**ABSTRACT**

Silver nanoparticles (AgNP) are widely used in consumer products, mostly due to their excellent antimicrobial properties. One of the well-established antibacterial mechanisms of AgNP is their efficient contact with bacteria and dissolution on cell membranes. To our knowledge, the primary mechanism of cell wall damage and the event(s) initiating bactericidal action of AgNP are not yet elucidated.

In this study we used a combination of different assays to reveal the effect of AgNP on i) bacterial envelope in general, ii) outer membrane (OM) and iii) on plasma membrane (PM). We showed that bacterial PM was the main target of AgNP in Gram-negative bacteria *Escherichia coli* and *Pseudomonas aeruginosa*. AgNP depolarized bacterial PM, induced the leakage of the intracellular K⁺, inhibited
respiration and caused the depletion of the intracellular ATP. In contrast, AgNP had no significant effect on the bacterial OM. Most of the adverse effects on bacterial envelope and PM occurred within the seconds and in the concentration range of 7–160 µM AgNP, depending on the bacteria and assay used, while irreversible inhibition of bacterial growth (minimal bactericidal concentration after 1-h exposure of bacteria to AgNP) occurred at 40 µM AgNP for *P. aeruginosa* and at 320 µM AgNP for *E. coli*.

Flow cytometry analysis showed that AgNP were binding to *P. aeruginosa* but not to *E. coli* cells and were found inside the *P. aeruginosa* cells. Taking into account that AgNP did not damage OM, we speculate that AgNP entered *P. aeruginosa* via specific mechanism, e.g., transport through porins.

**INTRODUCTION**

Silver nanoparticles (AgNP, 1-100 nm-sized) are most widely used NP in consumer products, mostly due to their excellent antimicrobial properties (1). However, the mechanisms of antibacterial action of AgNP are still under debate. Recent comprehensive review summarized four main proposed mechanisms of NP-bacteria interaction explaining the antibacterial effects of metal oxide NP including (i) generation of reactive oxygen species (ROS), (ii) partial dissolution and release of toxic metal ions, (iii) NP accumulation on membrane surface and (iv) internalization of
Bacterial plasma membrane is a target of silver nanoparticles

Although all these mechanisms have been shown to apply also in case of AgNP, the prevailing mechanism of toxic action of antibacterial properties of AgNP is the oxidative dissolution on bacterial surface (3). Indeed, in our previous study we showed that the interaction of NP with bacterial cell wall accompanied by the release of toxic Ag$^+$ ions that contributed significantly to the antibacterial mechanisms of various AgNP to different Gram-negative and Gram-positive bacteria (4). In addition, we observed that medically important pathogenic bacteria *Pseudomonas aeruginosa* were inherently more susceptible to AgNP (especially to the colloidal form of AgNP, Collargol) than *Escherichia coli* cells. The current study is a continuation of our previous work that aims to provide the detailed insights into the interactions of AgNP with Gram-negative bacteria *E. coli* and *P. aeruginosa* with the focus on the effects on bacterial cell membranes. We selected the colloidal form of AgNP, Collargol, as the model AgNP since it has a long history of usage and is prescribed as a medication in several countries (1).

Opportunistic pathogens *E. coli* and *P. aeruginosa* were selected as bacterial models. Both are Gram-negative bacteria, i.e., have two membranes in their cell envelope - the outer membrane (OM) and the plasma membrane (PM) that possess different composition and therefore, distinct functions (Fig. 1). OM is covered by the dense layer of highly negatively charged lipopolysaccharides (LPS) and serves as a selective permeability barrier. OM hinders the entrance of hydrophobic substances and macromolecules (5) but allows the entrance of small charged molecules into the periplasm through the porins - narrow channels for ions and nutrients. In contrast, PM is relatively permeable for hydrophobic compounds but not for the inorganic ions and hydrophilic compounds (6, 7). PM is of utmost importance for bacteria since all the membrane-related functions of prokaryotic cells are performed in the PM (e.g.,
Bacterial plasma membrane is a target of silver nanoparticles

respiratory chain functions, lipid biosynthesis, protein secretion and transport events) (5, 8).

To reach the PM of Gram-negative bacteria, Ag ion/AgNP should first pass OM. Most likely, Ag⁺ ions traverse the OM through porins (9, 10, 11). Next, Ag⁺ ions induce several successive toxic events targeting PM. For instance, Dibrov et al (12) showed that Ag⁺ ions induce a proton (H⁺) leakage through the membrane vesicles of *Vibrio cholerae*. Authors suggested that H⁺ leakage is the main mechanism behind the bactericidal action of Ag⁺ ions in *V. cholerae*, and assumed that it occurs due to the unspecific, Ag⁺-induced modification of proteins or phospholipid bilayer.

