We provide a succesful fit for neutron-proton scattering below pion production threshold up to LAB energies of 350MeV. We use seven high-quality fits based on potentials with different forms as a measure of the systematic uncertainty. We represent the interaction as a sum of delta-shells in configuration space below the 3fm and a charge dependent one pion exchange potential above 3fm together with electromagnetic effects. Special attention is payed to estimate the errors of the phenomenological interaction.

Keywords: Potential Scattering, np interaction, One Pion Exchange

The study of the NN interaction has been a central and recurrent topic in Nuclear Physics for many years (see e.g. [1,2] and references therein). The standard approach to constrain the interaction is to analyze NN scattering data below pion production threshold and to undertake a partial wave analysis (PWA), the quality of the fit being given by the \( \chi^2 / \text{d.o.f} \) value. Only by the mid 90’s was it possible to fit about 4000 selected NN scattering data after discarding about further 1000 of 3σ inconsistent data with a \( \chi^2 / \text{d.o.f} \lesssim 1 \) and incorporating charge dependence (CD) for the One Pion Exchange (OPE) potential as well as magnetic and vacuum polarization effects [3]. This benchmark partial wave analysis (PWA) was carried out using an energy dependent potential for the short range part for which nuclear structure calculations become hard to formulate. Thus, energy independent high quality potentials were subsequently produced with almost identical \( \chi^2 / \text{d.o.f} \sim 1 \) for a gradually increasing database [4–7]. While any of these potentials provides individually satisfactory fits to the available data there are no published error estimates of the potential parameters. Moreover it should also be noticed that the existing high-quality potentials are different in their specific form; they range from local to non-local in different versions of nonlocality. Thus, scattering phase-shifts and observable amplitudes are not identical and in fact the existing set of high quality potentials as a whole provides a distribution of scattering observables accounting for systematic uncertainties in addition to the statistical uncertainties obtained from the fitted data for each individual potential. Given the fact that these interactions are just constrained to the elastic scattering data (and eventually to the deuteron) which go up to the pion production threshold, one is physically probing the interaction with a resolution not finer than the shortest de Broglie wavelength \( \Delta \lambda = h / \sqrt{M_N m_\pi} \sim 0.5\text{fm} \). Thus, for practical purposes it may be advantageous to consider coarse grained interactions [12]. This is actually the physics underlying the so-called \( V_{\text{lowk}} \) approach [8] in which an effective interaction in a restricted model space is built. By starting from different high-quality potentials with a common charge dependent OPE interaction, the CM-momenta above \( \Lambda \sim \sqrt{M_N m_\pi} \) are eliminated by a suitable transformation and a remarkable universal interaction is obtained for \( p \leq \Lambda \). Many of the applications of such an appealing interaction have recently been reviewed [9].

On the other hand, when switching from the NN problem to the many body nuclear problem the features and the form of the interaction are relevant in terms of computational cost and feasibility (see e.g. [10] and references therein). The lack of knowledge of a precise potential form with finer resolution than \( \Delta r \sim 0.5\text{fm} \) suggests to search for a description of scattering data directly in terms of a coarse grained potential sampled at some sensible “thick points”. Any sampling procedure necessarily redistributes the interaction strength and smoothes the potential as compared to the zero resolution limit \( \Delta r \to 0 \) implicit in most potential approaches and generating the troublesome short distance cores. This requires short distance correlations in the wave function to ensure the finiteness of the energy [10]. A desirable way to sample the interaction is to provide an acceptable \( \chi^2 \)-fit with the minimal number of sampling points [11]; by implementing this minimal sampling we just try to avoid statistical dependence between the strengthes of the potential at the chosen sampling points. Our motivation to proceed in this fashion is to make error propagation in nuclear structure calculations more direct since in the absence of statistical correlations errors may just be added in quadrature [12].

In the present work we provide another high-quality potential accommodating these desirable features and (unlike the previous approaches) we undertake an analysis of the systematic errors. We do this by assuming that the systematic error inherent to any specific choice of the potential form corresponds to individual uncorrelated measurements [1]. Hence we

---

1 We have actually checked that, within the corresponding statistical uncertainty, the absence of correlations among the different partial waves of the PWA and the six high quality potentials by a direct evaluation of the correlation coefficient (see Ref. [11] for a definition) holds for every single LAB energy below 350MeV.
V component of the NN interaction was already suggested by FIG. 1. np phase shifts in degrees with in coupled channels is straightforward; for any long-distance tail of the NN potential may invoke the central limit theorem to undertake the traditional statistical treatment to the mean average and the corresponding standard deviation of Refs. [3–7] without any further ado. We will use this compilation as our database.

