1. Introduction

The unique electron properties of graphene sparked a significant interest in applications of graphene and, more generally, 2D systems supporting massless electron excitations, Dirac electrons. The main challenge in such applications has appeared to stem from the same unique properties. In order to control the electron flow, it is necessary to be able to restrict its motion in a desired way and the effect of Klein tunneling (KT) [1, 2] makes this very difficult: a simple scalar potential is not sufficient for keeping the electron from escaping. This circumstance made researchers consider more general potentials and it was found that Dirac massless electrons can be confined with the help of magnetic barriers [3–5]. This resulted in the significant attention to the problem of propagation of Dirac electrons in the presence of barriers created by both electric and magnetic fields [6–12]. Experimentally, the vector potential barrier can be implemented with the help of ferromagnetic stripes with the opposite orientations of magnetization [13–15] as is illustrated in figure 1(a).

Even in the case of piece-wise constant vector and scalar components of the potential, the scattering problem on such a barrier turned out to be unexpectedly cumbersome due to the number of parameters characterizing and determining the electron motion and inapplicability of the intuition built by the standard problem of a particle described by the Schrödinger equation scattering on a barrier. As a result, the main analysis of the scattering of Dirac electrons on magneto-electric barriers is done for barriers with specific parameters. This makes it difficult to draw a general conclusion about the effect of such barriers on the electron motion.
We consider the problem of the electron propagation in the presence of a rectangular matrix potential barrier and approach it using the developed formalism of spinor transfer matrices. This technique proves to be efficient and allows us to provide the general description of the effect of the barrier. We were able to derive compact expressions relating to the reflection and transmission coefficients to the geometry of spinor eigenstates. They show that in the absence of a mismatch of the electron mass inside and outside the barrier, the barrier may admit the KT at oblique directions. Moreover, in the case when the barrier is created by the ferromagnetic gate on the surface of a topological insulator, the Zeeman interaction may lead to the appearance of two distinct directions corresponding to the KT.

We apply the formalism of spinor transfer matrices to a detailed analysis of waveguiding properties of the matrix potential barrier. This problem considered for the case of combined magnetic-electrostatic barriers on graphene and other 2D materials was the object of consideration of many publications [11, 16–26] with the most attention, however, paid to the bulk states, when the electron states are extended across the barrier. The edge states, with the electron localized near the boundaries of the barrier, appeared only in the context of the mass mismatch [11]. Here we show that waveguiding modes, based on both edge and bulk states, can be approached equally. The dispersion equation governing the waveguiding modes can be easily derived using the formalism of the spinor transfer matrices. We analyze the obtained transcendental equations in order to describe the dependence of general properties of the waveguiding modes on parameters of the barrier. In particular, we show that in order to support waveguiding based on edge states the mass mismatch is not required.

The rest of the paper is organized as follows: in section 2 we introduce spin coherent states in a spatially homogeneous matrix potential, in section 3 we develop the formalism of spinor transfer matrices and apply it for studying scattering on the rectangular barrier, in section 4 we consider waveguiding properties of the barrier, and in section 5 we consider the case when the magnetic field at the boundaries of the barrier affects the electron motion due to the Zeeman term in the Hamiltonian.

2. Electron states in the presence of the barrier

The equation of motion of the Dirac electron with energy \( \varepsilon \) in the presence of rectangular matrix potential barrier \( \bar{U}(x) \) has the form

\[
[V \cdot \sigma + \bar{U}(x)] \psi(r) = \varepsilon \psi(r),
\]

where \( V \) is the Fermi velocity. In order to shorten formulas, it is convenient to exclude \( V \) by redefining either spatial \( r \rightarrow r/V \) or energy \( \varepsilon \rightarrow \varepsilon V \) scales. Thus, in what follows we take \( V = 1 \).