In contrast to Ag⁺ ions, the mechanism by which AgNP interact with the cells and possess the antibacterial effect is not yet convincingly revealed. It is hypothesised that AgNP enter the cells by creating irregular-shaped pits on bacterial surface, inducing the LPS release and damaging the bacterial OM (10, 13, 14, 15). These events allow the penetration on AgNP into periplasm where AgNP act similarly to Ag⁺ ions, i.e., destroy functions of SH-groups containing enzymes due to the very high affinity of Ag ions towards sulfur (15).

The main aim of this study was to investigate the effects of Ag ions (AgNO₃) and AgNP (Collargol, protein coated AgNP) on bacterial outer and plasma membranes in more detail. Effects of silver compounds on bacterial membranes were studied using different approaches: (i) bioluminescence inhibition assay to estimate the general damage of bacterial cell envelope and associated loss of energy (ATP) production; (ii) bacterial viability testing to determine minimal bactericidal concentration (MBC) of Ag compounds; (iii) flow cytometry to assess the bacteria-NP interaction and possible uptake of AgNP; (iv) 1-N-phenylnaphthylamine (1-NPN) assay to estimate the integrity of OM, (v) tetraphenylphosphonium (TPP⁺) assay to discriminate the
Bacterial plasma membrane is a target of silver nanoparticles

effect of Ag compounds on PM and OM and (vi) K⁺ content and respiration of cells to show the effects of Ag compounds on PM. All the assays addressed the short-term effects of studied compounds on cell envelope in general, bacterial OM or PM as depicted in Fig 1.

MATERIALS AND METHODS

Chemicals
All the chemicals were at least of analytical grade. Polymyxin B (PMB) was purchased from Sigma–Aldrich, 3,5-dichlorophenol (3,5-DCP) from Pestanal, AgNO₃ from J.T.Baker, protein (casein)-coated colloidal AgNP from Laboratorios Argenol S. L. (batch No 297), propidium iodide from Fluka, tetraphenylphosphonium chloride (TPP⁺) from Sigma–Aldrich. The stock solutions of AgNO₃ and AgNP were prepared at 2 mM (215.7 mg Ag/l, 20 ml) in autoclaved deionized (DI) water and further stored in the dark at +4 °C. The stock solutions were vortexed before each use. If not stated otherwise, all subsequent dilutions and experiments were performed in Ag⁺ ions non-complexing buffer consisting of 50 mM 3-(N-morpholino)propanesulfonic acid (MOPS) adjusted to pH 8 with (hydroxymethyl)aminomethane (Tris) and further referred as MOPS-Tris buffer.

Characterization of silver nanoparticles
The shape, primary size and coating (casein) content of AgNP were determined in our previous publication (16). Hydrodynamic size (measured by dynamic light scattering, DLS), polydispersity index (pdi) and ζ-potential in MOPS-Tris buffer were measured at concentration 200 mg/l using Malvern Zetasizer (Nano-ZS, Malvern Instruments, UK). Dissolution of AgNP was quantified using atomic absorption
Bacterial plasma membrane is a target of silver nanoparticles spectroscopy (AAS). For that AgNP were incubated in MOPS-Tris at concentration 10 mg/l for 10 min, 1 h or 24 h, ultracentrifuged (390,000 g, 30-60 min) and the supernatant was analyzed by GF-AAS in accredited (ISO/IEC, 2017 (17)) laboratory of the Institute of Chemistry of Tallinn University of Technology, Estonia. The ratio of determined dissolved Ag to total nominal metal in AgNP was designated as dissolution (%).

Bacterial strains and cultivation of bacteria

*E. coli* MC1061 (obtained from Prof. Matti Karp, Turku, Finland) and *P. aeruginosa* DS10-129 (isolated from soil, (18)) were used in all experiments. In addition, *Pseudomonas aeruginosa* PAO1 (obtained from Prof. Patrick Plesiat, Besanc, France) was used to confirm the results of TPP⁺, K⁺ and respiration assays. All cultivations were performed on a shaker at 200 rpm, 30°C. Bacteria were pre-grown overnight in 3 ml of NaCl-free Luria-Bertani medium (LB, 10 g tryptone and 5 g yeast extract per litre, pH=7). In case of bioluminescent *E. coli* and *P. aeruginosa* (see the next section), medium was supplemented with appropriate antibiotics (100 mg ampicillin per litre for *E. coli* and 10 mg tetracycline – for *P. aeruginosa*). 10-50 ml of fresh medium was inoculated with 1/20 diluted overnight culture and bacteria were grown until mid-exponential phase (OD₆₀₀ of 1), centrifuged at 6000 g for 5 min, washed twice with equal amount of 50 mM MOPS-Tris and adjusted to OD₆₀₀~1 corresponding to approximately 10⁹ cells/ml.

