also characterized the ability of these *L. braziliensis* strains to impair phagosome maturation and to infect and replicate within macrophages.

Our results revealed an unexpected diversity of expression patterns for both LPG and GP63 among the evaluated *L. braziliensis* strains. Although some strains expressed LPG levels similar to those of *L. donovani* LV9 promastigotes, other strains expressed very low LPG levels. Similarly, some *L. braziliensis* strains expressed GP63 levels comparable to those observed in *L. donovani* LV9, whereas other strains expressed very low GP63 levels. Interestingly, we noted that GP63 activity varies from strain to strain, and does not correlate with GP63 levels detected by Western blot. Whether the polymorphisms detected in the GP63 genes of *L. braziliensis* (Medina et al., 2016) affected the recognition of GP63 by our anti-GP63 antibody is however unclear. Clearly, the significance of these observations deserves to be further investigated.

As part of their strategy to colonize host phagocytes, *Leishmania* promastigotes alter the composition and properties of the parasitophorous vacuole (Moradin and Descoteaux, 2012; Séguin and Descoteaux, 2016). Phagosomal recruitment of the lysosomal protein LAMP-1 is a widely used marker of phagosome maturation (Huynh et al., 2007). In the case of *Leishmania* promastigotes, delayed phagosomal acquisition of LAMP-1 following phagocytosis supported the notion that these parasites impair phagolysosomal biogenesis (Scianimanico et al., 1999; Lerm et al., 2006; Verma et al., 2017). Interestingly, we found that the ability to inhibit the phagosomal recruitment of LAMP-1 varies significantly among our panel of *L. braziliensis* strains. Phagosomal acidification is an important consequence of the maturation process and we previously reported that it is efficiently inhibited by *L. donovani* promastigotes (Vinet et al., 2009). Similar to the recruitment of LAMP-1, we observed an important variation among promastigotes of the *L. braziliensis* strains tested in their capacity to inhibit phagosomal acidification. Interestingly, whereas promastigotes of *L. donovani* LV9 efficiently inhibited both phagosome acidification and recruitment of LAMP-1, we observed no correlation between the ability to inhibit phagosomal recruitment of LAMP-1 and phagosome acidification among the *L. braziliensis* strains. Previous work from our group revealed that acquisition of LAMP-1 and of the v-ATPase by phagosomes occurs through two distinct mechanisms (Vin et al., 2009). In the case of *L. donovani*, LPG is the molecule responsible for inhibiting both the phagosomal recruitment of LAMP-1 and acidification (Scianimanico et al., 1999; Vin et al., 2009). However, the ability of *L. braziliensis* strains to interfere with phagosome maturation does not appear to correlate with LPG levels.

In addition to LPG, *Leishmania* promastigotes use the metalloprotease GP63 to modulate the composition and function of phagosomes through the cleavage of host proteins such as VAMP3, VAMP8, and Synaptotagmin XI (Matheoud et al., 2013; Arango Duque et al., 2014; Gasgrain et al., 2016; Matte and Descoteaux, 2016; Matte et al., 2016). Since VAMP8 is required for antigen cross-presentation (Matheoud et al., 2013), its cleavage by the various *L. braziliensis* strains suggests that they efficiently inhibit antigen cross-presentation. Future experiments will specifically address this issue. On the other hand, the endoplasmic reticulum- and Golgi-resident SNARE Stx5 is partially cleaved, to varying extents, by our *L. braziliensis* strains. This SNARE regulates trafficking between the phagosome and the secretory pathway (Cebrian et al., 2011; Arango Duque et al., 2019) and contributes to the expansion of communal parasitophorous vacuoles harboring *L. amazonensis* (Canton and Kima, 2012). The significance of its cleavage by *L. braziliensis* for establishment and replication within macrophages is an issue that will deserve further investigation.