In equation (1) \( \sigma = \sigma_x e_x + \sigma_y e_y + \sigma_z e_z \) is the usual vector of Pauli matrices and \( p \cdot \sigma \equiv p_x \sigma_x + p_y \sigma_y + p_z \sigma_z \). Employing the fact that any \( 2 \times 2 \) matrix can be expanded over \( \{ \hat{I}, \sigma_x, \sigma_y, \sigma_z \} \), where \( \hat{I} \) is the identity matrix, we present

\[
\bar{U}(x) = V(x) \hat{I} + U(x) \cdot \sigma,
\]

Both \( V(x) \) and \( U(x) \) are assumed to be non-zero only inside the barrier, \( x_L < x < x_R \), where \( V(x) = V \) and \( U(x) = U \), as illustrated in figure 1(b). It should be noted, however, that arbitrary \( U_r(x) \) can be accounted for by the gauge transformation \( \psi(r) \rightarrow \psi(r) \exp \left\{ i \int_{x_L}^{x} dx' \bar{U}_r(x') \right\} \). Thus, the effect of this component of the matrix potential reduces to simply acquiring the phase factor and, therefore, without the loss of generality one can assume that \( U_r(x) \equiv 0 \).

The scattering of the Dirac electron on such a barrier can be analyzed in the usual way considering the appropriate solutions in regions I, II, III and imposing the condition of continuity of \( \psi(r) \) at the boundaries of the barrier. Within the regions with constant \( U \) and \( V \) the solutions are sought in the form of plane waves \( \psi(r, k) = \psi_k e^{ik \cdot r} \). The spinor \( \psi_k \) satisfies

\[
\sigma \cdot h(k, U) \psi_k = \tilde{\varepsilon} \psi_k, \tag{3}
\]

where \( \tilde{\varepsilon} = \varepsilon - V \) and the effective field \( h \) is defined as

\[
h(k, U) = k + U. \tag{4}
\]

Equation (3) has the form of the equation for stationary states of spin 1/2 in the magnetic field \( h \). The energies of the states are \( \varepsilon_\pm = \pm |h| \), where \( |h| = \sqrt{h_x^2 + h_y^2 + h_z^2} \). Taking for definiteness \( \varepsilon > V \) we obtain

\[
\tilde{\varepsilon} = \sqrt{k^2 + (k_x + U)^2 + U_z^2}. \tag{5}
\]

Thus inside regions I, II and III the general solution of equation (1) is presented as a superposition of \( \psi(r, k) \) corresponding to the same energy \( \varepsilon \). The invariance with respect to translations along the y-axis implies that \( k_y \) is a good quantum number and therefore scattered states can be characterized by \( \varepsilon \) and \( k_y \). Thus for the given barrier and energy the effective field \( h \) has definite \( |h| = |h| \), where \( h_x, h_y \) and \( h_z \). On the other hand, the barrier breaks the translational symmetry along the x-axis and for given \( \varepsilon \) and \( k_y \) we have two possible values for \( k_x \) corresponding to different signs of \( h_x \) keeping \( |h| \) intact,

\[
h_x = k^{(1,2)}_x = \pm q, \tag{6}
\]

where \( q^2 = \tilde{\varepsilon}^2 - h_y^2 - h_z^2 \). Considering the scattering of a particle incident on the left boundary of the barrier, the components with \( k^{(1)}_x \) and \( k^{(2)}_x \) correspond to the incoming and reflected state, respectively.
This consideration shows that the representation in terms of the superposition of plane waves is not trouble free. When \( q = 0 \) it provides only one solution, while equation (1) for fixed \( \kappa_\gamma \) is essentially the second order ODE and should have two linearly independent solutions. Since \( q = 0 \) is rather an exceptional case we postpone its detailed discussion to the next section, while for now we assume that \( q = 0 \) and that, indeed, plane wave expansion covers all solutions.

Once the effective fields, \( \mathbf{h}^{(1,2)} = \mathbf{h}(\kappa^{(1,2)}, U) \), are found, we can use equation (3) to describe the respective spin states. They are conveniently presented in terms of spin coherent states [27, 28]. To vector \( \mathbf{n} \) with Cartesian coordinates \((\sin(\theta)\cos(\phi), \sin(\theta)\sin(\phi), \cos(\theta))\), where \( \theta \) is the polar angle and \( \phi \) is the azimuthal angle, we assign the state
\[
|\mathbf{n}\rangle = \exp\left[-i\mathbf{r} \cdot \mathbf{m} \theta / 2\right]|+\rangle,
\]
where \( \mathbf{m} = (-\sin(\phi), \cos(\phi), 0) \) is a unit vector in the xy-plane perpendicular to \( \mathbf{n} \) and \( \mathbf{e}_z \). In terms of amplitudes with respect to the quantization axis along \( \mathbf{e}_z \), the state \(|\mathbf{n}\rangle\) is
\[
|\mathbf{n}\rangle = \begin{pmatrix} \cos(\theta/2) \\ e^{i\phi} \sin(\theta/2) \end{pmatrix}.
\]

