For the purpose of reducing the energy consumption and construction cost of buildings, the preparation process of geopolymer based foamed concrete, which is a novel material of the wall and roof of building, had been studied in detail. Water glass and sodium hydroxide were used as the alkali activator to excite the mixture consists of slag, fly ash and Kaolin to form the geopolymer matrix, and finally the foams generated using the physical foaming method were filled into the geopolymer matrix to produce geopolymer-based foamed concrete blocks. In the preparation process, firstly one of the four parameters of foam content, water-binder ratio, water glass content, and water glass modulus had been changed separately to study the influence of a single factor on the compressive strength, dry density, thermal conductivity and specific strength of foamed concrete blocks. The experimental results show that the above four factors have different degrees of influence on the concerned performances. Next, some representative combinations of these factors were constructed by orthogonal experiment method, and the influence degree of each combination on the concerned performances was determined by means of range analysis. According to the results of analysis, the most important influencing factor in terms of thermal conductivity was the water-binder ratio, followed by foam content, water glass modulus and water glass content. When the foam content is 1.58%, the water-binder ratio is 0.45, the water glass content is 30%, and the water glass modulus is 1.2, the thermal conductivity of the prepared geopolymer foam concrete reaches 0.044 W/(m·K), which satisfies the expected requirements for heating in severe cold areas.

Keywords: geopolymer, foamed concrete, orthogonal experiment, thermal conductivity, range analysis

1 INTRODUCTION

With the development of society and the increase of population, the problem of energy shortage has become increasingly prominent, and countries all over the world have attached great importance to energy conservation and environmental protection in the construction industry (Huang, 2013). The Chinese government proposed the development of “applicable, economical and green buildings” in the “13th Five-Year Plan” (Fan et al., 2019). As an important part of the building, the design of the enclosure structure is closely related to the building energy consumption (Liu et al., 2014). In recent years, with the continuous enhancement of China’s scientific research and economic strength, relevant functional departments have put forward higher requirements on building environmental
bubbles (Ramamurthy et al., 2009). In different countries such as concrete with light weight and uniformly distributed discrete Thailand, foam concrete has become a common material the United Kingdom, Germany, Turkey, the Philippines and and practical (Hill, 2013). In 1923, Axel Eriksson was granted a major improvements in production equipment and process, proportion of doped components and material properties of foam concrete are yet to be studied.

This article mainly studies the preparation technology of foam concrete, and then expands it to introduce in detail the optimized design of the raw materials and doping ratio of foam concrete to obtain the ideal compressive strength, dry density, thermal conductivity, and specific strength in the fresh and hardened state. The remainder of this paper is structured as follows: Section 2 provides a complete solution of preparing the geopolymers-based foam concrete referred in this article. Next, the influence of a single factor among foam content, water-binder ratio, water glass content and water glass modulus on the compressive strength, dry density, thermal conductivity, and specific strength of foam concrete blocks are described and discussed in Section 3. Apart from this, the results of orthogonal experiment (Xuan and Leung, 2011) and range analysis (Tang et al., 2011) of the combination of various influencing factors will also be presented. At last, the conclusions are drawn in Section 4.