ζ-potential of bacteria was measured in MOPS-Tris buffer using Malvern Zetasizer (Nano-ZS, Malvern Instruments, UK).

Bacterial bioluminescence inhibition assay and calculation of 10-min EC₅₀
Constitutively luminescent recombinant bacteria *E. coli* MC1061 (pSLlux) (19) and *P. aeruginosa* DS10-129 (pDNcadlux) (18) bearing bioluminescence encoding plasmid were used. Bacterial acute bioluminescence inhibition assay (exposure time 10 min) was conducted at room-temperature on white sterile 96-well polypropylene microplates (Greiner Bio-One GmbH) following the Flash-assay protocol (ISO 21338:2010, (20)) essentially as described by Kurvet et al (21). For each compound, 5–7 sequential exponential dilutions were analysed. The following concentrations of test chemicals were used: AgNP and AgNO₃ from 2.5 to 320 µM (0.27 to 35 mg Ag/l); PMB from 1.2 to 160 µM (1.66 to 222 mg/l); 3,5-DCP from 47.9 to 6135 µM (7.8 to 1000 mg/l). Testing was performed in MOPS-Tris environment. The 10-min EC₅₀ values (the concentration of a compound reducing the bacterial bioluminescence by 50% after being in contact for 10 minutes) were calculated from the concentration versus 10-min inhibition curves based on nominal exposure concentrations and using the log-normal model of MS Excel macro Regtox (22).

**Evaluation of the minimal bactericidal concentration (MBC)**

Since bioluminescence inhibition test do not fully reflect the viability of cells, the viability assay was performed essentially as described by Suppi et al (23). Briefly, in the end of the bioluminescence inhibition assay (see above) microplates were incubated for 1 hour at room-temperature in the dark, and 3 µl of each test suspension was pipetted onto LB agar plates to assess the viability (1-h MBC) of the cells after exposure to studied compounds. The inoculated agar plates were incubated at 30 °C for 24 h and the 1-h MBC was defined as the lowest tested concentration of the toxicant yielding no visible bacterial growth (i.e., irreversible growth inhibition) on nutrient agar.
Assessment of bacteria-nanoparticle interaction by flow cytometry

Flow cytometry analysis was performed on the basis of protocol by Kumar et al (24). 600 µl of bacterial suspension (OD$_{600}$~1) in 50 mM MOPS-Tris was exposed to 10 µM of AgNO$_3$ or 100 µM AgNP for 0 and 10 min in polypropylene microcentrifuge tubes. Unexposed cells in 50 mM MOPS-Tris served as a control. After desired incubation time samples were vortexed and analysed using BD Accuri™ C6 (BD Biosciences). For all flow cytometry experiments data for 10 000 events was collected. The dot plots were obtained by plotting the forward scattering (FSC) intensity (X-axis, log-scale) and side scattering (SSC) intensity (Y-axis, log-scale); BD Accuri C6 software was used to analyse the results. The gating of the data as SSC-A High and SSC-A Low in individual experiments was set relatively to SSC-A of unexposed cells (control) to obtain SSC-A High of 0.2-0.5%. In addition, propidium iodide staining (in the final concentration of 5 µg/ml; exposure time 10 min) was applied to determine the viability of cells (25).

Extracellular and intracellular AgNP in exposed bacterial suspensions were discriminated using chemical procedure described by Braun et al (26). Briefly, 600 µl of bacterial suspension (OD$_{600}$~1) in 50 mM MOPS-Tris was exposed to 10 µM of AgNO$_3$ or 100 µM AgNP for 0, 10 and 30 min in microcentrifuge tubes. After exposure, cell suspension was washed (centrifuged at 6 000 g for 5 min) twice in phosphate buffered saline (PBS), incubated with two solutions (20 mM of K$_3$Fe(CN)$_6$ and Na$_2$S$_2$O$_3$, final concentrations) for 5 min, centrifuged at 6 000 g for 5 min and resuspended in 600 µl PBS. The removal of extracellular AgNP (oxidation of cell wall-bound AgNP first to Ag$^+$ ions by K$_3$Fe(CN)$_6$ and then followed by the complexation of Ag$^+$ ions by Na$_2$S$_2$O$_3$) was verified by colour change of AgNP from characteristic
yellow to colourless. After the oxidation, the flow cytometry analysis was performed as described above.