The overlap of two coherent states can be presented in a ‘covariant’ form [27]
\[
\langle \mathbf{n}|\mathbf{n}\rangle = \left[\frac{1}{2} + \mathbf{n} \cdot \mathbf{n}'\right]^{1/2} \exp\left[-\frac{1}{2}A(\mathbf{n}, \mathbf{n}')\right],
\]
where \( A(\mathbf{n}, \mathbf{n}') = A(\mathbf{n}, \mathbf{n}', \mathbf{e}_z) \) is the oriented area of the spherical triangle with vertices at \( \mathbf{n}, \mathbf{n}' \) and \( \mathbf{e}_z \).

When all components of \( \mathbf{h} \) are real numbers (i.e. when \( q^2 > 0 \)), solutions of equation (3) have the simple form: \( |\mathbf{n}(1,2)\rangle = |\mathbf{n}'(1,2)\rangle \exp[i\varphi] \) with \( |\mathbf{n}'(1,2)\rangle = h(1,2)[\mathbf{e}_z] \). It should be noted that the condition \( q^2 > 0 \) holds only when \( |\varphi| > 0 \), thus the direction of the spin coherent state in this case is always well-defined.

The situation is more complex when \( q^2 < 0 \). In this case \( \mathbf{h} \) has an imaginary x-component and the orientation of the coherent state should be found directly from equation (3). First, we assume that \( h_z > 0 \) and \( U_z = 0 \) and then extend the consideration to the general case. Let \( \kappa = i\kappa \), then equation (3) can be written as
\[
-\varphi \psi_1 - i(h_y - \kappa)\psi_2 = 0,
\]
\[
(ih_y + \kappa)\psi_1 - \varphi \psi_2 = 0.
\]

Taking into account that \( \varphi^2 = h_y^2 - \kappa^2 \) (notice that \( \kappa^2 < h_y^2 \)) we find
\[
\psi_2 = i \text{sign}(\varphi) \sqrt{\frac{h_y + \kappa}{h_y - \kappa}} \psi_1.
\]

Comparing with equation (8) we can see that equation (11) describes a state \(|\mathbf{n}\rangle\) with \( \mathbf{n} \) lying in the \( \mathbf{yz}\)-plane. The polar angle of \( \mathbf{n} \) can be presented as \( \theta = \pi/2 + \Delta\theta \), where \( \Delta\theta \) is the angle of deviation from the \( \mathbf{y}\)-axis and is found to be
\[
\tan(\Delta\theta) = \frac{\kappa}{\varphi}.
\]

\[\text{Figure 2.} \quad \text{Directions of spins corresponding to } h_z^2 > 0 \text{ (spins are in the } xy\text{-plane) and } h_z^2 < 0 \text{ (spins are in the } yz\text{-plane) for the case } U_z = 0. \text{ When } U_z = 0 \text{ one should substitute } h_{yz}, \text{ the projection of the effective field on the } yz\text{-plane, in place of the } y\text{-axis.}\]

The azimuthal angle is \( \phi = \pi/2 \) when \( \epsilon > V \) and \( \phi = -\pi/2 \) otherwise. The second solution, corresponding to \( h_z = -i\kappa \) is found by simply reversing the sign of \( \kappa \). Thus, it is characterized by the same azimuthal angle but is deviated from the \( y\)-axis down.