2 RAW MATERIALS AND PREPARATION METHOD OF FOAMED CONCRETE

2.1 Raw Materials

The most important raw material for preparing geopolymers-based foam concrete is geopolymer. Its basic material is usually aluminosilicate in industrial waste residue, roasted clay or natural minerals produced after smelting, or a mixture of the above substances. Here we mixed Kaolin (Inner Mongolia Hnggi Co., Ltd.), slag (Shenyang Huacheng Slag Powder Manufacturing Co., Ltd.) and fly ash (Tongliao General Power Plant Co., Ltd.) in a certain proportion to form the basic material of geopolymer. The main components of slag are calcium oxide and glass body. As a by-product of coal combustion, fly ash is usually classified as siliceous (class F) or cementitious (class C). In the experiment, class C fly ash (Type I) conforming to the ASTM C 618 standard was used as the auxiliary cementing material. The chemical composition of slag and fly ash are listed in Table 1. The alkali activator was made by water glass (Shandong You suo Chemical Technology Co., Ltd.) and sodium hydroxide (Shenyang Chemical Reagent Factory). In order to enhance the compressive strength of the geopolymer, in addition to the above-mentioned raw materials, a small amount of H46 hollow glass beads jointly developed by Ma’anshan Institute of Mining
Research and Chinese Academy of Sciences were added. The physical foaming method is used to realize the preparation of geopolymer-based foamed concrete. The current physical foaming agents mainly include rosin, synthetic, protein, and composite. Among them, the composite has the highest foaming efficiency. The high-performance composite foaming agent produced by Qingdao Xinyu Machinery Technology Co., Ltd., was used in the experiments. The foaming agent used is a nearly colorless and transparent liquid, and the dilution ratio, pH value, bleeding and foam density are 50, 7.1, <20 ml and 50 kg/m³, respectively. For extending and stabilizing the foam to maintain its long-term performance, hydroxypropyl methyl cellulose produced by a Beijing company was introduced as a foam stabilizer.

2.2 Preparation Method
The preparing process of geopolymer-based foamed concrete was shown in Figure 1. First, sodium hydroxide, water glass and water were mixed to form an alkali activator of the required modulus; subsequently, dry materials such as Kaolin, slag and fly ash are mixed in a certain proportion and poured into a pot and stirred evenly (about 3 min); then, the prepared alkali activator was poured into the uniformly mixed powder and continue stirring to form a geopolymer slurry (about 1 min); finally, the prefabricated foam containing foam stabilizer was passed into a mixer filled with geopolymer slurry and quickly stirred for about 45 s to form a paste-like foamed concrete. In order to prevent the rapid loss of moisture and cause cracks, we poured the above paste into a mold and covered it with a film, and cured it in a standard curing chamber for 24 h under constant temperature and humidity (20 ± 2°C, RH 90%). After demolding, the environmental parameters were kept unchanged until the foamed concrete specimen reached the predetermined age of 28 days.

2.3 Evaluating the Properties of Foamed Concrete
The demoulded foam concrete blocks were divided to obtain 9 small blocks in 3 groups with a length, width and height of 10 cm. The measurement of the compressive strength and dry density of the foamed concrete in this test follows the relevant regulations in the industry standards of the Chinese construction industry (JG/T...
Before carrying out the experiments, first put the test block in a drying box and dry it to a constant weight. Next, measure the length, width and height twice and then take the average to calculate the volume and surface area. Finally, the average values of each group were calculated using the volumes, surface areas and masses of the 3 test blocks. The IMDRY3001 thermal conductivity tester was used to measure the thermal conductivity. In order to ensure accurate and reliable measurement results, the upper and lower surfaces of the selected test block are required to be as parallel, smooth and uniform in thickness as possible. The compression strength test uses NYL-2000D universal press, and its pressurizing speed can be set to 0.5–1.5KN/s. During the pressurization process, the load is continuously and uniformly increased until the test block is damaged. At this time, the pressure reading of the universal press is recorded as the maximum failure load. The compressive strength $f$ is expressed as

$$f = \frac{F}{A}$$  \hspace{1cm} (1)

where $F$ is the maximum failure load and $A$ is the area of Surface. The calculation of dry density follows the following formula:

$$\rho_0 = \frac{m_0}{V}$$  \hspace{1cm} (2)

In Eq. 2, $\rho_0$ is dry density, $m_0$ is quality after drying, and $V$ is the volume. Compared with the simple compressive strength index, the specific strength $S$ obtained after the introduction of dry density is more objective for foam concrete performance evaluation:

$$S = \frac{f}{\rho_0}$$  \hspace{1cm} (3)

### 3 RESULTS AND DISCUSSION

#### 3.1 Influencing Factors of Geopolymer-Based Foam Concrete

The performance of geopolymer-based foam concrete is affected by foam content, water-binder ratio, water glass content and
water glass modulus. The foam content is defined as ratio of the mass of foaming agent and gelling material required to prepare the foam. The water-binder ratio refers to the ratio of the total water consumption to the mass of the cementations material in the material preparation process. The water glass content is the ratio of the pure water glass in the liquid water glass to the mass of...
the cementitious material. The water glass modulus is $n$ in the molecular formula of water glass ($n$ in Na$_2$O-$n$SiO$_2$).

