Intracellular Calcium and the Mechanism of the Dip in the Anodal Strength-Interval Curve in Cardiac Tissue

Sunil M. Kandel, BSc; Bradley J. Roth, PhD

**Background:** The strength-interval (SI) curve is an important measure of refractoriness in cardiac tissue. The anodal SI curve contains a “dip” in which the S2 threshold increases with interval. Two explanations exist for this dip: (1) electrotonic interaction between regions of depolarization and hyperpolarization; and (2) the sodium-calcium exchange (NCX) current. The goal of this study is to use mathematical modeling to determine which explanation is correct.

**Methods and Results:** The bidomain model represents cardiac tissue and the Luo-Rudy model describes the active membrane. The SI curve is determined by applying a threshold stimulus at different time intervals after a previous action potential. During space-clamped and equal-anisotropy-ratios simulations, anodal excitation does not occur. During unequal-anisotropy-ratios simulations, electrotonic currents, not membrane currents, are present during the few milliseconds before excitation. The dip disappears with no NCX current, but is present with 50% or 75% reduction of it. The calcium-induced-calcium-release (CICR) current has little effect on the dip.

**Conclusions:** These results indicate that neither the NCX nor the CICR current is responsible for the dip in the anodal SI curve. It is caused by the electrotonic interaction between regions of depolarization and hyperpolarization following the S2 stimulus. (Circ J 2014; 78: 1127–1135)

**Key Words:** Anodal dip; CICR current; Intracellular calcium; NCX current; Strength-interval curve

Electrical defibrillation of the heart is a complex process, which we cannot understand without an adequate description of the more simple process of electrical stimulation by a unipolar electrode. One behavior that must be understood completely is the strength-interval (SI) curve.

The strength-interval curve describes how refractory cardiac tissue responds to an electrical stimulus; the critical event during electrical defibrillation. The SI curve is determined by applying 2 stimuli: a first (S1) that initiates an action potential (AP), and then a second (S2), and measuring the threshold S2 strength as a function of the S1–S2 interval. If a cathodal S2 stimulus is applied through a unipolar electrode, the SI curve decreases monotonically with the interval because the tissue becomes easier to stimulate as it recovers from the refractoriness of the S1 AP. If an anodal stimulus is applied through the same electrode, however, the response is more complicated. A section of the curve has a positive slope; the threshold increases as the interval increases. \(^1\)\(^-\)\(^7\) This “dip” in the anodal SI curve is surprising; excitation should get easier as the tissue recovers from refractoriness, not more difficult. It is also fundamental; threshold excitation with a unipolar electrode is the simplest example of electrical stimulation. We cannot be confident that we understand defibrillation until we thoroughly understand the dip in the anodal SI curve.

Two competing hypotheses exist to explain the shape of the anodal SI curve.\(^8\) The first is electrotonic interaction of adjacent regions of depolarization and hyperpolarization. Dekker identified 4 mechanisms of excitation: cathode make, cathode break, anode make, and anode break.\(^3\) Roth used the bidomain model of cardiac tissue to explain these mechanisms,\(^6\) and Wikswo et al\(^19\) verified them by using optical mapping in rabbit hearts. Suppose a S2 anodal stimulus is applied to refractory tissue. The hyperpolarization under the anode causes the tissue to recover from refactoriness by removing sodium channel inactivation. Adjacent regions of depolarization are created along the fiber direction by anisotropy.\(^1\) After the stimulus pulse ends (the “break” of the pulse), depolarization diffuses into the previously hyperpolarized and now excitable tissue, exciting it.

Roth used the bidomain model to explain the mechanism of the dip in the anodal SI curve.\(^7\) To understand why the dip is present, realize that anode-break excitation requires a source of depolarization that interacts electrotonically with the hyperpolarized and excitable tissue under the anode. This depolarization arises from 2 sources. One is caused directly by the S2 stimulus (the virtual cathode), and another arises from the previous S1 AP. If S2 is applied during the repolarization phase of the S1 AP, then shortening the S1–S2 interval increases the S1 depolarization present, reducing the S2 threshold. Thus, the dip in the anodal SI curve arises from the electrotonic interaction of hyperpolarized tissue under the anode and

_д_\_t V_m = -J_{ion} - \nabla \cdot (g_i \mathbf{E} \nabla V_e) \quad (1)

\nabla \cdot (g_e \mathbf{E} \nabla V_e) = \nabla \cdot (g_i \mathbf{E} \nabla V_m) \quad (2)

where \( V_m \) and \( V_e \) are the transmembrane and extracellular potentials, \( g_i \) and \( g_e \) are the intracellular and extracellular conductivity tensors, \( C \) is the membrane capacitance per unit area (0.01 F/m²), \( \beta \) is the ratio of membrane surface area to tissue volume (0.3 μm⁻¹), and \( J_{ion} \) is the membrane ion current density.

