Abstract

This work reports on the bulk properties of the quaternary Heusler alloy $\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}$ with the Fe concentration $x = \ldots$. All samples, which were prepared by arc melting, exhibit $L2_1$ long range order over the complete range of Fe concentration. Structural and magnetic properties of $\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}$ Heusler alloys were investigated by means of X-ray diffraction, high and low temperature magnetometry, Mößbauer spectroscopy, and differential scanning calorimetry. The electronic structure was explored by means of high energy photo emission spectroscopy at about 8 keV photon energy. This ensures true bulk sensitivity of the measurements. The magnetization of the Fe doped Heusler alloys is in agreement with the values of the magnetic moments expected for a Slater-Pauling like behavior of half-metallic ferromagnets. The experimental findings are discussed on the hand of self-consistent calculations of the electronic and magnetic structure. To achieve good agreement with experiment, the calculations indicate that on-site electron-electron correlation must be taken into account, even at low Fe concentration. The present investigation focuses on searching for the quaternary compound where the half-metallic behavior is stable against outside influences. Overall, the results suggest that the best candidate may be found at an iron concentration of about 50%.

I. INTRODUCTION

Kübler et al. [1] recognized that the minority-spin state densities at the Fermi energy nearly vanish for Co$_2$MnAl and Co$_2$MnSn. The authors concluded that this should lead to peculiar transport properties in these Heusler compounds because only the majority density contributes. The so-called half-metallic ferromagnets have been proposed as ideal candidates for spin injection devices because they have been predicted to exhibit 100% spin polarization at the Fermi energy ($\epsilon_F$) [2]. From the applications point of view, a high Curie temperature for a half-metallic ferromagnet may be an important condition. For this reason, Heusler alloys with $L2_1$ structure have attracted great interest. Some of these alloys exhibit high Curie temperatures and, according to theory, should have a high spin polarization at the Fermi energy [3, 4, 5]. Calculations also show that anti-site disorder will destroy the high spin polarization [6], implying that precise control of the atomic structure of the Heusler alloys is required.

The Heusler alloy Co$_2$MnSi has attracted particular interest because it is predicted to have a large minority spin band gap of 0.4 eV and, at 985 K, has one of the highest Curie temperatures, among the known Heusler compounds [7, 8]. Structural and magnetic properties of Co$_2$MnSi have been reported for films and single crystals [9, 10, 11, 12, 13, 14]. In accordance with theoretical predictions, bulk Co$_2$MnSi has been stabilized in the $L2_1$ structure with a magnetization of 5 $\mu_B$ per formula unit. From tunneling magnetoresistance (TMR) data with one electrode consisting of a Co$_2$MnSi film Schmalhorst et al. [15, 16] inferred a spin polarization of 61% at the barrier interface. Although the desired spin polarization of 100% was not reached, the experimental value of the spin polarization is larger than the maximum 55% effective spin polarization of a variety of 3$d$-transition metal alloys in combination with Al$_2$O$_3$ barriers [17]. However, the spin polarization of photoelectrons emerging from single crystalline Co$_2$MnSi films grown on GaAs by pulsed laser deposition indicate a quite low spin polarization at the Fermi level of only 12% at the free surface [14]. Wang et al. [13, 14] assumed that partial chemical disorder was responsible for this discrepancy with the theoretical predictions.

Photoemission spectroscopy is the method of choice to study the occupied electronic structure of materials. Low kinetic energies result in a low electron mean free path being only 5.2 Å at kinetic energies of 100 eV (all values calculated for Co$_2$FeSi using the TPP2M...
equations \[18\]) and a depth of less than one cubic Heusler cell will contribute to the observed intensity. The situation becomes much better at high energies. In the hard X-ray region of about 8 keV one will reach a high bulk sensitivity with an escape depth being larger than 115 Å (corresponding to 20 cubic cells). High energy photo emission (at about 15 keV excitation energy) was first performed as early as 1989 \[19\] using a \(^{57}\)Co Mößbauer \(\gamma\)-source for excitation, however, with very low resolution only. Nowadays, high energy excitation and analysis of the electrons become easily feasible due to the development of high intense sources (insertion devices at synchrotron facilities) and multi-channel electron detection. Thus, high resolution - high energy photo emission (HRHEPE) was recently introduced by several groups \[20, 21, 22, 23, 24, 25\] as a bulk sensitive probe of the electronic structure in complex materials. In the present work, HRHEPE at \(h\nu \approx 8\) keV was used to study the density of states of \(\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}\) with \(x = 0, 1/2, 1\).

Recent investigations \[26, 27, 28, 29\] of the electronic structure of Heusler compounds indicate that on-site correlation plays an important role in these compounds and may serve to destroy the half-metallic properties of \(\text{Co}_2\text{MnSi}\). In addition, if on-site correlation is considered in electronic structure calculations \(\text{Co}_2\text{FeSi}\) becomes a half-metallic ferromagnet with a magnetic moment of 6 \(\mu_B\).

The present investigation focuses on searching for a mixed compound in the series \(\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}\) where the half-metallic behavior is stable against the variation of on-site correlation and other outside influences.

II. COMPUTATIONAL DETAILS

The present work reports, besides experiments, on calculations of the electronic and magnetic properties of ordered Heusler compounds of the \(\text{Co}_2(\text{Mn}_{(1-x)}\text{Fe}_x)\text{Si}\) type. The random alloys were treated as virtual crystals of the \(\text{Co}_2\text{Mn}_{(1-i/4)}\text{Fe}_{i/4}\text{Si}\) type with \(i = 0, 1, 2, 3, 4\). Non-rational values of \(x\) as well as random disorder (for examples see references \[30, 31, 32\]) will not be discussed here.

