Abstract
This proposed method is a promising way, which can be implemented in pulp and paper industries by effective removal of the color and chemical oxygen demand (COD) and the resulting treated water may surely reuse to the other streams. Fourier Transformer Infra Red spectra confirmed the presence of the respective functional groups in the removed pollutants from the wastewater. The efficiency of Non-ferric Alum (NF Alum) and cationic polyacrylamide (C-PAM) with and without power boiler fly ash was also studied. The reduction efficiency of color and chemical oxygen demand (COD) is evaluated at the optimum dosage of NF Alum, fly ash, and C-PAM. At the optimized pH attained from these coagulants using to treat the wastewater, the flocs formation/settling and the pollutant removal efficiency are encouraging and the resulting color of the wastewater is to 40 PtCo units from 330 PtCo units and COD to 66 mg/L from 218 mg/L. While using NF Alum alone with C-PAM for the treatment of wastewater, the highest reduction efficiency of COD is 97 mg/L from 218 mg/L and the color is 60 from 330 PtCo units at pH 4.8 was noted. From these observations, NF Alum and power boiler fly ash with C-PAM can effectively remove the pollutants from the pulp and paper mill wastewater and the water can be reused for other streams.

Keywords Cationic polyacrylamide • Chemical oxygen demand • Color • Fly ash • Non-ferric alum

Introduction
The pulp and paper mill effluent formed at the mill is made up of large number of component streams and it generates different varieties of pollutant. Pulp mill bleach plant wastewater is the major source of the pollutant in pulp and paper industries (Razali et al. 2012). Because of the chemicals used in the pulping and bleaching processes, such as sodium hydroxide, sodium carbonate, sodium sulfide, chlorine dioxide or elemental chlorine, hydrogen peroxide, sulphuric acid, etc., (Kamali and Khodaparast 2015). During bleaching of the pulp, the main aim is to be the removal of lignin (Sunakar et al. 2012). Lignin is a complex, highly cross-linked hydroxylated, and methoxy-lated organic polymer (Garg et al. 2004). During the cooking stage, the most of the lignin have been removed in the form of black liquor and it burned in the recovery boiler to generate energy and spent chemicals. The remained lignin has been eliminated during bleaching stages and it drained as effluent/wastewater.

The pulp mill wastewater contains varieties of organic compounds, such as chlorinated phenols, resin acids, chlorinated lignins, unsaturated fatty acids, carboxylic acids, terpenes, and other organics, which contains chlorine/sulphur compounds (Kumar et al. 2014). In addition, it contains nitrogen and phosphorus compounds and the source is wood as a raw material. Water is also used for process cooling, equipment cleaning, general facilities.
operations, and to generate steam for use in processes and on-site power generation. During bleaching, chromophoric and highly oxidized polymeric lignin derivatives are formed that give rise to a dark colorization in the wastewater (Choudhary et al. 2013; Sahoo and Gupta 2005). Therefore, the pulp and paper industries have several treatment systems, such as anaerobic treatment, activated sludge lagoon, clarifier system for remove organics, and inorganic substances from the wastewater and to meet the effluent discharge standards.

Project background

The use of inorganic salts for coagulation–flocculation has been well documented. Now, the trend is also moving towards this technique as fashion for pulp and paper mill wastewater treatments. Kumar et al. (2011) have investigated a comparative study for treatment of this type of effluent using various coagulants, such as aluminum chloride, polyaluminum chloride, and copper sulphate. They observed that PAC reduced COD to 84 and 92 % of color was removed at an optimum pH 5, aluminum chloride reduced 74 % COD and 86 % color at an optimum pH 4, and copper sulphate reduced COD to 76 % and color to 78 % at an optimum pH 6.

Srivastava et al. (2005) were observed that polyaluminum chloride (PAC) as a coagulant and bagasse fly ash as an adsorbent for the removal of COD and color are 80 and 90 %, respectively, at optimum pH 3. Ahmad et al. (2008) were studied the efficiency of alum and polyaluminum chloride (PAC) when used alone and in coupled with cationic polyacrylamide (C-PAM) and anionic polyacrylamide (A-PAM) on the treatment of pulp and paper mill wastewater. They found that Alum coupled with C-PAM is the best system and it gives 99.7 % reduction of turbidity, 99.5 % removal of TSS, and 95.6 % reduction of COD.