### 3.1.1 Foam Content
For the research of influence of foam content on the performance of geopolymer-based foam concrete, the foam content was increased from 0.30 to 1.58% during the preparation process while keeping other conditions unchanged. The elementary mix proportions are summarized in Table 2. The compressive strength, dry density and specific strength of geopolymer-based foam concrete at the age of 28-day are shown in Figure 2. It can be found that the compressive strength and dry density of the geopolymer-based foamed concrete decreases continuously with the increase of the foam content. The above phenomenon is the result of the continuous decrease of the concrete density as the foam content increases. On the other hand, the continuous increase of foam content will cause the foam to burst and merge, which in turn makes the pores larger. Moreover, the curve of specific strength shows a trend of first increasing and then decreasing. This is because there is a significant change in the rate of decrease of the concrete dry density as the foam content increases. When the foam content increases to 0.62%, the specific strength reaches the maximum. As is shown in Figure 3, the thermal conductivity of foam concrete decreases with the increase of foam content, which indicates that the voids inside the concrete help to improve its thermal insulation performance.

### 3.1.2 Water-Binder Ratio
In Table 2, the foam content was fixed at 0.94%, the water-binder ratio was changed in the range of 0.35–0.55, and the preparation process was repeated. As the water-binder ratio increases, the consistency of the slurry decreases, the fluidity increases, and the stability of the concrete structure decreases. In addition, the shear resistance of the slurry to the bubbles is also continuously reduced, the bubbles continue to float up and tend to concentrate, and stress defects are prone to appear in the concentrated position. The above factors will cause the compressive strength and dry density of concrete to decrease, as shown in Figure 4. In the same way as above (Figure 2), the sudden change in the rate of decrease of the concrete dry density results in the fluctuation of the specific strength curve. When the water-binder ratio is between 0.35 and 0.45, the curve has an inflection point. The pores of foamed concrete increase with the water-binder ratio, which in turn leads to a decrease in thermal conductivity. The changing trend of the curve in Figure 5 just confirms this process.

### 3.1.3 Water Glass Content
Among the materials listed in Table 2, the foam content was kept at 0.94% while the water glass content was gradually increased from 10 to 30%, and the preparation process was repeated. In Figure 6, with the increase in the amount of water glass, the compressive strength of the concrete first increases and then decreases. The main reason for this condition is the change in the degree of alkali excitation: as the content of water glass increases, the content of NaOH must be increased to keep the modulus of the water glass unchanged, resulting in stronger alkali excitation and compressive strength. However, when the content of water glass reaches a certain level, it will directly react with the geopolymer and weaken the excitation effect, thereby reducing the compressive strength. The increase of the water glass content
improves the stability of the unhardened concrete paste, that is, increases the shear resistance. As can be seen in Figure 6, the larger shear resistance causes a large amount of foam to break, reducing the voids of the concrete, and thereby increasing the dry density of the concrete. While the water glass content is increasing, the specific strength of the geopolymer-based foam concrete first increases and then decreases. When the water glass content is 20%, the specific strength reaches the maximum. The increase in the amount of water glass will reduce the voids of the foamed concrete, thereby accelerating the process of heat conduction, as described in the experimental results given in Figure 7.

### 3.1.4 Water Glass Modulus

The foam content listed in Table 2 was kept at 0.94%, while the water glass modulus was gradually increased from 1.0 to 1.4. The compressive strength, dry density and specific strength of geopolymer-based foam concrete at the age of 28-day are shown in Figure 8. The increase in the modulus of the water glass causes a corresponding increase in the Si component. The appropriate increase of the Si component is conducive to the formation of C-S-H gel, thereby increasing the compressive strength of concrete and reducing its dry density. However, when the modulus of the water glass is too large, the alkaline solution will not be able to fully stimulate the activity of the slag because the pH value is not high enough. At this time, the changes in compressive strength and dry density are opposite to the above, and then the maximum value of the specific strength curve appears. In Figure 9, the fluctuation of the thermal conductivity curve indicates that a moderate increase in the modulus of the water glass produces more pores, but when it

| the optimal combination | | A1B2C2D2 | B>A>D>C |
reaches a certain level, the effect of increasing the pores is no longer obvious. Instead, the increase in dry density caused by the introduction of Si components dominates.