The self-consistent electronic structure calculations were carried out using the scalar-relativistic full potential linearized augmented plane wave method (FLAPW) as provided by Wien2k \[33\]. In the parameterization of Perdew \textit{et al} \[34\] the exchange-correlation functional was taken within the generalized gradient approximation (GGA). A \(20 \times 20 \times 20\)
mesh was used for integration of cubic systems, resulting in 255 \( k \)-points in the irreducible wedge of the Brillouin zone.

The properties of pure compounds containing Mn or Fe were calculated in \( Fm\bar{3}m \) symmetry using the experimental lattice parameter \( (a = 10.658a_{0B}, a_{0B} = 0.529177 \text{ Å}) \) determined by X-ray powder diffraction. Co atoms are placed on 8c Wyckoff positions, Mn or Fe on 4a and Si on 4b \[51\]. All muffin tin radii were set as nearly touching spheres with \( r_{\text{MT}} = 2.3a_{0B} \). A structural optimization for the pure compounds showed that the calculated lattice parameter deviates from the experimental one only marginally.

The calculation of mixed random alloys is not straightforward in the FLAPW as is used here. However, the substitution of some Mn atoms of the \( L2_1 \) structure by Fe leads in certain cases to ordered structures that can be easily used for the calculations. Those ordered, mixed compounds have the general formula sum \( \text{Co}_8(\text{Mn}_{(1-x)}\text{Fe}_x)_4\text{Si}_4 \) and have integer occupation of Mn and Fe if \( x = i/4 \) where \( i = 1, 2, 3 \). (for more details see Ref.\[32\]).

To verify that ordered compounds could be used instead of random alloys, the full relativistic Korringa-Kohn-Rostocker (KKR) method with the coherent potential approximation (CPA) was employed \[35\]. The exchange-correlation functional was parameterized by using the plain GGA. No significant differences in the integrated properties, such as the density of states or the magnetic moments, were found between the methods.

For the case of \( \text{Co}_2\text{FeSi} \), it has recently been demonstrated that LSDA or GGA schemes are not sufficient for describing the electronic structure correctly. Significant improvement was found, however, when the LDA+\( U \) method \[26, 29\] was used and this computational scheme was used here as well. LDA+\( U \), as described by Anisimov \textit{et al} \[36\], adds an orbital dependent electron-electron correlation, which is not included in the plain LSDA or GGA schemes. It should be mentioned that the \( +U \) was used in the FLAPW scheme with the GGA rather than the LSDA parameterization of the exchange-correlation functional. No significant differences were observed using either of these parameterizations.

\section*{III. EXPERIMENTAL DETAILS}

\( \text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si} \) samples were prepared by arc melting of stoichiometric amounts of the constituents in an argon atmosphere at \( 10^{-4} \text{ mbar} \). Care was taken to avoid oxygen contamination. This was ensured by evaporating Ti inside of the vacuum chamber before melting
the compound as well as by additional purifying of the process gas. The polycrystalline ingots that were formed were then annealed in an evacuated quartz tube for 21 days. This procedure resulted in samples exhibiting the Heusler type \( L_2 \) structure, which was verified by X-ray powder diffraction (XRD) using excitation by Cu K\(_\alpha\) or Mo K\(_\alpha\) radiation.

Flat disks were cut from the ingots and polished for spectroscopic investigations of bulk samples. For powder investigations, the remainder was crushed by hand using a mortar. It should be noted that using a steel ball mill results in a strong perturbation of the crystalline structure.

X-ray photo emission (ESCA) was used to verify the composition and to check the cleanliness of the samples. After removal of the native oxide from the polished surfaces by Ar\(^+\) ion bombardment, no impurities were detected with ESCA. The samples were afterwards capped in-situ by a 2 nm layer of Au at room temperature to prevent oxidation of the samples during transport in air.

Magneto-structural investigations were carried out using Mößbauer spectroscopy in transmission geometry using a constant acceleration spectrometer. For excitation, a \(^{57}\)Co(Rh) source with a line width of 0.105 mm/s (5 neV) was used. The spectra from powder samples were taken at 290 K.

The magnetic properties were investigated by a super conducting quantum interference device (SQUID, Quantum Design MPMS-XL-5) using nearly punctual pieces of approximately 5 mg to 10 mg of the sample. Differential scanning calorimetry (DSC) measurements (NETZCH, STA 429) were performed to detect phase transitions below the melting point. In particular, attempts were made to find the Curie temperature \( (T_C) \), but this turned out to be too high to be determined directly by the SQUID, which is limited to 775 K even in the high temperature mode.

The electronic structure was explored by means of high energy X-ray photo emission spectroscopy. The measurements were performed at the beamline BL47XU of the synchrotron SPring 8 (Hyogo, Japan). The photons are produced by means of a 140-pole in vacuum undulator and are further monochromized by a double double-crystal monochromator. The first monochromator uses Si(111) crystals and the second a Si(111) channel-cut crystal with 444 reflections (for 8 keV X-rays). The energy of the photo emitted electrons is analyzed using a Gammadata - Scienta R 4000-12kV electron spectrometer. The ultimate resolution of the set up (monochromator plus analyzer at 50 eV pass energy using a 200 µm slit) is
83.5 meV at 7935.099 eV photon energy. For the here reported experiments, a photon energy of 7939.15 eV has been employed. Under the present experimental conditions an overall resolution of 250 meV has been reached. All values concerning the resolution are determined from the Fermi-edge of an Au sample. Due to the low cross-section of the valence states from the investigated compounds, the spectra had to be taken with $E_{\text{pass}} = 200$ eV and a 500 µm slit for a good signal to noise ratio. The polycrystalline samples have been fractured in-situ before taking the spectra to remove the native oxide layer. Core-level spectra have been taken to check the cleanliness of the samples. No traces of impurities were found.