To indicate position, we use cylindrical coordinates (\( z, \rho, \theta \)) with the potential independent of the angle \( \theta \). The myocardial fibers are straight and lie along the \( z \)-axis. The tissue is characterized by 4 parameters: the intracellular \( (i) \) and extracellular \( (e) \) conductivities in the direction parallel to \( (z) \) and perpendicular to \( (\rho) \) the fibers. Their values \( g_{zi}=0.1863, g_{zi}=0.0179, g_{ze}=0.1863, \) and \( g_{ze}=0.0894 \) S/m are chosen so the tissue has unequal-anisotropy-ratios: \( g_{zi}/g_{zi}=10.4, g_{ze}/g_{ze}=2.08 \). For simulations using equal-anisotropy-ratios, \( g_{zi}=0.1863, g_{zi}=0.0298, g_{ze}=0.1836, \) and \( g_{ze}=0.0298 \) S/m.\(^{16}\)

We apply the unipolar stimulus through a cylindrical electrode centered at the origin, with a length of 1 mm along the \( z \) direction, a diameter of 0.4 mm along the \( \rho \) direction, and a surface area of 1.51 mm². Three boundary conditions are applied at the tissue-electrode interface: the normal component of the intracellular current density is zero; the extracellular potential is constant; and the total current passing from the electrode into the extracellular space is equal to the stimulus current. In space-clamped simulations, we apply the stimulus as an extra membrane current. The tissue has a length of 20 mm and a diameter adjacent to depolarized tissue. Sidorov et al performed optical mapping studies of rabbit hearts and verified that the dip occurs during break excitation.\(^{12}\)

Recently, Joung et al proposed another explanation for the dip in the anodal SI curve, related to the intracellular calcium concentration (Cai) and the sodium-calcium exchange (NCX) current.\(^{13}\) They “tested the hypothesis that the maximum slope of the Cai decline \( (–(dCai/dt)_{\text{max}}) \) corresponds to the timing of the anodal dip on the SI curve and the initiation of repetitive responses and ventricular fibrillation (VF) after a premature stimulus (S2).” Their alternative mechanism is fundamentally different from the electrotonic mechanism. They conclude “The anodal dip (supernormal) period results from a complex interplay of factors, among which the Cai transient plays a critical role in shaping the balance between depolarizing and repolarizing forces during late phase 3 to reduce the excitation threshold.”\(^{13}\)

In this study, we use mathematical modeling to test these hypotheses regarding the response of refractory tissue to an anodal shock, and to determine which of these mechanisms is the cause of the dip in the anodal SI curve.\(^{14}\)

**Methods**

Cardiac tissue is represented by a three-dimensional bidomain model, and the active properties of the membrane are described by the Luo-Rudy dynamic (LRd) model,\(^{15}\) which includes a representation of calcium dynamics and the NCX current (I_{NCX}). The coupled partial differential equations in the bidomain model with LRd kinetics are:

**Figure 1.** (A) Transmembrane potential \( (V_m) \), (B) intracellular calcium concentration \( \text{(Cai)} \), (C) \( dV_m/dt \), and (D) \( d\text{Cai}/dt \), vs. time following the S1 stimulus, at \( z=1 \) mm and \( \rho=0.2 \) mm. The peak value of \( dV_m/dt \) and \( d\text{Cai}/dt \) are 269 V/s and 0.415 μmol·L⁻¹·ms⁻¹, respectively.
of 8 mm. At the tissue’s outer edge, the normal component of the intracellular current density is zero and the extracellular potential is zero. During unipolar cathodal stimulation, the outer edge of the tissue behaves as the anode and has negligible influence on the electrical behavior near the stimulating electrode.

We solve the bidomain equations numerically by replacing the temporal and spatial derivatives with finite differences. At each time step, we solve Equation 1 for \( V_m \) by using Euler’s explicit method, using \( V_r \) from the previous time step in the source term, and then solve Equation 2 for \( V_e \) by using systematic overrelaxation, using the updated \( V_m \) in the source term. The time step is 0.01 ms, the space step is 0.1 mm and 0.04 mm in \( z \) and \( \rho \) directions. The spatial grid consists of 101\( \times \)101 nodes. Approximately 40 min of CPU time are required for a 300 ms simulation. Symmetry allows us to consider only 1 quadrant of the \( z-\rho \) plane.