The case with the arbitrary sign of \( h_z \) and \( U_z = 0 \) can be studied using the same approach. For this we rotate the coordinate system for equation (3) around the \( x\)-axis in such a way that the transformed \( y\)-axis is oriented along the projection of \( \mathbf{h} \) on the \( yz\)-plane, that is along the vector \( \mathbf{h}_{yz} = (0, h_z, h_x) \). In these coordinates equation (3) takes the same form as (10) with \( h_y^2 + h_z^2 \) instead of \( h_y \). The polar angle of \( \mathbf{n} \) is presented then as \( \theta = \theta_0 + \Delta\theta \), where \( \theta_0 \) is the polar angle of \( \mathbf{h}_{yz} \) and \( \Delta\theta \) is determined by equation (12).

The azimuthal angle, in turn, depends on the sign of \( h_x \); if \( h_x > 0 \), then \( \phi \) is determined by the same rule as above: \( \phi = \text{sign}(\varphi)\pi/2 \); if, however, \( h_x < 0 \), then the rule is reversed \( \phi = -\text{sign}(\varphi)\pi/2 \).

Thus, roughly speaking, when \( h_z \) is imaginary its magnitude determines the deviation of the spinor from the direction of vector \( \mathbf{h}_{yz} \) in the \( yz\)-plane (see figure 2).

As we can see, when \( q^2 < 0 \), for a given energy \( \epsilon \) as well have two states characterized by \( k^{(1,2)}_\epsilon = \pm |q|/\epsilon \) and spins oriented along \( n^{(1,2)} \). We enumerate the solutions in such a way that \( k^{(1)}_\epsilon \) corresponds to an exponentially decaying state by increasing the penetration depth, while \( k^{(2)}_\epsilon \) corresponds to the exponentially growing one.

An important symmetry of vectors \( n^{(1)} \) and \( n^{(2)} \) representing spinor states should be noted. For both cases, \( q^2 > 0 \) and \( q^2 < 0 \), vectors \( n^{(1)} \) and \( n^{(2)} \) lie in the same plane, and \( n^{(1)} \) and \( n^{(2)} \) are related through reflection about \( h_{yz} \) in this plane. This symmetry will be extensively used below.

In order to formally manifest the symmetry it is convenient to present eigenstates of equation (3) using dilatation operators. For the case \( q^2 > 0 \), we have
\[
|n^{(1,2)}\rangle = K^{(1,2)} \exp(\pm i/2) \langle h_{yz} | \pm e_n\rangle,
\]
where $K^{(1,2)} = e^{\pm i \phi / 2} \sqrt{q/|\varepsilon|}$, $\cosh(h_{yz}) = |\varepsilon||q|$, $\sinh(h_{yz}) = \text{sign}(\varepsilon) h_{yz}/q$. When $q^2 < 0$, so that $q = i \kappa$ with $\kappa > 0$, we obtain

$$|\psi^{(1,2)}\rangle = C^{(1,2)} \exp(b_{yz} \cdot \vec{I}/2)|\pm\vec{I}\rangle,$$

where $I = h_{yz} \times e_i h_{yz}$, $C^{(1)} = \sqrt{\kappa/h_{yz}}$, $C^{(2)} = i \sqrt{\kappa/h_{yz}}$, $\cosh(h_{yz}) = h_{yz} \kappa$, $\sinh(h_{yz}) = \varepsilon/\kappa$.

3. Transfer matrix approach for spinors

The analysis above shows that equation (3) can be regarded as defining two distributions of directions $n^{(1)}(x)$ and $n^{(2)}(x)$, corresponding to forward and backward propagating modes. The spatial inhomogeneity of $U(x)$ and $V(x)$ together with the continuity condition couple these distributions leading to scattering, which is conveniently described by the formalism of transfer-matrices.

Inside regions I, II and III we have

$$\psi(x) = \sum_{j=1}^2 \alpha_i^{(j)} |n_i^{(j)}\rangle e^{i \alpha_i^{(j)}x},$$

where $i$ runs over I, II, III, $\alpha_i^{(j)}$ are some complex amplitudes and we have omitted the common factor $\exp(ik_3 y)$.