The valence band spectra shown in section IV.E were collected over 2-4 h at about 100 mA electron current in the storage ring in the top-up mode. All measurements have been taken at a sample temperature of 20 K.

IV. RESULTS AND DISCUSSION

A. Electronic and Magnetic Structure

The electronic structure of the substitutional series $\text{Co}_2\text{Mn}_i\text{Fe}_{1-i/4}\text{Si}$ with $i = 0, \ldots, 4$ was calculated using the LDA+$U$ method. This method was used because it was found that plain GGA calculations are not sufficient to explain the magnetic moments in $\text{Co}_2\text{FeSi}$ [26]. Using the impurity model of Anisimov and Gunnarsson [37] along with self consistent calculations, the effective Coulomb-exchange parameter $U_{\text{eff}}$ was determined for the pure compounds containing Mn and Fe. Details of the procedure and the implementation of the constrained LDA calculations in FLAPW are reported by Madsen and Novak [38]. The values found in the present work are $U_{\text{Co}} = 0.30$ Ry and $U_{\text{Mn}} = 0.39$ Ry for $\text{Co}_2\text{MnSi}$, and $U_{\text{Co}} = 0.31$ Ry and $U_{\text{Fe}} = 0.32$ Ry for $\text{Co}_2\text{FeSi}$.

Comparing the semi-empirical values used in [29] to the values found here from the constrained LDA calculations, it is evident that the latter are too high to explain the magnetic moments. Additional calculations for the elemental 3$d$ transition metals revealed that all values for $U_{\text{eff}}$ found in the constrained LDA calculations are considerably too high to explain those metallic systems correctly. This is despite the fact that such calculations may result in reliable values for Mott insulators [39].

For these reasons, the semi-empirical values corresponding to 7.5 % of the atomic values
(see: Ref. 29) will be used and discussed here for the case of the FLAPW calculations. These values ensure that the calculated magnetic moments agree with the measured values over the entire range of the Fe concentration (compare Sec.: IV D). In particular, the values for $U_{\text{eff}}$ were set to $U_{\text{Co}} = 0.14 \text{ Ry}$, $U_{\text{Fe}} = 0.132 \text{ Ry}$, and $U_{\text{Mn}} = 0.13 \text{ Ry}$, independent of the iron concentration. These values are closer to the values for the Coulomb interaction $U_{dd}$ for $d$ electrons in the elemental 3$d$ transition metals reported by Bandyopadhyay and Sarma 40 even before the LDA+$U$ method itself was introduced.

The use of $U_{\text{eff}} = U - J$ suppresses multipole effects. That means, it neglects the non-spherical terms in the expansion of the Coulomb interaction. Additionally, full potential linearized muffin tin orbitals (FPLMTO) calculations were performed to check for the influence of the non-spherical terms. Differently, the LMTART 6.5 program provided by Savrasov 41 uses the Slater integrals $F^0 \ldots F^4$ for the calculation of the on-site correlation with $U = F^0$ and $J = (F^2 + F^4)/14$ (see also Refs.: 36, 37).

As in FLAPW, the use of the $U$ values from the constrained LDA calculations leads also in FPLMTO to much too large values for the magnetic moments compared to the experimental findings. In a next step, only reduced values for $F^0$ were used. Following the arguments of Ref.: 42, only $F^0$ should be effected by the screening in the solid state. However, the use of the atomic values for $F^2$ and $F^4$ as proposed in Ref.: 42 still did not lead to satisfactory values for the magnetic moments. Finally, the reduction of all Slater integrals to 10% of their atomic values was leading to results being compatible to the measured magnetic moments. Moreover, nearly identical results as in FLAPW were obtained concerning not only the magnetic moments but also the band structures. The slightly higher values resulting in the most appropriate for FPLMTO are caused by the fact that these calculations used the $U$ on top of the LDA exchange-correlation functional and not on top of the GGA parameterization. This behavior reveals that GGA includes some more correlation compared to pure LDA. It is also observed within the FLAPW scheme.

The different values for $U$, $U_{dd}$, $U_{\text{eff}}$, and $F^0 \ldots F^4$ are summarized in Table I. The values according to Ref.: 40 where calculated for the $d$-state occupation as found from calculations using spherical potentials. The values for FLAPW are calculated from the Slater integrals reduced to 7.5% of the atomic values as calculated by Cowans program 29, 43 and the values for FPLMTO correspond to 10% of the atomic values. The use of these values leads to nearly identical results comparing FLAPW and FPLMTO.
TABLE I: LDA + U parameter for Co$_2$Mn$_{1-x}$Fe$_x$Si. (All values are given in Ry.)

| element | $U_{dd}$ | $U$   | $U_{eff}$ | $F^0$  | $F^2$  | $F^4$  |
|---------|----------|-------|-----------|--------|--------|--------|
| Co      | 0.194    | 0.3(1)| 0.140     | 0.185  | 0.085  | 0.053  |
| Fe      | 0.171    | 0.32  | 0.132     | 0.175  | 0.081  | 0.050  |
| Mn      | 0.148    | 0.39  | 0.130     | 0.164  | 0.076  | 0.047  |

In the following, only the results from the FLAPW calculations are discussed to allow for a better comparison with previous work. However, all results shown below are compatible and agree very well with those using LDA+U in FPLMTO calculations. Figure 1 shows the spin resolved band structure and the total density of states for the pure compounds Co$_2$MnSi and Co$_2$FeSi as calculated within the framework of the LDA+U. In all cases, the band structures are very similar and the gap in the minority bands is clearly revealed.