**Results**

**The Action Potential in Normal Tissue**

We apply a cathodal stimulus \( S_1 \) of 0.15 mA (twice threshold) for 2 ms to resting tissue. This stimulus excites an AP that propagates outward from the electrode with propagation speeds of 0.33 and 0.13 m/s along the \( z \) and \( \rho \) axes. Figure 1A shows \( V_m \) as a function of time. The action potential duration (APD) is approximately 192 ms. Figure 1B shows \( C_{ai} \) as a function of time. The maximum \( C_{ai} \) transient is 1.3 \( \mu \)mol/L, achieved soon after the AP begins. Calcium ions move in and out of the sarcoplasmic reticulum (SR). The mechanism by which \( C_{ai} \) is released from the junctional sarcoplasmic reticulum (JSR) into the myoplasm is called calcium-induced-calcium-release (CICR). The plot of \( dV_m/dt \) vs. time shows the maximum upstroke velocity (269 V/s), which is important for CICR. In the Luo-Rudy model, the CICR current (Icicr) is only activated if \( (dV_m/dt)_{\text{max}} \) is greater than 100 V/s. The rate of change in \( C_{ai} \) (d\( C_{ai} \)/dt) is shown in Figure 1D. The d\( C_{ai} \)/dt values are highest during phase 1 (depolarization upstroke) and lowest during phase 3 (repolarization) of the AP.

**The Strength-Interval Curve**

A second stimulus, \( S_2 \), is applied later through the same electrode. The \( S_1–S_2 \) interval is defined as the time from the start of \( S_1 \) to the start of \( S_2 \), where \( S_2 \) has a duration of 20 ms and can be cathodal or anodal. In space-clamped simulations using the LRd model, we obtain no excitation from anodal stimulation, so there is no anodal SI curve. We also performed simulations using the bidomain model with equal-anisotropy-ratios. Although this case is non-physiological, it does eliminate the presence of virtual cathodes surrounding an anode and virtual anodes surrounding a cathode, and thereby supresses break excitation. Therefore, it allows us to better identify which features of the SI curve arise from electrotonic interactions between regions of depolarization and hyperpolarization, and which do not. We did not observe anodal excitation.

When we perform tissue simulations using the bidomain model with unequal-anisotropy-ratios, we find a complicated distribution of \( V_m \) including adjacent regions of depolarization and hyperpolarization. Figures 2A and 2B show the calculated SI curves for normal tissue with unequal-anisotropy-ratios. During cathodal stimulation, the SI curve falls with increasing interval, reflecting the recovery of excitability following the \( S_1 \) AP. However, during anodal stimulation, the SI curve contains a dip; a section has positive slope (174–188 ms). The anodal threshold stimulus during the dip is 0.84 mA (interval =175 ms). The local maximum after the dip is 0.90 mA (interval =188 ms). After reaching its peak, the SI curve falls abruptly. The SI curves are divided into 2 sections, corresponding to ‘make’ and ‘break’ stimulation. There is an abrupt change in the SI curve that marks the transition from break to make (indicated by arrows in Figure 2); make and break stimulation occurs for intervals greater and less than 193 ms. There is a minimum interval below which the break mechanism does not stimulate the tissue; 156 and 143 ms for cathodal and anodal stimulation, respectively. For diastolic tissue, the thresholds for cathode make and anode make are 0.04 and 0.41 mA. The level of accuracy for the threshold is 0.01 mA in all calculations for SI curves.

To determine the cause of the dip in the anodal SI curve, we calculated the negative of the membrane current (\( J_{\text{ion}} \)) and the
electrotonic current ($\nabla \cdot \mathbf{j}_e \nabla V_e / \beta$) following the S2 shock at the location where excitation begins. To find where anode-break excitation occurs, $V_m$ and $I_{Na}$ are plotted as functions of time at 5 locations along the z-axis ($z=0.6, 0.7, 0.8, 0.9$ and 1 mm; Figures 3A,B). In each case, during the first few milliseconds after the end of the anodal stimulus, depolarization at the virtual anode diffuses into the hyperpolarized tissue under the anode (electrotonic interaction). At $z=1$ mm, the membrane current is nearly zero and does not contribute significantly to depolarization. At $z=0.9$ mm and below, the membrane current contributes significantly to the depolarization upstroke. We consider $z=0.9$ mm as the first excitation site because the upstroke happens first at this location (purple curve, Figure 3A). This is near the boundary between the virtual anode and virtual cathode. Figure 3C illustrates the spatial distribution of $V_m$ at 3 times following the stimulus. The black dot represents the location ($\rho=0$ mm, $z=0.9$ mm) where excitation begins.

