In patients with Cushing’s syndrome, development of *Pneumocystis* pneumonia (PCP) is associated with extreme cortisol production levels. In this setting, immune reconstitution after abrogation of cortisol excess appears to induce development of symptomatic PCP. The high mortality rate warrants timely initiation of chemoprophylaxis or even preemptive treatment of PCP.

**Keywords.** Cushing’s syndrome; immune reconstitution; PCP; *Pneumocystis jirovecii*; prophylaxis.

Implementation of prophylaxis guidelines reduced the incidence of *Pneumocystis* pneumonia (PCP) in human immunodeficiency virus (HIV)-infected and transplant recipient populations over the past decades [1, 2]. However, there is an increasing number of patients who develop PCP due to other causes of acquired immunodeficiency [3]. Because of deprivation of leukocyte, T-cell, and macrophage function by prolonged exposure to supra-physiological levels of cortisol, patients with Cushing’s syndrome are at risk of acquiring PCP. The endogenous cortisol excess responsible for the clinical phenotype of Cushing’s syndrome can be either caused by an adrenocorticotropic hormone (ACTH)-producing pituitary adenoma, adrenal adenoma or hyperplasia, or ectopic (sometimes malignant) sources of ACTH or corticotropin-releasing hormone (CRH) production [4].

The clinical presentation and course of PCP in patients with Cushing’s syndrome may differ from patients with PCP due to other underlying conditions [5, 6]. Treatment for Cushing’s syndrome involves surgical treatment, ie, (1) removal of the pituitary or adrenal adenoma or ectopic tumor and/or (2) blockage of cortisol production by metyrapone or ketoconazole [7]. Thereafter, the functional recovery of immune cells commences [8, 9]. This may subsequently lead to a potent inflammatory reaction to *Pneumocystis jirovecii* in the lungs, resulting in a clinical presentation of PCP as an immune reconstitution inflammatory syndrome [10]. Because of the very low annual incidence of Cushing’s syndrome (approximately 0.2–5.0 per million individuals), reliable estimates of the incidence of PCP in this population as well as risk-enhancing characteristics and PCP-attributable mortality rates are unknown. We report the observations on 5 patients with PCP in a cohort of 53 patients with Cushing’s syndrome, and our institution serves as a national referral center for this disease. The issue of appropriate chemoprophylaxis in this patient population is concisely discussed in conjunction with a systematic review of the literature.

**METHODS**

All patients diagnosed with Cushing’s syndrome and treated between January 1, 2003 and July 1, 2015 were included. Data about the cause of Cushing’s syndrome, levels of morning serum cortisol, ACTH serum levels, midnight salivary cortisol, 24-hour urinary free cortisol excretion (24-h UFC), and outcome were obtained from the electronic patient records. *Pneumocystis pneumonia* was regarded as confirmed if clinical and radiological findings were suggestive for PCP and a bronchoalveolar lavage fluid provided microbiological evidence of the presence of *P. jirovecii* (by polymerase chain reaction and/or Giemsa and silver staining). Univariate non-parametric tests were performed for comparison of patient characteristics and laboratory results between patients with and without PCP. Standard PCP chemoprophylaxis was not prescribed. A waiver for informed consent and permission for conduct of the study was obtained from the institutional review board.

A systematic review of PCP in patients with Cushing’s syndrome was conducted using Medline databases (search strategy: see Supplement 2). All articles describing patients with Cushing’s syndrome and PCP, for whom at least 1 cortisol measurement was reported, were included. Articles were independently assessed by 2 of the investigators (K. v. H. and L. V.). Of the selected articles, the literature references were reviewed to identify potential articles missed by the initial search strategy.

**RESULTS**

Between January 2003 and July 2015, 53 patients were diagnosed with Cushing’s syndrome and they were included in the study. The median age was 49 years (range, 15–74 years), and 39
(73.6%) patients were female. Common causes of Cushing's syndrome, i.e., pituitary micro- and macroadenoma, adrenal gland adenoma, or hyperplasia, were present in 46 (87%) patients, and 7 patients had a malignant and/or ectopic cause of hypercortisolism. Five patients developed PCP after initiation of cortisol-lowering therapy. The characteristics of these patients are described in Table 1. In 4 of these patients, Cushing's syndrome was caused by an ectopic source of ACTH or CRH production.

Higher levels of morning serum cortisol, midnight salivary cortisol, and 24-h UFC were associated with increased risk for development of PCP ($P = .02$, $P = .05$, and $P = .003$, respectively; Mann-Whitney $U$ test). Of patients with Cushing's syndrome, 4 of 53 patients (7.5%) had a 24-h UFC above 10000 nmol (>67 times upper limit of normal [ULN]), all of whom developed PCP (see Supplement 1, Figure 1).

The systematic review identified 25 publications, 11 of which were excluded because cortisol values were not reported (10 patients) and/or lack of a confirmed PCP diagnosis (3 patients). The 14 included articles reported a total of only 15 patients with Cushing's syndrome and PCP (Table 1). In 13 of 15 patients, development of PCP was reported to occur after initiation of cortisol blocking therapy. All but 1 patient had ectopic Cushing's syndrome. Twenty-four-hour UFCs were only available in 8 cases, and, of these, 5 patients had levels above 10000 nmol/24 hours. The case fatality rate was high: 11 of 15 patients died. If reported, the most common cause of death was respiratory insufficiency.