When explaining the Heusler half-metallic ferromagnets using simple rigid band-like or
molecular orbital-like models, it is expected that the additional $d$ electron of the Fe compound fills the majority states while not affecting the minority states. As may be seen from Fig.:\[1\] this is clearly a strong oversimplification. The additional electron must be absorbed in the strongly dispersing unoccupied $d$-bands seen in the Mn compound just above $\epsilon_F$. Comparing the majority DOS, it can be seen that the high density $d$-states at -1.4 eV (or -3.5 eV) in Co$_2$MnSi are shifted to approximately -3 eV (or -5 eV) in Co$_2$FeSi. Keeping the minority DOS fixed, this would imply an additional exchange splitting of about 1.6 eV, when compared to Co$_2$MnSi, between the majority and minority states in Co$_2$FeSi. This large and rather unphysical shift indicates that the rigid band model fails and that other alterations of the band structure must take place.

After inspecting the electronic structure in more detail, some particular changes are found. For example, the rather large shift of the occupied majority $d$-states is compensated by a shift of the occupied minority $d$-states, and this keeps the exchange splitting rather fixed. This then results in a shift and splitting of the occupied minority $d$-states (seen at -1 eV in the Mn compound and at -1.7 eV or -2.3 eV in the Fe compound) as well as a shift of the unoccupied minority $d$-states towards the Fermi energy. In addition, the splitting of the unoccupied minority $d$-states just above the gap is reduced from 0.7 eV in Co$_2$MnSi to 0.4 eV in Co$_2$FeSi. The most striking effect, however, is the shift of the Fermi energy from the top of the minority valence band to the bottom of the minority conduction band. These particular positions of the minority gap with respect to the Fermi energy make both systems rather unstable with respect to their electronic and magnetic properties. Any small change of a physically relevant quantity may serve to destroy the HMF character by shifting the Fermi energy completely outside of the minority gap. As long as the shift is assumed to be small, the magnetic moment may still be similar to the one expected from a Slater-Pauling behavior, even so, the minority gap is destroyed. For this reason, the magnetic moment may not provide evidence for a half-metallic state.

It is to be immediately expected that the situation improves in the mixed compounds containing both Mn and Fe. Figure 2 shows the spin resolved total density of states for the compounds with an intermediate Fe concentration ($x \neq 0, 1$). In all cases, the gap in the minority bands is kept.

The shift of the majority $d$-states with low dispersion away from the Fermi energy is clearly visible in Fig.:\[2\] The additional charge (with increasing Fe concentration $x$) is filling
FIG. 2: Spin resolved density of states of Co$_2$Mn$_{1-x}$Fe$_x$Si for $x = 1/4, 1/2, \text{ and } 3/4$.

the strongly dispersing $d$-states in the majority channel. At the same time, the minority DOS is shifted with respect to the Fermi energy such that $\epsilon_F$ moves from the top of the minority valence bands at low $x$ to the bottom of the minority conduction bands at high $x$. In general, it can be concluded that the additional electrons affect both majority and minority states.

Table II summarizes the results for the gap in the minority states as found from LDA+$U$ calculations. The largest gap in the minority states is found for Co$_2$MnSi. The size of the gap decreases with increasing Fe content $x$, and at the same time, the position of the Fermi energy is moved from the top of the valence band to the bottom of the conduction band. It is also seen that the compounds with $x = 0$ and 1 are on the borderline to half-metallic ferromagnetism, as the Fermi energy just touches the top of the valence band or the bottom of the conduction band. In both cases, a slight change of $U_{eff}$ in the calculation is able to shift $\epsilon_F$ outside of the gap in the minority states.

For intermediate Fe concentration, the Fermi energy falls close to the middle of the gap in the minority states (see also Fig. 2). This situation makes the magnetic and electronic
TABLE II: Properties of the minority gap of ordered Co$_2$Mn$_{1-x}$Fe$_x$Si.

Given are the extremal energies of the valence band maximum (VB$_{\text{max}}$), the conduction band minimum (CB$_{\text{min}}$), and the resulting gap ($\Delta E$) in the minority states as found from LDA+$U$ calculations. The extremal energies are given with respect to $\epsilon_F$. All energies are given in eV.

| $x$ | VB$_{\text{max}}$ | CB$_{\text{min}}$ | $\Delta E$ |
|-----|-----------------|-----------------|-----------|
| 0   | 0.003           | 1.307           | 1.3       |
| 1/4 | -0.181          | 0.970           | 1.15      |
| 1/2 | -0.386          | 0.495           | 0.88      |
| 3/4 | -0.582          | 0.181           | 0.86      |
| 1   | -0.810          | -0.028          | 0.78      |

properties of the compound very stable against external influences that will not be able to change the number of minority electrons. This applies both to the parameters in the theoretical calculations as well as the actual experimental situation. From this observation it can be concluded that Co$_2$Mn$_{1/2}$Fe$_{1/2}$Si exhibits a very stable half-metallic character in this series of compounds, as well as those with a concentration close to $x = 0.5$.