Figure 4 plots the membrane and electrotonic contributions to $V_m$ at the location where excitation first occurs. We applied a 0.85 mA anodal S2 pulse for 20 ms starting at 175 ms. After the stimulus ends (195 ms), the electrotonic contribution rapidly becomes positive as the depolarization at the virtual cathode diffuses into this region. When $V_m$ approaches threshold (~55 mV), $I_{Na}$ activates, causing the membrane contribution to become positive. After 202 ms, the electrotonic contribution becomes small compared to the membrane current. But in the crucial few milliseconds before $I_{Na}$ activates, the electrotonic current is much larger than the membrane current, and acts as the trigger for launching the AP. The wave front originates from the region where depolarization and hyperpolarization are adjacent; the
Impact of Individual Currents on the Anodal SI Curve

Joung et al suggested that the dip in the anodal SI curve is related to INCX. We remove INCX or reduce it by 50% or 25% of its normal value to represent different amounts of block (Figure 5). Elimination of INcx results in an AP with a shorter duration of approximately 90 ms, a 56% reduction compared to normal. 75% and 50% of the normal INcx resulted in 1% and 7% reduction of the APD. For all cases, the amplitude of the AP is similar (Figure 5A). Figure 5B shows INcx as a function of time, and Figure 5C shows Cai for different modulations of INcx. A complete block of INcx increases the peak value of Cai by 400%. To determine the cause of this large calcium transient, we examine the Ca\(^{2+}\) in the myoplasm and SR during an AP. At rest, INCX is normally inward, moving Ca\(^{2+}\) out of the cell. This current helps maintain the low Cai, which in turn ensures that the JSR concentration is relatively low. In the absence of INCX, the total Ca\(^{2+}\) concentration in the JSR at the resting state increases to 14.0 mmol/L (1.8 times the Ca\(^{2+}\) concentration present in the normal model). After the stimulus, Cai increases due to the entry of Ca\(^{2+}\) ions, and as a result, Ca\(^{2+}\) is released by CICR from the JSR into the myoplasm, resulting in a peak intracellular Ca\(^{2+}\) transient of 6.4 μmol/L, which is significantly larger than a 1.4 μmol/L peak transient when NCX is active. The

Figures 6B, C and D compare the anodal SI curves at different amplitudes of $I_{\text{cicr}}$ and $I_{\text{up}}$ and combinations of both currents. Removal of these currents individually or collectively results in the AP having a longer APD and larger amplitude (Figure 7). These modifications change the transition of the make and break section in the anodal SI curves. The break section needs a larger threshold stimulus for AP propagation. We see a larger dip in the break section of each curve. Even if the removal of $I_{\text{cicr}}$ results in a larger break section and longer APD (purple curve of Figure 6B), the timing of the dip does not change. In the absence of $I_{\text{up}}$ and combined $I_{\text{cicr}}$ and $I_{\text{up}}$, the timing of the dip changes to 165 and 162, respectively, from 175 ms (purple curve of Figures 6C and D). In all cases, the dip regions of the curves have almost twice the S2 threshold compared to the normal model. A reduction in these currents by 25% and 50% results in a smaller dip. In all our simulations with different amplitudes of $I_{\text{cicr}}$ or $I_{\text{up}}$ or their combination, we did not find a case where the dip is completely eliminated.

Figures 6A shows the anodal SI curves with 100%, 75%, 50% and 0% of normal $I_{\text{cicr}}$. Removal of $I_{\text{cicr}}$ causes a nearly flat anodal SI curve shifted to short intervals; the entire curve corresponds to break excitation and the dip disappears. A 50% reduction in the normal $I_{\text{cicr}}$ not only results in a steeper dip but also changes the timing of the dip from 175 to 155 ms. When we reduce $I_{\text{cicr}}$ by 25%, the timing of the dip changes from 175 to 170 ms. The shapes of the anodal SI curves are similar for different reductions of $I_{\text{cicr}}$, but the curves shift towards shorter intervals as we reduce $I_{\text{cicr}}$.