First, let us consider two points $x_a$ and $x_b$ arranged as $x_a < x_b < x_c$. One can see that $\psi(x_b)$ differs from $\psi(x_a)$ by phase factors acquired by amplitudes $\alpha_i^{(1,2)}$. We present the relation in the form

$$\begin{bmatrix} \alpha_1^{(1)} \\ \alpha_2^{(1)} \end{bmatrix} = \tilde{T}_{\Omega}(x_b - x_a) \begin{bmatrix} \alpha_1^{(1)} \\ \alpha_2^{(1)} \end{bmatrix},$$

which defines the transfer matrix within region I

$$\tilde{T}_{\Omega}(x) = \begin{pmatrix} e^{i A x} & 0 \\ 0 & e^{i B x} \end{pmatrix}$$

In a similar way the transfer matrix $\tilde{T}_{\Omega II}(x)$ within region II can be defined. It has the same form as $\tilde{T}_{\Omega}(x)$ but with $K^{(1,2)}$ replaced by $K^{(1,2)}_{II}$. In order to simplify notations we denote $K^{(1,2)}_{II} = \pm q$ with $q^2 = \varepsilon^2 - h_{yz}^2 - h_{II}^2$. Thus, the transfer matrix within the barrier has the form

$$\tilde{T}_{\Omega II}(x) = \begin{pmatrix} e^{i a x} & 0 \\ 0 & e^{-i a x} \end{pmatrix}\begin{pmatrix} e^{i b x} & 0 \\ 0 & e^{-i b x} \end{pmatrix}$$

The form of the transfer matrices inside the regions allows us to incorporate phases at the boundaries of the barrier into the amplitudes and define $\alpha_i^{(j)} = \alpha_i^{(j)} e^{i A_1 n_1^{(j)}}$, $\alpha_i^{(j)} = \alpha_i^{(j)} e^{i B_2 n_2^{(j)}}$ and $\alpha_i^{(III)} = \alpha_i^{(III)} e^{i A_1 n_1^{(III)}}$. In other words, except for $\alpha_i^{(j)}$ we have included into amplitudes their phases at the outmost left points of the discontinuity of the potential.

In terms of such amplitudes the continuity condition at the left boundary of the barrier takes a simple form

$$\alpha_i^{(1)} |n_i^{(1)}\rangle + \alpha_i^{(2)} |n_i^{(2)}\rangle = \alpha_i^{(III)} |n_i^{(III)}\rangle + \alpha_i^{(III)} |n_i^{(III)}\rangle$$

and can be presented as

$$\begin{pmatrix} \alpha_1^{(1)} \alpha_2^{(1)} \\ \alpha_1^{(2)} \alpha_2^{(2)} \end{pmatrix} = \tilde{T}_{\Omega II} \begin{pmatrix} \alpha_1^{(III)} \alpha_2^{(III)} \\ \alpha_1^{(III)} \alpha_2^{(III)} \end{pmatrix}.$$
\[ \tilde{T}_{IL, I} = \left( \begin{array}{c} \langle n_{II}^{(1)} | n_{II}^{(1)} \rangle \\ \langle n_{II}^{(1)} | n_{II}^{(2)} \rangle \\ \langle n_{II}^{(2)} | n_{II}^{(1)} \rangle \\ \langle n_{II}^{(2)} | n_{II}^{(2)} \rangle \end{array} \right) \]  

Due to the mutual arrangement of \( n_{II}^{(1)} \) the form of \( \tilde{T}_{IL, I} \) is far from arbitrary. When \( q^2 > 0 \), we have

\[ \tilde{T}_{IL, I} = \left( \begin{array}{c} e^{i\alpha} be^{-i\beta} \\ be^{i\beta} ae^{-i\alpha} \end{array} \right) \]  

and when \( q^2 < 0 \)

\[ \tilde{T}_{IL, I} = \left( \begin{array}{c} ae^{i\alpha} \\ be^{i\beta} \end{array} \right) \]  

where

\[ a = \left| \langle n_{II}^{(2)} | n_{II}^{(1)} \rangle \right| = \frac{1 - n_{II}^{(2)} \cdot n_{II}^{(1)}}{1 - n_{II}^{(1)} \cdot n_{II}^{(1)}}, \]

\[ b = \left| \langle n_{II}^{(1)} | n_{II}^{(1)} \rangle \right| = \frac{1 - n_{II}^{(1)} \cdot n_{II}^{(1)}}{1 - n_{II}^{(1)} \cdot n_{II}^{(1)}}. \]  

When there are no propagating modes either inside and outside of the barrier, i.e. when \( (k_{ex}^{(1,2)})^2 < 0 \) and \( q^2 < 0 \), \( \tilde{T}_{IL, I} \) has form (24) with \( \alpha = \beta = 0 \).