Assessment of interaction of studied compounds with bacterial membranes using 1-N-phenylnaphthylamine (1-NPN)

The cell wall permeabilization of *E. coli* and *P. aeruginosa* by AgNO₃, AgNP and PMB was assayed by the cellular uptake of a hydrophobic probe 1-N-phenylnaphthylamine (1-NPN) essentially as described by Helander and Mattila-Sandholm (27). As compared to hydrophilic environments, the fluorescence of 1-NPN is significantly enhanced in hydrophobic environments (e.g. membrane lipid bilayer), rendering it a suitable dye to probe outer membrane integrity of Gram-negative bacteria (27). Briefly, 50 µl of 40 µM 1-NPN and 50 µl of tested compound in 50 mM MOPS-Tris buffer were pipetted into black microplates. 100 µl of bacterial suspension in 50 mM MOPS-Tris was dispensed into each well and the fluorescence was immediately measured (Fluoroskan Ascent FL plate luminometer; excitation/emission filters 350/460 nm). The 1-NPN cell uptake factor was calculated as a ratio between intensity of fluorescence values of the bacterial suspension incubated with and without test compounds.

Electrochemical measurements

Bacterial cultures were grown overnight in LB broth, containing also 0.5% NaCl (Sigma-Aldrich, Munich, Germany), diluted 1:50 in fresh medium, and the incubation was continued until the OD₆₀₀ reached 1.0. The cells were harvested by centrifugation at 4 °C for 10 min at 3000 g (Heraeus™ Megafuge™ 16R, Thermo Scientific, Germany). The pelleted cells were re-suspended in LB medium without
NaCl (to avoid the formation of insoluble AgCl while exposing bacteria to silver compounds), pH 8.0, to obtain \( \sim 2 \times 10^{11} \) cells ml\(^{-1}\). The concentrated cell suspensions were kept on ice until used, but not longer than 4 h.

TPP\(^+\) and K\(^+\) concentrations in the incubation media were potentiometrically monitored using selective electrodes as described previously (28, 29). In the experiment with TPP\(^+\), ethylenediaminetetraacetic acid (EDTA) was used to increase OM permeability of bacteria to TPP\(^+\) and to equilibrate TPP\(^+\) across the cell envelope.

Since *P. aeruginosa* cells are sensitive to the incubation in EDTA-containing MOPS/Tris buffer (29), 100 mM NaPi was used instead of MOPS/Tris in the experiments with these cells. The thermostated magnetically stirred glass vessels were filled with 5 ml of 50 mM MOPS-Tris, pH 8.0. After calibration of the electrodes the concentrated cell suspension was added to obtain an OD\(_{600}\) of 1 or 2. To register potential of the electrodes we used the electrode potential-amplifying system with an ultralow-input bias current operational amplifier AD549JH (Analog Devices, Norwood, MA, USA). The data acquisition system PowerLab 8/35 (ADInstruments, Oxford, UK) was used to connect the amplifying system to a computer. The agar salt bridges were used for indirect connection of the Ag/AgCl reference electrodes (Thermo Inc.; Orion model 9001) with cell suspensions in the vessels. The measurements were performed simultaneously in 2-4 reaction vessels and three independent series of measurements were conducted.

Dissolved oxygen level in the medium was monitored by dissolved oxygen probe (Orion model 9708, Thermo Scientific) as described previously (28). At the end of every experiment solid Na\(_2\)S\(_2\)O\(_5\) (Sigma) was added to vessels to obtain a final concentration of approximately 20 mM and deplete the dissolved oxygen (0 % base
Bacterial plasma membrane is a target of silver nanoparticles

Concentration of the dissolved oxygen in the medium before addition of cells was set as 100%.

Statistical analysis
All tests were performed in duplicates and in at least three independent experiments. The data were expressed as mean ± standard deviation (SD) or shown as representative figure. To define statistically significant differences, the data were analyzed with unpaired two-tailed t-test assuming equal variances at p<0.01.

RESULTS
Physico-chemical characterization of silver nanoparticles
AgNP formed stable dispersion in the MOPS-Tris buffer (polydispersity index of 0.31 nm) and were in nano-size of 50 nm (Table 1). The dissolution of AgNP in the test conditions was time-dependent and relatively high: 26.9% already after 10 minutes of incubation.

To rule out the reactive oxygen species (ROS)-associated antibacterial mechanism of toxicity, the potential of AgNP to generate ROS was measured. No ROS were induced by 0.3–10 µM AgNP in abiotic conditions after 1-h incubation in 50 mM Tris-MOPS according to 2′,7′-dichlorofluorescin assay (data not shown).