Some researchers treated pulp and paper mill wastewater by the electrochemical degradation method followed by coagulation/flocculation, ozone treatment, and biological methods for COD and color removal but mostly not deal with reuse of the resources. Coagulation/flocculation are not only the economic but also the effective method for removal of COD and color from pulp and paper mill wastewater (Nawaz et al. 2014). The treatment using this method is fashion; because of these processes, it is a promising way of removal of pollutants in short reaction time (Tzoupanos and Zouboulis 2008).

Nowadays, resource recovery is a main thing, especially water resource is very important in all types of industries. In this work, an effort has been made to reuse after treating the huge volume of (∼32000 M³ per day) wood and bagasse-based integrated pulp and paper mill wastewater by NF Alum and fly ash along with C-PAM through the coagulation–flocculation method. Some researchers have been worked with the alum and C-PAM for wastewater treatment (Wong et al. 2006). However, the major drawback is not able to reduce the total dissolved solids during the treatment and hence possess lots of problems in water recycle and reuse. Most of the researchers deal with the total suspended solids, but not deal with total dissolved solids during wastewater treatment. However, in this work, the TDS levels are maintained in the same trend and not much enhanced due to raw material selection for treatment and find out the optimum dosage. The removal of pollutants was achieved through two simultaneous mechanisms, which includes coagulation by charge neutralization and flocculation by bridging. The removal of pollutants was proved through FTIR spectra by their functional groups. Wastewater released from this integrated pulp and paper industry is approximately 22 to 35 M³ per ton of paper produced. If treated this high-colored wastewater by this proposed method, the resulting treated water may definitely reuse to other streams.

Experimental

Materials

The wastewater sample has been collected from the Secondary Clarifier Inlet (Fig. 1) in an integrated pulp and paper mill, Tamilnadu, India. Then, the water sample was characterized and the analyzed using IS 3025 (Indian Standards) standard methods at various dosages which are given in Table 1.

pH

For measuring pH, 100 ml of the sample taken in a clean dry beaker stirred well until reached the stable value.

COD: (standard reference: IS 3025 (Part 58)

0.4 g of Mercury(II) sulphate was placed in a reflux tube. An aliquot of sample was diluted to 20 ml with de-mineralized (DM) water and mixed well (simultaneously for blank, used 20 ml of DM water), and, then, add 10 ml of 0.25 N standard potassium dichromate solution to the sample containing reflux tube. Finally, 30 ml of concentrated sulphuric acid, already contains silver sulphate (prepared by 10.12 g, silver sulphate was added to 1 l of concentrate sulphuric acid, kept overnight for dissolution and shook well after dissolution), was slowly added and mixed well. Reflux the contents of the flask for 2 h at
150 ± 2 °C, then cooled and washed down the condensers with 60 ml DM water. Then, it was titrated against 0.1 N standard ferrous ammonium sulphate using ferroin as indicator. The end point is attained when the color changes sharply from green blue to wine red.

**Color:** standard reference: IS 3025 (Part 4)

**Platinum–cobalt method** Color is measured by visual comparison of the sample with platinum–cobalt standards. One unit of color is produced by 1 mg of platinum per litre in the form of chloroplatinate ion. Prepare standard solutions having color units of 5, 10, 15, and up to 70 as prescribed above said reference. The clear supernatant solution was taken for analysis. If the color exceeded 70 units, the sample was diluted using DM water until the color is in the range of the standard solutions.

**Methods**

The coagulants–flocculants were chosen by depending on the nature of the pollutants present in the effluent. Normally, pulp and paper mills have strong anionic nature due to the major source of lignin/chromophore derivatives contained pulp mill bleach effluent.

Jar test procedures carried out using 1000 ml of the pulp and paper mill wastewater samples with the various dosages of NF Alum and C-PAM with and without fly ash. The selected coagulants/flocculants were added to 1000 ml of wastewater and it was stirred for a period of 3 min at 50 rpm and it was followed by further slow mixing of 2 min at 30 rpm. The flocs formed were allowed to settle for 30 min. After settling, the pH, color, and COD were analyzed for the further process. This analysis was repeated for ten times for getting average values using the Indian Standards IS 3025 standard methods.

**Results and discussion**

Coagulants–flocculants required dose depends on the concentration of colloidal impurities present in the water. In this study, various dosages of coagulants and flocculants have been used to treat the wastewater and keeping other as a constant to find the optimum dosage level. The average test resulted and the various dosages of NF Alum and fly ash (in grams per one litre of wastewater) have been shown in Table 1.