### 3.2 Orthogonal Experiment and Range Analysis

#### 3.2.1 Orthogonal Experiment

Orthogonal experiments can not only reduce the number of repeated experiments, but also help to understand the overall experimental situation through the analysis of some representative points. For this research, the foam content, water-binder ratio, water glass content and water glass modulus are considered as independent factors. Within the optimal range of these factors, three typical values are taken for each to design the $L_9(3^4)$ orthogonal scheme shown in Table 3, where 9 represents the orthogonal combinations of factors, 3 represents the levels of each factor, and 4 represents the number of factors. As shown in Table 3, the orthogonal experiment table must satisfy orthogonality, representativeness and comprehensive comparability. Orthogonality requires that the number of occurrences of each level in the same column is equal. Representativeness means that the experimental points in the orthogonal experiment table are evenly distributed among all possible experimental points. The comprehensive comparability ensures that the interference of other factors is eliminated to the greatest extent in the effect of each level of each factor, so that the influence of different levels of the factor on the experimental indicators can be comprehensively compared.

#### 3.2.2 Range Analysis

In order to meet the main requirements of light weight, sturdiness and heat preservation of building enclosure materials, the orthogonal experiments were carried out with specific strength and thermal conductivity as the indicators. Range analysis is an intuitive data processing method for orthogonal experiments. Through this method, the degree of influence of each factor on a certain indicator can be evaluated, and the optimal combination of each factor for the indicator can be obtained. In Tables 4, 5 used for data analysis, $K_i$ represents the sum of experimental results corresponding to the $i$th level of a certain factor, and $k_i$ in the bracket is the mean value of $K_i$. When $k_i$ reaches the maximum value, $i$ is the optimal level of this factor. Once the optimal levels of each factor are determined, the optimal combination can be obtained directly. The difference between the maximum and minimum values of $k_i$ is the range $R$:

$$R = \max(k_i) - \min(k_i). \quad (4)$$

The larger the $R$ value, the greater the influence of the change of this factor on the experimental results. According to this, the order of the factors affecting the certain indicator can be determined. From the results listed in Table 4, it can be seen that the water glass modulus has the greatest influence on the specific strength, followed by the foam content, the water glass content and the water-binder ratio. When the foam content, water-binder ratio, water glass content and water glass modulus are 0.30%, 0.45, 20%, and 1.2, the maximum specific strength can be obtained. Similarly, it can be seen from Table 5 that the factors affecting the thermal conductivity are water-binder ratio, foam content, water glass modulus and water glass content in order. For severe cold regions, heat preservation is the basic requirement of building enclosure structure, so the optimal combination of parameters should correspond to the minimum value but not the maximum value of thermal conductivity. This explains why the optimal combination in Table 5 is A3B2C3D2 instead of A1B1C1D1. The thermal conductivity obtained by a separate experiment is 0.044.

### 4 CONCLUSION

The preparation and characterization methods of geopolymer-based lightweight foam concrete are reported in the paper. The influences of foam content, water-binder ratio, water glass content and water glass modulus on the performance indicators of the prepared foam concrete are studied. Based on the experimental results, the following conclusions are drawn:

1) Compared with several other parameters, the water-binder ratio has the most significant effect on the thermal conductivity.
2) With the continuous increase in the foam content or water-binder ratio, the compressive strength, dry density and thermal conductivity of geopolymer-based foam concrete at the age of 28-day have been continuously reduced.
3) When the content of water glass increases, the compressive strength of geopolymer-based foam concrete at the age of 28-day first increases and then decreases, while the dry density and thermal conductivity continue to increase.
4) Through orthogonal optimization experiment and range analysis, it can be known that the optimal levels of foam content, water-binder ratio, water glass content and water glass modulus for thermal conductivity is 1.58%, 0.45, 30%, and 1.2.