**Effect of exposure of bacteria to studied compounds on bacterial bioluminescence**

The inhibition of bacterial bioluminescence was used as the toxicity endpoint describing the rapid general adverse effect of studied compounds on bacterial membranes. In bioluminescent bacteria, any disturbance of bacterial membranes leads to the decrease in the light output (inhibition of bioluminescence) that can be registered (31). As the production of light is correlating with the ATP production that proceeds in bacterial PM, the assay is suitable for the rapid analysis of the effect of chemicals on the intactness of bacterial cellular membranes. Our data showed that Ag⁺ ions and AgNP had rapid effects cell membrane-linked ATP production (Fig. 2A-D) and bacterial viability (Fig. 2E-F). As expected, in both assays *P. aeruginosa* was
more susceptible to Ag⁺ ions and AgNP than *E. coli*, whereas *E. coli* was more susceptible to antibiotic PMB. 3,5-DCP that was included as the control due to its wide use as a standard in various toxicological tests (32) had similar 10-min EC₅₀ and 1-h MBC values to both bacteria (Fig. 2E-F). Thus, differently from PMB and 3,5-DCP, Ag compounds were more toxic to *P. aeruginosa* compared to *E. coli*, probably because the former cells are mostly dependent on membrane ATP-synthase (33). Thus, it can be hypothesized that Ag compounds interfered with the systems involved into ATP synthesis.

In viability assay, Ag compounds completely abolished bacterial growth at concentrations from 10 µM (AgNO₃) to 40 µM (AgNP) for *P. aeruginosa* and from 80 µM (AgNO₃) to 340 µM (AgNP) *E. coli* (Fig. 2C-D). The four-times difference between the toxicity of AgNO₃ and AgNP evident for both bacteria was most probably at least partly due to dissolution of AgNP (26.9 % in the test medium, Table 1).

**Assessment of cell-nanoparticle interaction by flow cytometry**

Bacterial suspensions were incubated either with 10 µM AgNO₃ or 100 µM AgNP, and the intensity of the side scattering (SSC-A) was visualized and quantified by flow cytometry (Fig. 3A-B). SSC-A is an universal parameter reflecting the changes in cell granularity and is often interpreted as an indication of the internalization of NP by cells (24, 34). However, we also considered that interaction of AgNO₃/AgNP with the cell envelope from outside can lead to the disorganization of cell membranes (9) and changes in the light scattering. Thus, both, the outside interaction of the cells with NP and actual internalization of NP by the cells can potentially lead to the increase of SSC-A. Flow cytometry analysis showed that the incubation of *P. aeruginosa* cells with 100 µM AgNP increased the intensity of SSC-A (Fig. 3A). The 33.2 % increase...
Bacterial plasma membrane is a target of silver nanoparticles

of SSC-A of AgNP-exposed *P. aeruginosa* cells was observed compared to unexposed cells already after 10 minutes of exposure (Fig. 3B). Remarkably, the incubation of *P. aeruginosa* cells with 10 µM AgNO$_3$ did not cause the SSC-A changes, showing that AgNP interacted with *P. aeruginosa* cells in a specific manner, differently from the effects of ionic silver.

To exclude the possibility that SSC-A shift was an artefact indicating the death of *P. aeruginosa* cells after the 10-minute exposure to AgNP, we measured the bacterial viability using fluorescein diacetate dye that stains all cells (viable+dead) (23) and propidium iodide (PI) dye that stains only dead cells (25). The viability of unexposed cells according to PI staining was over 90%. The viability of cells exposed to 100 µM AgNP and 10 µM Ag ions was over 85% for *E. coli* and over 75% for *P. aeruginosa* (data not shown). As the viability of *P. aeruginosa* cells exposed to Ag ions and AgNP was similar but the SSC-A shift was observed only for AgNP, we concluded that the shift of SSC-A was indeed observed due to effects of AgNP and not because of death of the cells or possible membrane changes in the dying.

No changes in SSC-A for *E. coli* cells was observed at any time point (Fig. 3A-B) suggesting that AgNP did not attach to the *E. coli* cell envelope and did not enter the bacterial cell or this interaction was weaker than in case of *P. aeruginosa*.

We further asked, whether the SSC-A shift in case of *P. aeruginosa*-AgNP interaction was caused by the outside adsorption of AgNP to bacterial cells walls or the actual internalization of AgNP by bacteria. To discriminate between intra- and extracellular AgNP, the method described by Braun et al (26) was used, i.e., two chemicals were utilized to remove (oxidize) NP and Ag ions from the bacterial surface. The oxidizing efficiency was verified by the visual observations, since AgNP lost their characteristic yellowish color after the oxidation (Fig. 3C). Flow cytometry analysis showed that the
Bacterial plasma membrane is a target of silver nanoparticles

SSC-A shift observed for *P. aeruginosa* cells incubated with AgNP was still observed even after several washing rounds of the cells (Fig. 3A-B), suggesting that some fraction of AgNP crossed at least the OM and localized in the PM or cytosol.