In *L. braziliensis*, GP63 is present on chromosome 10 and strains isolated from different clinical manifestations from the same geographical region have conserved domains and display specific polymorphisms in their catalytic sites (Medina et al., 2016; Sutter et al., 2017; Quaresma et al., 2018). This variability could result in different virulence patterns and clinical outcomes. Of interest, a recent genomic analysis of *Leishmania* clinical isolates revealed important differences among genetically highly related *Leishmania* strains, including both in amplification and in loss of genes linked to parasite infectivity such as GP63 (Bussotti et al., 2018). Whether the diversity of GP63 levels and activity portrayed by the *L. braziliensis* strains is the consequence of gene amplification associated to environmental adaptation is a likely possibility that deserves further investigation. Similar to LPG and GP63, GPIs are highly expressed on the *Leishmania* surface (Assis et al., 2012). They are inhibitory molecules impairing NO and cytokine production by murine macrophages and their role on phagosome maturation and intracellular survival will be assayed in prospective studies. Together, our findings underline the importance of performing functional genetic analyses with these clinical *L. braziliensis* strains to directly assess the importance of LPG and GP63 in the colonization of host phagocytes, and ultimately in the pathogenesis of ATL.

For the past several decades, research on virulence or immune subversion mechanisms of *Leishmania* has been for the most part performed with reference or laboratory strains. Results obtained with those strains allowed for the discovery of several biological processes. For instance, the Th1/Th2 dichotomy and
the importance of IL-4 in mediating susceptibility to infection were discovered using a particular L. major strain (Heinzel et al., 1989). However, studies using other L. major strains led to opposite results (Noben-Trauth et al., 1996, 1999). In the case of L. braziliensis ATL strains, our study revealed an unexpected diversity in terms of expression of virulence molecules and ability to interfere with phagosome maturation. Clearly, these studies highlight the fact that it is important to exert caution when drawing broad conclusions based on observations obtained with a single strain or isolate of a given Leishmania species.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the supplementary files.

ETHICS STATEMENT

Mice were manipulated under the guidelines of protocol 1706-07 of the Comité Institutionel de Protection des Animaux of the INRS-Institut Armand-Frappier, which respects animal handling practices promulgated by the Canadian Council on Animal Care. Leishmania braziliensis field strains were obtained from patients living in the Xakriabá indigenous community located in São João das Missões municipality, Minas Gerais State, Brazil. Isolates from other endemic areas were obtained from the outpatient care facility at Centro de Referência em Leishmanioses—Instituto René Rachou/Fiocruz Minas from 1993 to 1998. Patient samples were obtained under informed consent procedures approved by the IRB Research Ethics Committee in Human Research, the National Committee for Research Ethics (Comissão Nacional de Ética em Pesquisa—CONEP) n° 355/2008, and the National Indian Foundation (Fundação Nacional Índio—FUNAI) n° 149/CGEP/08.

AUTHOR CONTRIBUTIONS

GA, TS, RS, and AD conceived and designed the study, contributed to the data analysis, and drafted and revised the manuscript. GA, TS, and AD performed the experiments. CG provided the L. braziliensis strains. GA, TS, RS, and AD wrote and revised the manuscript. All authors read and approved the final version of this manuscript.

FUNDING

This work was supported by the Canadian Institutes of Health Research (CIHR) (grants PJT-156416 and MOP-125990 to AD), by the Conselho Nacional de Pesquisa e Desenvolvimento (CNPq) (grant 305065/2016-5 to RS), and the Fundação de Amparo do Estado de Minas Gerais (FAPEMIG) (grant 00202-18 to RS). AD was the holder of the Canada Research Chair on the Biology of intracellular parasitism. TS was the recipient of a scholarship from FAPEMIG and from the Emerging Leaders in the Americas Program (Global Affairs Canada). GA was supported by a CIHR Banting and Best Doctoral Award.

ACKNOWLEDGMENTS

We thank W. R. McMaster (University of British Columbia) for providing antibodies against GP63, A. Jardim (McGill University) for providing the aldolase antiserum, and J. Tremblay for assistance with confocal immunofluorescence experiments.