A convenient representation to sample the the short distance component of the NN interaction was already suggested by Aviles [13] almost 40 years ago in terms of delta-shells which for any partial wave \(\ell \ell' l' I J \) we take as

\[
V_{\ell \ell' I J}^{l S}(r) = \frac{1}{2\mu_{np}} \sum_{n=1}^{N} (\lambda_n)^S_{l I J} \delta(r - r_n) \quad r \leq r_c
\]

(1)

with \(\mu_{np}\), the reduced np-mass and \(r_c\) to be specified below. In the spirit of Refs. [3–7], for \(r \geq r_c\) we use the well known long-distance tail of the NN potential

\[
V(\vec{r}) = V_{EM}(\vec{r}) + V_{OPE}(\vec{r}), \quad r > r_c,
\]

(2)

where \(V_{EM}\) is the electromagnetic potential of Ref. [5], and \(V_{OPE}\) is the one-pion-exchange potential.

The solution of the corresponding Schrödinger equation in coupled channels is straightforward; for any \(r_n < r < r_{n+1}\) with \(r_n < r_c\) we have free particle solutions and logarithmic derivatives are discontinuous at the \(r_n\)-points so that one generates an accumulated S-matrix at any sampling point providing a discrete version of Calogero’s variable phase equation [14]. Although this potential is formally local, the fact that we are coarse graining the interaction enables to encode efficiently nonlocalities operating below the finest resolution \(\Delta r\). Of course, once we admit that the interaction below \(r_c\) is unknown there is no advantage in prolonging the well-known charge-dependent OPE tail and other electromagnetic effects for \(r < r_c\). The low energy expansion of the discrete variable phase equations was used in Ref. [15] to determine threshold parameters in all partial waves. The relation to the well-known Nyquist theorem of sampling a signal with a given bandwidth has been discussed in Ref. [16]. Some of the advantages of using this simple potential for Nuclear Structure calculations as well as the connection to the \(V_{lowk}\) approach have been spelled out already [17].

We use the LAB energy values usually listed in the high-quality potentials, namely \(E_{LAB} = 1, 5, 10, 25, 50, 100, 150, 200, 250, 300, 350\) MeV and fit to the mean phase-shift values at those energies with an error equal to the standard deviation. This energy grid is sufficiently dense to account for the systematic errors due to the different representations of the potentials [3–7]. We find that

\[
\begin{array}{cccccc}
E_{LAB}[\text{MeV}] & \text{1S0} & \text{1P1} & \text{1P2} & \text{1P3} & \text{1P4} \\
0 & 0 & 0 & 0 & 0 & 0 \\
5 & 0 & 0 & 0 & 0 & 0 \\
10 & 0 & 0 & 0 & 0 & 0 \\

they are generally larger than those quoted by the original PWA where only statistical uncertainties where explicitly discussed for a fixed potential form [3]. With these data sets and the given energies we undertake a phase-shift fit and determine errors using the standard covariance matrix.

As expected from Nyquist sampling theorem, we need at most \(N = 5\) sampling points which for simplicity are taken to be equidistant with \(\Delta r = 0.6\) fm between the origin and \(r_c = 3\) fm. This is the minimal number which provides an acceptable fit to the data compiled from Refs. [3–7]. Our results for the np phase-shifts for all partial waves with total angular momentum \(J \leq 5\) are depicted in Fig. [1] The fitting parameters \(\lambda_n^{JS}_{l,l'}\) entering the delta-shell potentials, Eq. (1), are listed in Table [I] with their deduced uncertainties. Of course, a
FIG. 2. Some np scattering observables for several energies in the laboratory system as a function of the CM angle. The short-dashed line denotes the predictions by our delta-shell model. The band represents the compilation the six high quality potentials [3–7] which provided a $\chi^2$/d.o.f $\lesssim 1$. For references for the experimental data see http://nn-online.org and http://gwdac.phys.gwu.edu/. The notation is as follows: $I_0$ differential cross section, $P$ polarization, $D$ depolarization, $R$ rotation parameter, $A_t$, $D_t$, and $R_t$, polarization transfer parameters, $C_{nn}$ spin correlation parameter. For notation and further explanations see Refs. [24, 25]