### Evaluation of outer membrane integrity by 1-N-phenylnaphthylamine assay

The impact of Ag⁺ ion and AgNP on the barrier properties of the cell envelope was studied using nonpolar dye 1-N-phenylnaphthylamine (1-NPN) that fluoresces strongly in the lipid environment but only weakly in the hydrophilic medium (27). A cationic peptide PMB was used as a positive control due to its ability to disrupt the OM barrier and diminish the membrane potential (7). When the membrane-active compounds disturb the integrity of OM, lipophilic phase of cell envelope becomes accessible to hydrophobic agents, such as 1-NPN. Thus, the increase of 1-NPN fluorescence could be interpreted as the loss of OM integrity (27). Alternatively, the fluorescence can increase in case of the general de-energization of cells leading to the inhibition of efflux of lipophilic compounds, including 1-NPN (35).

The results of our experiments showed that membrane-permeabilizing antibiotic PMB increased the 1-NPN fluorescence approximately 3-fold in both *E. coli* and *P. aeruginosa* suspensions (Fig. 4A and B). AgNO₃ affected the 1-NPN fluorescence in case of *E. coli* cells starting from 5 µM and AgNP starting from 40 µM, although their effect was weaker than in case of PMB. As the dissolution of AgNP was 26.9% at these conditions (Table 1), the effects of AgNP on 1-NPN fluorescence was most probably caused by Ag⁺ ions released from AgNP.

Differently from *E. coli*, no effect of Ag compounds (neither AgNO₃, nor AgNP) was observed in the case of *P. aeruginosa* suspensions (Fig. 4B). This was in contrast to higher toxicity of AgNO₃ and to AgNP towards *P. aeruginosa* compared to *E. coli* cells.
Bacterial plasma membrane is a target of silver nanoparticles

(Fig. 2) and the specific interaction of AgNP with *P. aeruginosa* AgNP cells (Fig. 3). These data suggest that the OM is not a primary target of Ag compounds. Thus, we analyzed AgNO₃ and AgNP effects on bacteria in more details monitoring their interaction with PM and OM using TPP⁺ assay.

**Evaluation of the permeability of bacterial membranes by TPP⁺ assay**

To assay effects of AgNP and Ag⁺ ions on the permeability of bacterial OM and PM, TPP⁺ accumulation inside the cells was analyzed. The OM (Fig. 1) forms a permeability barrier to lipophilic ions like TPP⁺. On the other hand, PM membrane is permeable to TPP⁺ and this indicator compound accumulates in bacterial cytosol in potential-dependent manner. Thus, accumulation of TPP⁺ by the cells would indicate permeabilization of the OM by the Ag compounds, whereas leakage of the accumulated TPP⁺ would indicate the depolarization of PM (7). *E. coli* and *P. aeruginosa* cells with the intact OM accumulated low amounts of TPP⁺ and additions of increasing concentrations of AgNO₃ to bacterial suspensions did not induce any additional binding of TPP⁺ to the cells, indicating that Ag compounds do not act on OM.

To induce the accumulation of TPP⁺ and to measure the effect of Ag compounds on PM, EDTA was added to the cells. EDTA removes divalent cations from the LPS layer, increasing the permeability of the OM to lipophilic compounds (7). Both bacteria accumulated considerable amounts of TPP⁺ when 0.1 mM EDTA was added to the cell suspensions (Fig. 5). 1-2.5 µM AgNO₃ did not induce any changes in the amount of cell-accumulated TPP⁺, but 5 µM and higher concentrations of Ag⁺ ions induced release of TPP⁺ from the cells. 20 µM Ag⁺ ions induced release of the maximal amount of TPP⁺. In experiments with AgNP, 160 µM concentration was
needed to depolarize the bacterial PM and induce the leakage of accumulated TPP⁺ (Fig. 5C,D).

**Evaluation of the permeability of the bacterial plasma membrane by K⁺ leakage assay**

K⁺ ions easily cross the OM through porins but the PM forms a barrier to this ion. Concentration of K⁺ ions in incubation medium was monitored to evaluate the effects of AgNP and Ag⁺ ions on barrier functions of the PM. 10 µM AgNO₃ induced a leakage of accumulated K⁺ from the cells of both bacteria (Fig. 6). Induction of the leakage of accumulated K⁺ ions at higher Ag⁺ concentrations than leakage of TPP⁺ indicates that depolarization of the PM is most likely the reason of dissipation of K⁺ gradient. Unfortunately, it was technically not possible to register AgNP-induced K⁺ release since high concentrations AgNP affected the K⁺ electrode.