**DISCUSSION**

A limited number of previous reports indicated that the risk for a spectrum of opportunistic infectious diseases in patients with Cushing's syndrome is related to the level of excess cortisol production [10, 11]. In accordance with this biologically plausible observation, we found a strong association between

| Table 1. Patients With *Pneumocystis* Pneumonia and Cushing's Syndrome |
|-------------------|----------------|-----------------|----------------|-----------------|-----------------|-----------------|
| Author (Ref. No.) | Age | Sex | Cause of Cushing's Syndrome | Serum Cortisol (nmol/L) | Urine Cortisol (nmol/24 h) | Onset PCP Before or After Start of Treatment | Microbiology Specimen (Method) | Outcome |

bTherapy for SCLC was started before PCP symptoms, no direct cortisol-lowering therapy.

cNo exact value available.
the development of PCP and the degree of exposure to cortisol excess (as reflected by 24-h UFC, serum, and midnight salivary cortisol levels). In addition, PCP was diagnosed in 1 of 46 (2%) patients who had a pituitary or adrenal adenoma versus 4 of 7 (57%) patients with ectopic Cushing’s syndrome. The former patient developed Cushing’s syndrome during pregnancy due to an adrenal adenoma, and the cortisol excess as reflected by 24-h UFC exceeded 50 000 nmol. Within our study population, ectopic or malignant neoplasms more frequently caused extreme levels of hypercortisolism. In concurrence, but possibly influenced by publication bias, the literature review showed that malignant and ectopic Cushing’s syndrome patients were over-represented as patients also diagnosed with PCP. The occult nature of these conditions may delay correct diagnosis and treatment. This further enhances the cumulative exposure to steroid hormones, which probably best defines the individual’s risk for development of PCP [12].

The high mortality rate of 60%–65% (study cohort and literature review, respectively) is of major concern. This exceeds reported PCP mortality rates of 10%–40% in populations with other underlying conditions, eg, HIV and solid organ transplantation [13]. Several factors may account for this observation. First, the very low incidence of Cushing’s syndrome may cause physicians to be unfamiliar with related infectious complications, delaying diagnosis and treatment of PCP. Second, a range of other fatal events is prone to occur in patients with severe Cushing’s syndrome. Furthermore, the treatment with high-dose steroids in severe cases of PCP may not have the maximum reducing effect on mortality because of the already maximal decreased sensitivity of immune cells for steroid compounds [14].

It is notable that, in the majority of patients, PCP was diagnosed after initiation of cortisol-lowering therapy. The systematic review confirmed that PCP often becomes manifest after initiation of treatment for hypercortisolism. This strongly suggests that immune reconstitution is an important component or even a prerequisite for development of clinically overt PCP in this population. During prolonged hypercortisolism, patients may acquire an ever-accumulating lung burden of \textit{P. jirovecii}, whilst the high level of cortisol suppresses the inflammatory response. A vigorous inflammatory reaction can develop only after an abrupt decrease of cortisol levels. Both—but in particular the combination of—a relatively high fungal burden and a sudden reversal of immune repression can be expected to negatively impact the outcome of PCP.

At present, the management of Cushing’s syndrome does not routinely include PCP prophylaxis or preemptive treatment [7, 9, 10]. Similar to all antimicrobial chemoprophylaxis, the indication of PCP prophylaxis in patients with Cushing’s syndrome depends on a harm-benefit analysis. Although larger cohorts would provide more reliable estimates, the number of patients needed to be treated with chemoprophylaxis to prevent 1 PCP case is probably <50. From the available but limited data, it can be deduced that the presence of ectopic or malignant causes of Cushing’s syndrome as well as extreme levels of cortisol (ie, in the 5th percentile, ie, >20 times the ULN) point towards a very high risk for development of PCP. Taking mortality rates into account, the benefits strongly outweigh the limited toxicity and side effects usually caused by a prophylactic dosage of trimethoprim-sulfamethoxazole (TMP-SMX). The duration of prophylaxis should be extended to the time that the effects of hypercortisolism on the immune system have waned.

CONCLUSIONS

Due to the very low incidence of Cushing’s syndrome, an adequate PCP chemoprophylaxis strategy should now be constructed based on the available observational data. Based on previous studies and on our own experience, we recommend PCP chemoprophylaxis for all patients diagnosed with Cushing’s syndrome, especially those with high 24-h UFCs. As a consequence of the potential role of immune reconstitution, a patient with Cushing’s syndrome should preferably start PCP chemoprophylaxis before initiation of cortisol-lowering therapy. Of note, any delay in optimal management of the Cushing’s syndrome should be avoided. In addition, with regard to the very high mortality rate of PCP in patients with Cushing’s syndrome, either preemptive therapy of PCP with high-dose TMP-SMX or chemoprophylaxis plus assertive monitoring is indicated for patients with an increased risk profile (ectopic Cushing’s syndrome or extreme cortisol levels).