Taking into account the general form of the transfer matrices we find for the case \( q^2 > 0 \)

\[ r = \frac{2i}{D} e^{i(\alpha + \beta)} ab \sin(qd), \]

\[ t = \frac{1}{D} (a^2 - b^2), \]  

where \( D = a^2 e^{-2ipl} - b^2 e^{ipl} \). In order to analyze the reflection and transmission properties closer it is convenient to employ the general property \(|r|^2 + |t|^2 = 1\) and to consider

\[ \left| \frac{r}{l} \right|^2 = \left( \frac{1 - n_{II}^{(2)} \cdot n_{II}^{(1)}}{[n_{II}^{(2)} \cdot (n_{II}^{(1)} - n_{II}^{(2)})]_1^2} \right)^2 \sin^2(qd) \]

\[ \left( \epsilon U_I + V_k \right)^2 + U_k^2 \]  

where

\[ (r U_I + V_k)^2 + U_k^2 \]  

Here we have taken into account that \( n_{II}^{(1,2)} = \mathbf{n}_{II}^{(1,2)} \cdot \mathbf{r} \) and, therefore, equation (28) is valid for an arbitrary relation between \( \epsilon \) and \( V \).

Equations (27) and (28) clearly distinguish between the effects of the mismatch of directions of the effective fields inside and outside the barrier and the effect of interference due to scattering from the front and back sides of the barrier. In particular, one can see that the reflection coefficient vanishes when either

\[ n_{II}^{(1,2)} \cdot n_{II}^{(1)} = \mathbf{h}_{II}^{(1,2)} \cdot \mathbf{r} \]

or when

\[ n_{II}^{(1,2)} \cdot n_{II}^{(1)} = 1. \]  

The first condition is responsible for the periodic variation of the reflection coefficient with the width of the barrier due to the interference effect. The second condition is satisfied when directions of the spins inside and outside the barrier coincide. In this case the reflection coefficient is zero regardless of the width of the barrier and thus is associated with the KT.

Obviously, condition (30) cannot be satisfied when \( U_I = 0 \). Thus the respective barriers (often called mass barriers) completely suppress the KT. The effect of \( V \) and \( U_I \) on the KT is less straightforward. It follows from equation (28) that in the case \( U_I = 0 \) the KT takes place when

\[ k_I = -\frac{U_I \epsilon}{V}. \]  

Thus, when the barrier contains both \( V \) and \( U_I \), the KT is not necessarily suppressed but may appear for an obliquely incident Dirac electron as is illustrated in figure 3.

With increasing \( U_I \), the Klein direction deviates more from normal until it becomes parallel to the boundary of the barrier. Further increase of \( U_I \) will lead to the suppression of the KT. Thus, in order for KT to exist, \( U_I \) and \( V \) in the barrier must satisfy

\[ |U_I| < |V|. \]  

Figure 3. The angular dependence of the transmission coefficient through the barrier with \( U_I/e = 1, V/e = 3 \) for two different widths: (dashed line) \( \epsilon d = 1 \) and (solid line) \( \epsilon d = 10 \) in the units adopted in the main text. For the magnetic barrier with \( B = 0.5 \) T the spectra correspond to \( \epsilon = 19 \) meV, \( V = 57 \) meV and \( d = 370 \) nm, respectively. The KT takes place at oblique incidence with \( \theta = \arcsin(-V/U_I) \approx -20^\circ \).
This analysis directly applies to an electron in graphene in the presence of a scalar and vector potential barrier. In this case \( V(x) \) has the meaning of the scalar potential and \( U_x \) and \( U_y \) are the respective components of the vector potential, which creates the magnetic field \( B(x) = -\partial_t \alpha \) where \( B \neq 0 \). We set \( \omega = \frac{\hbar}{\varepsilon} \) and \( \varepsilon \) is the magnitude of the electron charge. The effect of such a magnetic barrier on the KT was studied in [6, 10]. In [6] the KT at oblique directions was observed numerically, while in [10] it was concluded that the addition of the magnetic barrier to the scalar potential barrier suppresses the KT. Our consideration above resolves unambiguously this controversy. The magnetic barrier alone, indeed, does not demonstrate the KT. However, when it is accompanied with the scalar potential such that condition (32) is fulfilled, the KT restores at oblique incidence.