From these observations, 1.5:1.5 grams of NF Alum: fly ash per one litre of the wastewater are the optimum dosage and to get better resulting water for reuse when compared with other dosage levels. At pH 5.9, the color has been reduced to 20 from the untreated value 330 PtCo units and COD reduced from 218 to 50 mg/L. If treating this wastewater without fly ash, maximum reduction efficiency, i.e., the color of the treated water is 60 PtCo units and the COD is 97 mg/L at pH 4.8 and it cannot be reused due to acidic nature.
The dosage of 1:1 grams of NF Alum: fly ash per litre of the wastewater, test results showed COD, color, and total dissolved solids (TDS) of the treated water also getting better reduction efficiency at the neutral pH.

Effect of coagulants–floculants

The pH of the wastewater plays an important role, when NF Alum is used for coagulation process. Because the solubility of the aluminum species in effluent is pH dependent, it is generally present in the form of positive ions (i.e., Al(OH)\(^{3+}\) and Al\(^{3+}\)). The NF Alum may acts as an adsorbing agent for the condensate polymer/lignin complex. When applied to the wastewater, it may hydrolyze into aluminum hydroxide forming a large, insoluble particulate with a large surface area. Concurrently, C-PAM may bind to the hydroxyl or methoxyl groups of the lignin to create an insoluble complex. We know that the lignin has methoxyl (O–CH\(_3\)) groups, hydroxyl groups of primary and secondary aliphatic, phenolic hydroxyl groups, carboxyl (–COOH) groups, and carbonyl functional groups. This complex may then be adsorbed into the hydrolyzed aluminum hydroxide and become bound forming the insoluble agglomerate and removing the color from the effluent without re-solubilizing.

The main advantage of using C-PAM is the pH intensive and functioning well over a broad pH range. The cationic charge in this polymer is derived from nitrogen in the form of a secondary, tertiary, or quaternary amine group and the charge can be located on a pendant group or may be in the backbone of the polymer chain. The addition of the NF Alum and the C-PAM reacts with the lignin in the wastewater to form flocs and remove COD and color from the effluent, thus reducing the true color of the effluent (Fig. 2). However, when used without fly ash, the better removal efficiency occurs at pH 4.8, but it has corrosive nature due to acidic medium. In addition, it increases the TDS level in treating water. Using NF Alum and C-PAM with fly ash to treat the sample surprisingly showed that the TDS of the wastewater is not increased and maintained the same trend (Fig. 3). This is also one of the significant uses of power boiler fly ash for treating the pulp and paper mill wastewater.

In the case of using fly ash as an adsorbent, the metal salts get hydrolyzed in the presence of natural alkalinity to form metal hydroxides. The multivalent cations present in the fly ash can reduce the zeta potential value, while the metal hydroxides are good adsorbers. The carbon content of fly ash is significant, because the effectiveness of fly ash as an adsorbent improved with the increasing carbon content (Kulkarni et al. 2013). They form a monomolecular layer on the surface of suspended organic matter and remove it by trapping them and settling. So if fly ash used along with NF Alum and C-PAM to treat the pulp and paper mill wastewater, it gives better results and effectively removes the pollutants and certain to reuse the treated water to other waste facilities or streams.

FTIR spectral analysis

FTIR spectroscopy is a complementary and extensively used method, and gives more information about the presence of functional groups in their respective compounds. Every lignin of IR spectra has a strong wide band between 3500 and 3100 cm\(^{-1}\) assigned to –OH bond-stretching vibrations. This band is caused by the presence of alcoholic and phenolic hydroxyl groups involved in hydrogen bonds. The spectrum (Fig. 4) of integrated pulp mill wastewater sample collected from secondary clarifier showed that the broad band at 3325 cm\(^{-1}\) is mainly assigned for the carbonylated and hydroxylated functional groups, i.e., –OH bond of hydrated phenols, poly(vinyl phenol), poly(-ethylene oxide), and poly(vinyl isobutylether), and the wave number of 1635 cm\(^{-1}\) is assigned for N–H bond of hydrated primary amines, amino acids, C=C non-cyclic alkenes and cyclic alkanes, C=O stretching of polypeptides, and urease NO\(_2\) asymmetric stretching of nitrates (Pretsch et al. 2009).

After treating this wastewater, the pollutants were reduced due to the above said functional groups are broken

![Fig. 2 Color and COD reduction in various dosages](image)

![Fig. 3 TDS trend during treatment](image)
and gets de-linked from waste water along with the added coagulants and flocculants. Particularly, in this research work, it was observed that the main functional group is carboxylic group in the lignin which is cause of color, and another significant functional group of the –OH bond from hydrated phenol, subsequently, one more N–H bond from hydrated primary amines was segregated from the wastewater sample. These are made bond with the additives, such as NF Alum, fly ash, and C-PAM formed flocs. The broad band of the untreated sample spectra at 3325 cm$^{-1}$ is observed mainly due to the alcoholic and phenolic hydroxyl groups in lignin. After treating, these functional groups are de-linked from the wastewater and it appears in the treated wastewater sludge. After the removal of the above pollutants from the pulp and paper industry wastewater, the resulting water was taken for analysis.