If the Heusler alloys are half-metallic ferromagnets, then they will show a Slater-Pauling behavior for the magnetization, meaning that the saturation magnetization scales with the number of valence electrons [3, 5, 44]. The magnetic moment per unit cell (in multiples of the Bohr magneton $\mu_B$) is given by:

$$m = N_V - 24,$$  \hspace{1cm} (1)

with $N_V$ denoting the accumulated number of valence electrons in the unit cell. For Co$_2$MnSi there is a total of $2 \times 9 + 7 + 4 = 29$ valence electrons in the unit cell and accordingly 30 for Co$_2$FeSi. For this reason the magnetic moment is expected to vary linearly from 5 $\mu_B$ to 6 $\mu_B$ with increasing iron concentration in Co$_2$Mn$_{1-x}$Fe$_x$Si.

The results found from the LDA+$U$ calculations for the magnetic moments are summarized in Tab.: [III] and compared to pure GGA calculations without the inclusion of the $U$ type correlation. It is evident from Tab.: [III] that the GGA derived values do not follow the Slater-Pauling curve (with the exception of Co$_2$MnSi), whereas the values from the LDA+$U$ follow the curve closely. These results again indicate the loss of the minority gap - and thus
TABLE III: Total magnetic moments of ordered $\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}$. All moments were calculated for the given super-cells. Their values are in $\mu_B$ and respect 4 atoms in the unit cell for easier comparison.

| compound     | $x$  | GGA LDA+U |
|--------------|------|-----------|
| $\text{Co}_2\text{MnSi}$ | 0    | 5.00      |
| $\text{Co}_8\text{Mn}_3\text{FeSi}_4$ | 1/4  | 5.21      |
| $\text{Co}_4\text{MnFeSi}_2$ | 1/2  | 5.44      |
| $\text{Co}_8\text{MnFe}_3\text{Si}_4$ | 3/4  | 5.55      |
| $\text{Co}_2\text{FeSi}$ | 1    | 5.56      |

the loss of half-metallicity - if the on-site correlation is not included.

B. Structural Properties

Structural characterization has been performed with X-ray diffraction (XRD) of powders as the standard method. Due to the small differences in the scattering factors between the 3d metals Mn, Fe and Co, structural information, other than a simple confirmation of a single cubic phase can only be gained by measuring the comparatively small (5% of the (220)-peak) (111) and (200) superstructure peaks that are typical for the face centered cubic (fcc) lattice. The simulated powder diffraction pattern of $\text{Co}_2\text{MnSi}$ shows the decisive (111) and (200) peaks for the defect-free structure. Both of these super-lattice peaks vanish for a random occupation of all lattice sites (4a, 4b, and 8c) resulting in the $A2$ structure. In the case of random occupation of 4a and 4b sites by Mn, Fe, and Si, only the (200) super-lattice peak of the $B2$ structure type would be seen, while the (111) peak would vanish.

Such types of disorder would close the gap in the minority DOS so that the material would no longer be a half-metallic ferromagnet \[28,32\]. However, the magnetic moments may still follow a Slater-Pauling like behavior. The half-metallic character is also destroyed when only one of the Co atoms is exchanged by Mn/Fe ($X$ structure \[45\] with symmetry $F\bar{4}3m$). This type of disorder shows up as a (111) super-lattice peak with higher intensity than the (200) peak.

As expected for the defect-free structure, the experimental data show both the (111) and
(200) peaks with equal intensity for all Fe concentrations indicating the presence of a long range fcc structure for all samples (see Fig.: 3). Within the uncertainty of the experiment, the lattice parameter of 5.64 Å remains nearly independent of the Fe concentration.

Because the scattering factors of all three transition metals are very similar, X-ray diffraction cannot easily discern a disorder when the Mn and Fe are partially exchanged with Co atoms on both 8a positions (DO₃ like disorder). Because both have the same F m3m symmetry, this leads to nearly identical diffraction patterns when going from the L2₁ to the DO₃ structure. As will be shown in the next section, this type of disorder can be ruled out by means of Mößbauer spectroscopy.

C. Magneto-structural Properties

⁵⁷Fe Mößbauer spectroscopy was performed to investigate the magneto-structural properties. The transmission spectrum of Co₂Mn₀₅Fe₀₅Si is shown in Fig.: 4. Starting from 10 %, the spectra for the complete range of Fe concentration x are all similar and therefore not shown here. The observed sextet-like pattern is typical for a magnetically ordered system. The pattern is typical for the cubic symmetry and no asymmetric shift of the lines from a non-cubic quadrupole interaction is observed.