**Evaluation of the permeability of bacterial plasma membrane using cell respiration assay**

To understand the mechanism of Ag⁺ ion and AgNP action on bacterial PM, we analysed the respiration activity of the cells. Starting from 1 µM concentration the addition of AgNO₃ stimulated the respiration of *E. coli* cells but in 5 minutes the activation period was followed by a considerable Ag⁺ concentration-dependent inhibition (Fig. 7A). With the increase of Ag⁺ concentration, period of the enhanced respiration activity became shorter and the effect of inhibition stronger. Period of the stimulated respiration of *E. coli* cells was considerably less expressed in the medium without glucose (data not shown). AgNP did not have any respiration stimulating
activity at these conditions (Fig. 7B). In the case of *P. aeruginosa* cells, the
respiration enhancing activity of AgNO$_3$ was the highest at 5 µM, and the inhibitory
activity of Ag$^+$ was observed only at 10 µM. However, the AgNP started to stimulate
respiration at 40 µM and the inhibition started at 160 µM (Fig. 7D). Such activation of
respiration at low concentrations and inhibition at the higher ones is typical for
uncouplers of oxidative phosphorylation, i.e., compounds permeabilizing the PM to
H$^+$ ions (36).

In addition to *P. aeruginosa* DS10-129, *P. aeruginosa* PAO1 strain was used in the
TPP$^+$, K$^+$ leakage and respiration assays. The results for these two bacterial strains
were very similar (data not shown), suggesting that the effect of Ag is not specific to
one *P. aeruginosa* strain.

**TPP$^+$ assay using oxidized NP**

To get direct evidences that Ag$^+$ ions are responsible for the PM-damaging effects of
AgNP, the experiments with the oxidized AgNP were performed. Suspensions of
AgNP (final concentration 1 mM Ag) were made in KMnO$_4$ solutions of
concentrations from 0.05 to 0.5 mM (Fig. 8). When the concentration of the KMnO$_4$ in
the solution was 0.05 mM, 80 µM of AgNP was needed to induce the depolarization.
However, when the concentration of KMnO$_4$ was increased to 0.5 mM and AgNP
were fully oxidized, only 10 µM of AgNP was needed to induce the depolarization of
the PM. Thus, the efficiency of AgNP depended on the concentration of KMnO$_4$ in the
solution, i.e., on the oxidized fraction of Ag in the AgNP. Remarkably, the efficiency of
fully oxidized AgNP (Fig. 8) was very close to the efficiency of AgNO$_3$ solution (5 µM,
Fig. 5). Thus, the experiments with suspensions of AgNP in KMnO$_4$ solutions clearly showed, that Ag$^+$ ions are responsible for the PM depolarizing effect of AgNP.

**DISCUSSION**

Discussions on the mechanisms of AgNP interaction with the bacterial cells are continuing despite of the large set of experimental data on their toxicity and possible mode of action (37, 38, 39, 40). One among the well-established toxicity mechanisms of AgNP is their adhesion to the surface of bacterial envelopes, disruption of the integrity of membranes and subsequent damage of (intra)cellular biomolecules (41). To the best of our knowledge, the exact mechanism of damage of the envelope barrier and the toxicity initiating event of AgNP are not yet defined.

In this study we showed that the PM is the main target of AgNP in *E. coli* and *P. aeruginosa*. In the bioluminescence inhibition assay (Fig. 2) we observed that *P. aeruginosa* is inherently more susceptible to Ag compounds than *E. coli*, probably because the energy production of the former cells mainly depends on PM-linked ATP-ase (33). Using TPP$^+$, K$^+$ and respiration assays, we confirmed that the antibacterial effects of Ag and AgNP occur through PM. Indeed, exposure of bacteria to AgNP induced a set of toxic events targeting PM: inhibition of the respiration, depolarization of the PM and the leakage of the intracellular K$^+$ (Fig. 5-7). In addition, as many previous studies, we confirmed that AgNP toxicity is mediated *via* Ag ions (Fig. 8). The former was observed in bioluminescence inhibition assay (Fig. 2) in combination with dissolution studies (Table 1) and confirmed by AgNP oxidation assay that showed Ag$^+$ ions dissolving from AgNP are driving the quick toxic effects of AgNP on the bacterial PM (Fig. 8). Most likely, the action of Ag$^+$ ions on PM is
Bacterial plasma membrane is a target of silver nanoparticles

unspecific and occurs through the binding of Ag+ ions with the SH-groups of various enzymes localizing on PM (12, 15). PM-related mechanism of toxicity can explain why Gram-negative bacteria including clinical multidrug-resistant strains, are in general more susceptible to AgNP than Gram-positive bacteria (40, 42). Compared to the Gram-negative bacteria, the plasma membrane of Gram-positive bacteria is less accessible to the NP due to thick peptidoglycan layer. Thus, combination of AgNP with traditional antibiotics offers crucial therapeutic strategy on fighting multidrug-resistant Gram-negative bacteria.