definitive assessment on systematic errors would require testing all possible potential forms. Thus, the errors will generally be larger than those estimated here. We find that correlations among the different $(\lambda_n)^{JS}_{l,l'}$ values within a given partial wave channel are unimportant, and hence these parameters are essentially independent from each other. This is a direct consequence of our strategy to minimize the number of sampling points. We find that introducing more points or equivalently reducing $\Delta r$ generates unnecessary correlations. Also, lowering the value of $r_c$ below 3fm, requires overlapping the short-distance potential, Eq. (1), with the OPE plus em corrections.

We determine the deuteron properties by solving the bound state problem in the $3S_1 - 3D_1$ channel using the corresponding parameters listed in Table I. The predictions are presented in Table III where our quoted errors are obtained from propagating Table II. The comparison with experimental values or high quality potentials where the binding energies are used as
an input is satisfactory. This is partly due to the fact that theoretical errors are about 10%. Of course, one may improve on this by using the deuteron binding energy as an input as in Refs. [3–7].

Fitting to phase-shifts to some accuracy does not necessarily provide angle dependent scattering amplitudes to the same accuracy because errors are finite and the relation between phase shifts and observables is non-linear. This is often the case when the form of the potential is kept fixed, so that the channel by channel fit is usually taken as a first step which is afterwards refined by a full fledged analysis of differential or scattering observables and polarization data [26] for an exact analytical inversion). We follow an mined directly from experiment as shown in Ref. [24, 25] (see also [28] for an exact analytical inversion). We follow an alternative procedure and construct, out of the high-quality results as the Wolfenstein parameters and denote generically as dependent complex quantities, which we choose for definite-

ten observables afterwards we proceed as follows. The complete on-shell np scattering amplitude contains five independent complex quantities, which we choose for definiteness as the Wolfenstein parameters and denote generically as dependent complex quantities, which we choose for definite-

ten observables afterwards we proceed as follows. The complete on-shell np scattering amplitude contains five independent complex quantities, which we choose for definiteness as the Wolfenstein parameters and denote generically as dependent complex quantities, which we choose for definite-

\[
\chi^2(E_{\text{LAB}}, \theta) = \frac{1}{d.o.f.} \sum_{i=1}^{10} \left( \frac{\Delta a_i(E_{\text{LAB}}, \theta)}{\Delta a_i(E_{\text{LAB}}, \theta)} \right)^2
\]

The total \( \chi^2 \) value is obtained as an average over the chosen reference energies \( E_{\text{LAB}} = 1, 5, 10, 25, 50, 100, 150, 200, 250, 300, 350 \text{ MeV} \) and a dense sampling of \( \theta \)-values. The result is

\[
\chi^2/d.o.f. = 0.78
\]

which is equivalent to carry a complete \( \chi^2 \)-fit to the mean average scattering amplitude. In Fig. [2] we illustrate the situation for a set of observables as a function of the CM angle and for several energies. One sees that our model 1) describes the data within experimental uncertainties and 2) it mostly agrees with the six high quality potentials [3–7] except marginally when no data are available.

To summarize, we have determined a high-quality neutron-proton interaction which is based on a few delta-shells for the lowest partial waves in addition to charge-dependent electromagnetic interactions and one pion exchange and provides a good starting point for Nuclear Physics applications. We provide error estimates on our fitting parameters accounting both for systematic and statistical uncertainties of present day high-quality analyses of neutron-proton scattering data. Deuteron properties are compatible with experimental or recommended values. Our method allows to coarse grain long-range Coulomb interactions in a rather natural way and hence to discuss proton-proton scattering data.

We want to thank D.R. Entem and M. Pavón Valderrama for a critical reading of the manuscript and Franz Gross for communications. This work is supported by Spanish DGI (grant FIS2011-24149) and Junta de Andalucía (grant FQM225). R.N.P. is supported by a Mexican CONACYT grant.