The spectrum shown in Fig.: 4 for 50 % Fe is dominated by an intense sextet. With Fe occupying the 4a sites with cubic symmetry (O₅₈), this sextet indicates on the high order of the sample. In addition to the sextet, a much weaker line at the center of the spectrum is
The spectrum was taken at 290K and excited by a $^{57}$Co(Rh) source. Solid lines are results of a fit to determine the sextet and doublet contributions and to evaluate the hyperfine field.

visible. Depending upon the composition it can be explained as a singlet or doublet. Its contribution to the overall intensity of the spectrum is approximately 3.5 % at $x = 0.5$. The origin of the singlet or doublet may be caused by anti-site disorder leading to a small fraction of paramagnetic Fe atoms. The splitting of the paramagnetic line into a doublet is due to dynamic effects and, among others reasons, usually depends upon the size of the powder grains. The slight disorder arises most likely from surface regions of the sample that are destroyed when the sample is crushed to powder. A partial contamination of the relatively large surface area of the powder with oxygen can also not been excluded. The relative contribution of the doublet decreases exponentially from 9 % in low Fe-substituted Co$_2$Mn$_{0.9}$Fe$_{0.1}$Si to 1.8 % in pure Co$_2$FeSi. As was also suggested by the photo absorption and ESCA measurements, this may indicate a larger probability for oxidation in the Mn rich part of the series.

The line width of the sextet is approximately $(0.14 \pm 0.01)$ mm/s (corresponding to 6.7 neV) on average over the complete series of compositions. A pronouncedly higher line width of $\approx 0.19$ mm/s was found for the alloy with $x = 0.7$. This indicates a higher disorder in that sample and may also explain the slightly higher magnetic moment (compare Fig.: \(\text{\textbullet}\) in Sec.: IV D). The isomer shift increases linearly from 0.075 mm/s (3.6 neV) to 0.129 mm/s (6.2 neV) with increasing $x$, indicating the change in the environment of the Fe atoms, that appears here in the second nearest neighbor shell where the next Fe or Mn atoms are located. Despite this increase, the values suggest a Fe$^{3+}$-like character of the iron.

FIG. 4: $^{57}$Fe Mössbauer spectrum of Co$_2$Mn$_{0.5}$Fe$_{0.5}$Si.
TABLE IV: Mößbauer data for iron in Co$_2$Mn$_{1-x}$Fe$_x$Si.

Given are the measured and calculated values of the hyperfine field ($H_{hff}$) and the measured isomer shift ($IS$) for increasing Fe concentration $x$.

| $x$ | $H_{hff}$ [10$^6$ A/m] | $IS$ [neV] |
|-----|----------------------|------------|
| 0.1 | 25.937               | 3.61       |

| 0.25| -                    | 26.534     |
| 0.4 | 26.412               | 4.18       |
| 0.5 | 26.466               | 4.34       |
| 0.6 | 26.417               | 4.75       |
| 0.7 | 26.259               | 4.90       |
| 0.75| -                    | 26.962     |
| 0.8 | 25.915               | 5.33       |
| 0.9 | 25.480               | 5.77       |
| 1   | 24.997               | 27.013     | 6.21       |

atoms in Co$_2$Mn$_{1-x}$Fe$_x$Si. The increase points on a slight decrease of the valence electron concentration close to the iron atoms. Table IV summarizes the values for the isomer shift and the hyperfine field ($H_{hff}$) as function of the iron concentration.

The hyperfine field at the Fe sites amounts to $26.5 \times 10^6$ A/m in Co$_2$Mn$_{0.5}$Fe$_{0.5}$Si. This is the maximum value observed in the complete series with varying Fe concentration $x$. Overall, the hyperfine field varies non-linearly from $25.9 \times 10^6$ A/m at $x = 0.1$ to $25 \times 10^6$ A/m at $x = 1$ (see also: 52). For low iron concentration, it increases with $x$ and decreases from $x = 0.5$ to $x = 1$. It should be noted that the Mößbauer spectra taken at 85K from Co$_2$FeSi exhibited a considerably higher value ($26.3 \times 10^6$ A/m) without additional singlet or doublet contributions. Therefore, thermally activated fluctuations or disorder can not be excluded here. The values of the hyperfine field at the Fe atoms are comparable to those found by Niculescu et al [46, 47] using spin-echo nuclear magnetic resonance (NMR). For Co$_{3-x}$Fe$_x$Si, these authors reported approximately $26.9 \times 10^6$ A/m for iron on 4a sites. The values for partial occupancy of 8c sites, expected from NMR [47] ($\approx 16 \times 10^6$ A/m) for Co$_2$FeSi are
FIG. 5: DSC results for Co$_2$MnSi and Co$_2$Mn$_{0.8}$Fe$_{0.2}$Si. 

considerably smaller. This is in agreement with calculations for Co and Fe on interchanged sites ($\approx 17 \times 10^6$ A/m). Therefore, a DO$_3$ type disorder can be excluded. The calculated hyperfine fields are, however, nearly independent of the Fe concentration. They decrease linearly with $x$ by $-0.7 \times 10^6$ A/m from 27.01 $\times 10^6$ A/m for Co$_2$FeSi. A maximum in the $H_{hff}(x)$ dependence at $x = 1/2$ could not be verified. It was found neither for the ordered compounds using the FLAPW method with the LDA+U (see Tab.: IV), nor for random alloys calculated using a KKR-CPA scheme in the GGA approximation [53].

Differential scanning calorimetry was used to find the high temperature phase transitions in the substitutional series. Figure 5 shows a typical result from DSC, which was used to investigate the expected phase transitions. The figure displays the change of the DSC signal as a function of the temperature using nominal heating and cooling rates of 20 K/min. A strong signal arising from a phase transition is easily detected at about 1000 K to 1050 K during both heating and cooling. The shift of the maxima is mainly due to an intrinsic hysteresis effect of the method and depends on the temperature rates and the actual amount of material. The length of the error bars in Fig.: 5 corresponds to this hysteresis.