Joung et al’s experiments indicate that the CICR blocker, ryanodine, suppresses the dip in the anodal SI curve and the Ca-ATPase blocker, thapsigargin, blocks calcium uptake by the SR and does not change the timing of the dip. They also claimed that combined ryanodine and thapsigargin infusion eliminated the dip. To test these experimental findings, we reduce (by 25% and 50% of normal value) or remove the $I_{\text{cicr}}$ and the calcium uptake current ($I_{\text{up}}$) one at a time or at the same time and plot anodal SI curves at different amplitudes of those currents.
When tissue having equal-anisotropy-ratios was excited, we did not observe an electrotonic effect because the virtual cathodes disappear; cathode-break excitation does not occur and the entire cathodal SI curve corresponds to make excitation, and no excitation occurs during anodal stimulation. The equal-anisotropy-ratios simulations are similar to space-clamp simulations in that there are no adjacent regions of depolarization and hyperpolarization. Neither case resulted in anodal stimulation, suggesting the importance of electrotonic interactions in excitation. The shapes of the SI curves (Figure 2) are similar to those calculated previously using the Beeler-Reuter model. However, the cathodal and anodal SI curves started 127 ms earlier than the respective SI curves with the Beeler-Reuter model because of the different APDs in the 2 models. The calculated anodal SI curve has the same shape as measured experimentally by Sidorov et al. The curve has a dip, plateau phase, and descent at the end of the relative refractory period. The presence of the dip in the bidomain simulations but not in the space-clamped simulations or the simulations with equal-anisotropy-ratios suggests the dominance of the electrotonic interaction between virtual anodes and cathodes over the NCX current as a mechanism for the dip.

We find an abrupt transition from anode-make to anode-break stimulation, as noted by Roth. The fall in the anodal SI curve at 193 ms (Figure 2B) reflects the transition from make to break excitation. However, Sidorov et al. found a gradual transition in the anodal SI curve. The mean values of threshold current

Figure 7. Comparison of (A) transmembrane potential (Vm), (B) intracellular calcium concentration (Cai), (C) calcium-dependent inactivation gate (fCa), and (D) the calcium current (ICa) in the normal model and in the absence of calcium-induced-calcium-release current (Icicr). Blue and red curves represent the presence and absence of Icicr.
in diastolic tissue are 0.04 and 0.41 mA for cathodal and anodal stimulation. These results are consistent with Roth et al., who used bidomain calculations to find the cathodal and anodal diastolic threshold. However, there is a discrepancy between theoretical and experimental values of threshold stimulation. Experimentally, Dekker found mean values of 0.4 and 1.3 mA, and Sidorov et al. found 0.15 and 0.05 mA for cathodal and anodal diastolic stimulation. This disparity in threshold is well known and has been discussed previously, although a satisfactory explanation has not been determined.

Ranjan et al. suggested that the dip in the anodal SI curve could be explained by an effect of an slow hyperpolarization-activated inward current. Roth and Chen added such a current to the original Luo–Rudy model, and compared the SI curves with and without it. To determine the underlying cause of the dip in the strength–interval curve, they calculated the membrane and electrotonic currents following the S2 shock at the location where excitation begins. They found that while both electrotonic current and a hyperpolarization-activated current contribute to anode-break excitation, only the electrotonic interactions are responsible for the dip in the anodal SI curve. Roth and Chen also stressed that if the electrotonic current is responsible for excitation, the wave front should originate from the region where depolarization and hyperpolarization are adjacent, the edge of the virtual anode. To determine the cause of the dip in the SI curve, they calculated the membrane and electrotonic currents following the S2 shock at the location where excitation begins (z=0.9 mm, which is the edge of the virtual anode). Figure 4 indicates that electrotonic currents, not calcium or other membrane currents, are present during the critical few milliseconds before excitation. This simulation supports the hypothesis that virtual cathodes and anodes, and not membrane current, is responsible for the dip.

Genetic knockout mice exist that have reduced or augmented Na-Ca exchange. Previous space-clamped simulations in these mice have shown that a reduction of NCX has only a small effect on the AP amplitude and duration. In our studies, 75% and 50% of the normal NCX resulted in a slight reduction of the normal APD and no changes in the amplitude. This is in agreement with the experimental findings.