Surprisingly, we did not observe any effects of Ag compounds on the bacterial outer membrane (Fig. 4-5). Although AgNP clearly attached to P. aeruginosa cells (Fig. 3), this did not lead to the permeabilization of OM (Fig. 4-5). Several studies have previously shown structural changes in the surface of bacteria after exposure to AgNP and proposed that physical interaction with AgNP was the primary cause of cell death (13, 43). For example, Ramalingam et al (43) observed altered cellular morphology and diminished cellular integrity after exposure of E. coli and P. aeruginosa cells to AgNP and suggested that AgNP damage the cell membrane via binding to the cell surface proteins and lipopolysaccharides. Our study indicates that the observed morphological changes on bacterial surface could be rather the consequences of the action of Ag+ ions than the primary mechanism of AgNP cytotoxicity. The uptake of Ag+ ions leads to the formation of characteristic irregular pits on the surface of bacteria (44) that can be misleadingly interpreted as the toxicity initiating event of AgNP. Furthermore, depolarization of the PM induced by Ag+ ions can destabilize the OM and trigger the morphological changes of microbial envelope.

Since Ag+ ions dissolved from AgNP reached bacterial PM without causing a significant OM damage, these data support the idea that Ag+ transport occurs via
Bacterial plasma membrane is a target of silver nanoparticles

cation selective OM porins (45, 46). Previous studies showed that E. coli mutant
strains deficient in OmpF or OmpC porins were more resistant to Ag\(^+\) ions (9) and to
AgNP (11) as compared to the wild type strain. In addition, ompF gene was down-
regulated in response to Ag\(^+\) ions and AgNP (10) suggesting that porins are crucial in
antibacterial effects of Ag\(^+\) ions and AgNP. On the basis of our study and the
previous observations, we suggest that Ag\(^+\) ions dissolved from AgNP enter the
bacterial periplasm through porin channels and interact directly with the PM. Previous
study found that Omp proteins were among the molecules tightly bound to AgNP
after their incubation with the cell free extract of E. coli, implying that in addition to
Ag\(^+\) ions, AgNP under 10 nm can also pass through the porin channels to PM (40,
47). This can explain intracellular localization of AgNP in P. aeruginosa cells
observed in this study. However, we do not have the explicit answer, why AgNP were
associated and internalized by P. aeruginosa but not E. coli cells (Fig. 3). One
possible explanation could be the bigger porin channels in OM of P. aeruginosa. It is
known that channels formed by protein F in P. aeruginosa OM are much larger than
E. coli porin channels (48). In addition, the OM of P. aeruginosa cells possess high
number of different porins (49). Since AgNP are oxidized on the surface of bacteria,
creating the large pools of toxic Ag ions (4, 10) and reducing the size of AgNP, the
number and size of porins available for the transport of Ag\(^+\) ions and small AgNP can
be one of the determinants of the toxicity of AgNP to different bacteria.

Finally, the assays used in our study showed the short-term (0 – 1 h) dissolution-
dependent antimicrobial mechanisms of Ag compounds to both bacteria. We
observed that the short-term toxicity of Collargol to E. coli and P. aeruginosa differed
only several times (Fig. 2) in this study, while the long-term toxicity of Collargol was
almost two orders of magnitude different for these two bacteria as shown in our
previous article (4). Thus, the “quick” dissolution-dependent effects of AgNP might be universal but the time-dependent effects seem to be specific to different bacteria. For example, the long-term effects may be related to the capacity of bacteria to oxidase adsorbed AgNP to Ag$^+$ ions or/and the efficiency of Ag$^+$ efflux. For instance, it was shown that *E. coli* with the more active efflux transporters of Ag$^+$ ions (e.g., SilCFBA) are more resistant to Ag (50). The full oxidation of adsorbed AgNP to Ag$^+$ ions can take hours. The results of this slow oxidation process are not registered by our electrochemical analysis but can be reflected in the results of the long-term endpoints, i.e. the cell ability to grow. Thus, longer incubation times and bacterial growth-related endpoints might be more relevant and useful to reveal the whole toxic potential of NP *per se* compared to the effect of dissolved ionic fraction.

CONCLUSIONS

We demonstrated that Ag$^+$ ions and AgNP induced a set of toxic effects targeting PM of *E. coli* and *P. aeruginosa*, including inhibition of the respiration, depolarization, leakage of the intracellular K$^+$ and the decrease of ATP content in the cells. These fast effects of AgNP depended on the release of Ag ions. The role of Ag compounds on bacterial OM and the role of particles *per se* was negligible in our short-term (0-1 h) tests.