A series of DSC measurements was performed with different scanning rates for heating and cooling, but it was not possible to distinguish the magnetic transition temperature because it was too close to the structural transition temperature of the $L2_1$ to the $B2$ phase $T_t^{B2\leftrightarrow L2_1}$. To overcome the problem of nearby phase transitions of different kind, it would be necessary to obtain high temperature magnetization curves such as those that Kobayashi et al. [48] obtained in their examination of the series Co$_2$Cr$_{1-x}$Fe$_x$Ga, or the difference in
FIG. 6: Phase transitions in Co$_2$Mn$_{1-x}$Fe$_x$Si.

The straight line is the result of a linear fit of $T_c(x)$ as function of the Fe concentration. The given Curie temperatures are taken from Refs. [49] and [26] for Co$_2$MnSi and Co$_2$FeSi, respectively.

the transition temperatures should be more than 100 K.

Figure 6 displays the temperature dependence of the $L_2 \leftrightarrow B_2$ phase transition. It is nearly constant, increasing slightly, as the Fe content increases, from \( \approx 1024 \) K for Co$_2$MnSi to \( \approx 1031 \) K for Co$_2$FeSi. It is seen that the Curie temperatures of the end members of the substitutional series are slightly below or above the structural phase transition for the compound containing Mn or Fe, respectively. The Curie temperature is expected to increase with increasing $x$ from $T_C(0) = 985$ K [49] to $T_C(1) = 1100$ K [26], while in Co$_2$Mn$_{1-x}$Fe$_x$Si $T_{t_{B2\leftrightarrow L21}}$ hardly varies with increasing $x$, being around 1027 K for $x = 0.5$. It is therefore impossible here to unambiguously determine $T_C$ by using the DSC technique, because of the relative weakness of the magnetic transition compared to the structural transition and the overlap of those two transitions in the DSC spectra. It is interesting to note that the Curie temperature of the compounds with high Fe concentration appears to be above the order-disorder phase transition.

D. Magnetic Properties

The Co$_2$-based Heusler alloys that are half-metallic ferromagnets show a Slater-Pauling like behavior for the magnetization (see Sec.: IV A). The saturation magnetization scales with the number of valence electrons [5] and the magnetic moment per unit cell is given by
Eq.: A magnetic moment of:

\[ m(x) = (5 + x)\mu_B \]  

is expected for Co\(_{2}\)Mn\(_{1-x}\)Fe\(_x\)Si.

Low temperature magnetometry was performed by means of the SQUID to check the calculated saturation moment. Selected results are shown in Fig.: The increase of the saturation moment with the iron concentration is clearly visible. In addition, it is found that all Co\(_{2}\)Mn\(_{1-x}\)Fe\(_x\)Si samples are soft magnetic with a small remanence and a small coercive field. Results for the element-specific magnetic moments from X-ray magnetic circular dichroism are reported elsewhere [50].

The total magnetic moments, measured at 5 K and in saturation, are (4.97 ± 0.05)\(\mu_B\) and (5.97 ± 0.05)\(\mu_B\) for the pure compounds Co\(_2\)MnSi and Co\(_2\)FeSi, respectively. The latter is in perfect agreement with the recent investigation reported in Refs. [26, 27]. Figure displays the dependence of the saturation moment as a function of the Fe concentration \(x\). The series shows a nearly linear increase of \(m\) with increasing Fe concentration that closely fits the values expected from a Slater-Pauling like behavior.

Comparing the experimental results to the theoretical values as given in Tab.: it is evident that they closely agree with those from the LDA+\(U\) calculations. The agreement of the GGA result for Co\(_2\)MnSi may thus be seen as due to chance. The comparison also substantiates the use of correlation energies of about 0.135 Ry, as these can be used to predict the magnetic moment correctly over the entire range of Fe concentration \(x\).
E. Electronic Properties

The results from high energy photo emission are shown in Figure 9 and compared to the total density of states calculated for Co$_2$Mn$_{1-x}$Fe$_x$Si with $x = 0, 1/2, 1$). The calculated total DOS is the sum of the spin resolved majority and minority DOS shown in Figures 1 & 2 and convoluted with a Fermi-Dirac distribution using $T = 20$ K.

The spectra of all three compounds reveal clearly the low lying $s$-states at about $-11$ eV to $-9$ eV below the Fermi energy, in well agreement to the calculated DOS. These low lying bands are separated from the high lying $d$-states by the Heusler-typical hybridization gap being clearly resolved in the spectra as well as the calculated DOS. The size of this gap amounts typically to $\Delta E \approx 2$ eV in Si containing compounds.

Obviously, the emission from the low lying $s$-states is pronouncedly enhanced compared to the emission from the $d$-states. This can be explained by a different behavior of the cross sections of the $s$, $p$, and $d$ states with increasing kinetic energy as was recently demonstrated by Panaccione et al for the case of the silver valence band [24]. In particular, the cross section for $d$-states decreases faster with increasing photon energy than the one of the $s$-states. This behavior influences also the onset of the $d$-bands at about $-7$ eV. Just at the bottom of those $d$-bands, they are hybridized with $s, p$-like states, leading to a high intensity in this energy region.

The structure of the spectra in the range of the $d$ states agrees with the structures observed in the total DOS. However, one has to account for lifetime broadening and the experimental
FIG. 9: Valence density of $\text{Co}_2\text{Mn}_{1-x}\text{Fe}_x\text{Si}$ ($x = 0, 1/2, 1$).