Joung et al. claimed that the dip in the anodal SI curve is related to NCX. We reduced or removed NCX from our model to see if the dip disappears. The dip indeed disappears with no NCX, but is present with 50% and 75% of normal NCX, suggesting the dominance of the electrotonic mechanism over the NCX mechanism (Figure 6A). The bidomain model was first used to explain the dip in the anodal SI curve using a membrane model that did not include NCX. It is difficult to imagine that NCX plays a crucial role in explaining the dip if simulations predict the dip using a model that does not contain NCX.

We get the maximum value of \( \frac{d\text{Ca}^{2+}}{dt} \) at an interval between 180 and 190 ms, and this is when we have the dip in the anodal SI curve. This is consistent in every calculation we have done. So, the timing of \( \frac{d\text{Ca}^{2+}}{dt} \)max corresponds to the dip in the anodal SI curve, which is consistent with the findings by Joung et al. They argued that the peak of \( \text{NCX} \) (as measured by \( \frac{d\text{Ca}^{2+}}{dt} \)) occurs at the same time as the dip, "suggesting that NCX activation most likely played a role in the anodal dip of the SI curve." Our results indicate that although NCX and the dip do indeed occur at the same time, this is not a causal relationship. One virtue of numerical simulations is that we can easily isolate the causal factors. In space-clamped simulations and simulations using equal anisotropy ratios, NCX is present with a similar time-course, but there is no dip in the anodal SI curve (or even any anodal excitation). If we compare the shape of the curves of \( \frac{d\text{Ca}^{2+}}{dt} \) and NCX as functions of time, they look similar, but they are not identical (Figure 5). Even in the complete absence of NCX, we find a peak in the calcium concentration time-course. Hence, \( \frac{d\text{Ca}^{2+}}{dt} \) cannot be taken as equivalent to NCX in all cases.

The experiments by Joung et al used 3 and 10 \( \mu \text{mol/L} \) of ryanodine. It is known that at 1 mmol/L and 10 mmol/L ryanodine causes the ryanodine receptor, RyR, to open to a subconductance level, whereas at high concentrations of 0.3–2 mmol/L, ryanodine binds lower-affinity sites and completely blocks the RyR. Blocking the CICR (by the application of a high concentration of ryanodine) has resulted in APD prolongation but no shift in the dip of the anodal SI curve toward longer S1–S2 intervals. Even partial blockage of CICR has no profound effect on the timing and position of the dip in the anodal SI curve. Hence, NCX is not responsible for the dip, as suggested by Joung et al.

Their experiments indicate that thapsigargin blocks calcium uptake by the SR and does not change the timing of the anodal dip. But in our simulation, the dip occurs 10 ms earlier than the dip in the normal model. Also, we still find a dip present upon the reduction and elimination of ICaL and IKr, which is not consistent with the findings by Joung et al (Figures 6B–D).

We suggest that the crucial event leading to a dip in the anodal SI curve is the rapid repolarization at the end of the S1 action potential, and the electrotonic interaction of the repolarization with the virtual anodes and cathodes. As proposed previously, anode-break excitation requires a source of depolarization to excite the hyperpolarized and excitable tissue under the anode. S1 depolarization can replace a virtual cathode as the source of this depolarization, and the S1 depolarization is greater at shorter intervals, leading to a dip. The fact that the magnitude of NCX occurs at the same time as the repolarization of the action potential is a coincidence, and not a cause of the behavior.

Study Limitations

Our model has several limitations. We assume a uniform straight fiber geometry. Our membrane model is restricted to that proposed by Luo and Rudy. Other models are available, including other currents such as the calcium-activated potassium channel. Purkinje fibers might play a role in the recurrence of VF after defibrillation. We have not included Purkinje fibers in this calculation. Many experiments are performed by stimulating the epicardial surface, in which case the Purkinje fibers should play a smaller role than during endocardial excitation. We assume the experiment is performed on the surface of the heart in air, as in a Langendorff apparatus. If the tissue is bounded by a volume conductor, the results might be different.

Conclusions

We integrated the bidomain model together with the LRd model to obtain a detailed calculation of the mechanism of excitation and to understand the electrical behavior of the heart. The dominance of the electrotonic mechanism implies the importance of the spatial distribution of virtual electrodes during excitation. This study provides new and important insights into the response of cardiac tissue to strong electric shocks, and helps to distinguish the role of electrotonic and calcium interactions during excitation. This, in turn, will lead to a better understanding of how best to model tissue-shock interactions and optimize advanced defibrillation protocols.