The removed functional groups present in the treated wastewater sludge have also been proved through the FTIR spectra (Fig. 5). The bands appeared at around 1250–900 cm$^{-1}$ for the treated wastewater sludge mainly indicated the stretching vibration of cyclic ethers caused by the combination or overlapping of C–O as a result of several deformations in lignin by the action of the chemicals used in the processes. The bands at around 1369–1316 cm$^{-1}$ showed the stretching vibration of aromatic nitro compound (NO$_2$) and aromatic C–N stretching caused by agricultural residues and the chemicals used in the treatment system. The band at 1395 cm$^{-1}$ was assigned to the asymmetric stretching of SO$_2$ groups appeared due to the pulping process of chemicals and gets de-linked from the wastewater due to the added coagulants. Bands appeared at 1424 and 1458 cm$^{-1}$ denote the asymmetric deformation of C–H in lignin and C=C stretching vibration. There are also stretching vibrations of aromatic nitro compound NO$_2$, and secondary C=O and C–N groups at 1540–1515 cm$^{-1}$ have been observed. The band at 1648 cm$^{-1}$ was observed for the secondary amide C=O stretching, primary amide NH$_2$ bending, $\alpha$, $\beta$-unsaturated aromatic oximes/imines, and intra-molecular hydrogen-bonded carboxylic acid groups. The functional groups like C=O stretching of $\alpha$-amino acids, Aryl aldehydes, $\alpha$, $\beta$-unsaturated acids, carbamates, amide I band, –CO–NH–CO–, $\alpha$, $\beta$-unsaturated aldehydes, aryl carboxylic acids have also been observed at 1699 cm$^{-1}$. The band at 1744 cm$^{-1}$ was noted for C=O stretching vibrations of saturated aliphatic ketones, $\alpha$ halogen ketones, and dicarboxylic amino acids. The removal of color causing pollutants is strongly evidenced by these significant bands appeared in the sludge. The stretching vibrations of NH$^+$, CH, SH, PH, and SiH functional groups are confirmed through the peaks appeared at around 2250–2700 cm$^{-1}$. Other significant functional groups like O–H stretching vibration of chlorophenol appeared at 3550–3600 cm$^{-1}$ and the O–H free carboxylic acid groups at 3500–3580 cm$^{-1}$ were observed. This is also one of the witnesses for removing the pollutants from the wastewater after treatment. There is also a stretching vibration of oximes O–H, and Si–H at 3200–3700 cm$^{-1}$ was observed. The groups like tertiarybutyl phenols, the bands appeared at 3640–3650 cm$^{-1}$ and O–H stretching alcoholic groups showed that the phenolic/alcoholic groups and are gets de-linked due to the effectively treated with the wastewater. These are the evidences for the removal of pollutants from the wastewater.

**Conclusion**

The purpose of this work is to overcome the problem of disposal of colored high-strength wastewater released from the integrated pulp and paper industries. This particular research work is achieved by the reduction of the pollution caused due to the diluted chemicals, such as phenol, aromatic primary amines, carboxylic acids, and lignin etc.
from the wastewater. Moreover, the same research work is greatly useful to conquer the problem of discharging colored wastewater generated from integrated pulp and paper industries. From this work, the color and COD reduction were achieved by maximum removal of pollutants, such as hydrated lignin (C=O), phenolic hydroxyl groups, chlorinated phenols, carboxylic acid groups, and inorganic functional groups, such as sulphur, phosphorous compounds, etc., which can be highly appreciable and valuable and applicable for the pulp and paper industries. Now, in the present treatment system of this integrated pulp and paper industry, there is no such type of chemicals added to the secondary clarifier unit. Its major role is only to remove the suspended matters. By the addition of the recommended coagulants and flocculants in secondary clarifier unit, the resource recovery is definitely possible. Also to solve the effluent problem, the large quantity of water may be absolutely reused for the other streams/waste facilities and it will not give harmful effects to the environment.

Acknowledgments The authors are thankful to Dr. B. Nataraj and Dr. Moorthi Pichumani, Sri Ramakrishna Engineering College, Coimbatore, India, for providing the FTIR spectral facility. The authors are also thankful to Mr. Arvindh for assistance of this research work.