The calculated total density of states (a, b, c) has been convoluted by a Fermi-Dirac distribution using $T = 20$ K. The photoelectron spectra (e, f, g) have been excited by $h\nu = 7.939$ keV.

resolution if comparing that energy range. The lowest flat band of the majority band structure (see Fig. 1), accompanying the localized moment at the Y sites, results in a sharp peak in the DOS at about -3.5 eV and -5 eV for Mn and Fe, respectively (marked by arrows in Fig. 9a) and c). These peaks are shifted away from $\epsilon_F$ by the electron-electron correlation in the LDA+$U$ calculation and would appear without $U$ closer to the Fermi energy. Their energetic position corresponds to structures revealed in the measured spectra, thus they are a good proof for the use of the LDA+$U$ scheme.

Most interesting is the behavior of the calculated DOS and the measured spectra close to $\epsilon_F$ as this might give an advice about the gap in the minority states. The majority band structure contributes only few states to the density at $\epsilon_F$ emerging from strongly dispersing bands. This region of low density is enclosed by a high density of states arising from flat bands at the upper and lower limits of the minority band gap. The onset of the minority valence band is clearly seen in the total DOS as well as the low majority density at the Fermi energy. The same behavior is observed in the measured valence band spectra. From the spectra, it can be estimated that the Fermi energy is in all three cases about 0.5 eV
above the minority valence band. This gives strong evidence that all compounds of the 
Co$_2$Mn$_{1-x}$Fe$_x$Si series exhibit really half-metallic ferromagnetism.

The values for $U_{\text{eff}}$ used in section IV.A are the borderline cases for the half-metallic 
ferromagnetism over the complete series Co$_2$Mn$_{1-x}$Fe$_x$Si. They were used being independent 
of the Fe concentration, what was suggested for Co from the constrained LDA calculations. 
However, the valence band spectra shown in Figure 9 indicate that the Fermi energy of both 
end members may fall inside of the minority gap rather than being located at the edges of 
the minority gap. This situation may be simulated by a variation of $U$. A comparison to 
the $U$-dependence of the minority gap shown in Ref.: [29] suggests smaller effective Coulomb 
exchange parameters for the Mn rich part and larger ones for the Fe rich part of the series. 
This might also explain the non-linearity reported in section IV.D for the hyperfine field. 
A variation of those parameters for all contributing 3$d$ constituents in the calculations was 
omitted here because it would not bring more insight into the nature of the problem, at 
present.

Overall, the measured photoelectron spectra agree well with the calculated density of 
states and principally verify the use of the LDA+$U$ scheme. In particular, the shape of the 
spectra close to $\epsilon_F$ can be explained by the occurrence of a gap in the minority states and 
thus points indirectly on the half-metallic state of all three compounds investigated here by 
photo emission. For clarity about the gap, spin resolved photo emission spectroscopy at high 
energies would be highly desirable. However, this will make another step of improvement 
of the instrumentation necessary, for both photon sources as well as electron energy and 
spin analyzers, as the spin detection will need a factor of at least three to four orders of 
magnitude more intensity for a single energy channel at the same resolution as used here for 
the intensity spectra.

V. SUMMARY AND CONCLUSION

The substitutional series of the quaternary Heusler compound Co$_2$Mn$_{1-x}$Fe$_x$Si was syn-
thesized and investigated both experimentally and theoretically.

The results found from the LDA+$U$ calculations for the magnetic moments $m(x)$ closely 
follow the Slater-Pauling curve. The shift of the minority gap with respect to the Fermi 
energy, from the top of the minority valence band for Co$_2$MnSi to the bottom of the minority
conduction band for Co$_2$FeSi, makes both systems rather unstable with respect to their electronic and magnetic properties. The calculated band structures suggest that the most stable compound in a half-metallic state will occur at an intermediate Fe concentration. These theoretical findings are supported by the experiments.

All samples of the substitutional series exhibit an $L2_1$ order that is independent of the Fe concentration $x$. The observed structural order-disorder phase transition from $L2_1 \leftrightarrow B2$ is nearly independent of $x$ and occurs at about 1030 K. Mößbauer measurements show only a negligible paramagnetic contribution confirming the high degree of order over the whole substitutional series. In agreement with the expectation from the Slater-Pauling curve, the magnetic moment increases linearly with $x$ from 5 $\mu_B$ to 6 $\mu_B$. True bulk sensitive, high energy photo emission bearded out the inclusion of electron-electron correlation in the calculation of the electronic structure and gave an indirect advise on the gap in the minority states. Both, valence band spectra and hyperfine fields indicate an increase of the effective Coulomb exchange parameters with increasing Fe concentration.

From both the experimental and computational results it is concluded that a compound with an intermediate Fe concentration of about 50% should be most stable and best suited for spintronic applications.

**Acknowledgments**

The authors are grateful for the support by G. Schönhense and thank J. Thoenies and A. Lotz for help with the calculation of $U_{eff}$ as well as V. Jung, V. Ksenofontov, S. Reimann (Mainz) for performing the Mößbauer experiments, and Y. Takeda (Spring-8, Japan) for help during the beamtime. The synchrotron radiation experiments were performed at the beamline BL47XU of SPring-8 with the approval of the Japan Synchrotron Radiation Research Institute (JASRI) (proposal no. 2006A1476). This work was partially supported by a Grant-in-Aid for Scientific Research (A) (No.15206006), and also partially supported by a Nanotechnology Support Project, of The Ministry of Education, Culture, Sports, Science and Technology of Japan.