It should be emphasized that the KT takes place when the direction of the electron spin is uniform across the system. In the non-attenuated regime, i.e. when \( q^2 > 0 \), this is equivalent to a uniform distribution of the directions of the effective field, \( \mathbf{h}(x)(x) = \mathbf{n}(x) = \text{const} \). Thus the oblique KT is the local property of the matrix potential governing the motion of the Dirac electron and, therefore, it holds for barriers with more complex spatial variation of the potentials. Evidently, if \( U_x(x)V(x) = c < 1 \) is a constant across the barrier, then such a barrier is reflection-less for electrons incident at the angle \( \chi = \arcsin(c) \) counted from the normal to the boundary.

Conversely, this shows that in the barriers with a general spatial variation of the scalar and vector components the KT condition is, generally speaking, broken. For example, in antiparallel ferromagnetic gates of finite width, \( \Delta x \), the vector potential varies continuously and, except when the scalar potential is carefully chosen to satisfy \( U_x(x)V(x) = c < 1 \), the condition \( \mathbf{n}(x) = \text{const} \) does not hold.

A detailed analysis of a general coordinate-dependent matrix potential goes beyond the scope of the present paper. We limit ourselves to a qualitative discussion of the case of thin gates, such that \( \exp(\varepsilon \cdot \Delta x) \ll 1 \). The effect of the gradual variation of the matrix potential at, say, the left boundary of the barrier is taken into account by replacing \( \tilde{T}_{\mathbf{In}} \) in the expression for \( T_{\mathbf{In}} \) by \( \tilde{T}_{\mathbf{In}} \), where \( \tilde{T}_{\mathbf{In}} \) is the transfer matrix through the barrier described by \( \Delta \tilde{U}(x) = \tilde{U}(x) - \bar{U}(x) \), where \( \bar{U}(x) \) is the full potential and \( \tilde{U}(x) \) is its approximation by the rectangular barrier near its left boundary. Thus, \( \Delta \tilde{U}(x) \) differs from zero only inside the gate. Then it can be seen that along the direction corresponding to the KT for the rectangular barrier, the reflection coefficient does not vanish identically but is an oscillating function of the width of the barrier \( |q|^2 = 4|\mathbf{r}_1|^2 \sin^2(q\Delta x) \), where \( \mathbf{r}_1 \) is the reflection coefficient of the single barrier described by \( \Delta \tilde{U}(x) \) or, equivalently, of the single gate at the KT direction. Here we have taken \( \tilde{T}_{\mathbf{In}} \) in the first nonvanishing order of \( \Delta x \)

\[
\tilde{T}_{\mathbf{In}} = \tilde{\mathbf{I}} + i \int \mathbf{dx} \hat{Q}(x),
\]

where \( [\hat{Q}(x)]_{ij} = \langle \mathbf{n}^{(1)}_i | \mathbf{r}_1 \hat{\mathbf{U}}(x) | \mathbf{n}^{(1)}_j \rangle \), so that \( \mathbf{r}_1 = \int \mathbf{dx} Q_2,1(x) = O(\Delta x) \) and is small for thin gates.

In the case when \( q^2 < 0 \), denoting \( q = i \kappa \) the reflection and transmission amplitudes are found to be

\[
r = -\frac{\sinh(\kappa d) e^{i(\alpha + \beta)}}{\sinh \left[ x d - i(\alpha - \beta) \right]},
\]

\[
t = -\frac{i \sin(\alpha - \beta)}{\sinh \left[ x d - i(\alpha - \beta) \right]}.
\]

The reflection coefficient monotonously increases to 1 with the thickness of the barrier, while the transmission decreases asymptotically exponentially to zero.

The transition between forms (33) and (34) occurs through the point \( q = 0 \), where \( \mathbf{n}^{(1)}_I = \mathbf{n}^{(2)}_I \) and, as a result, \( \det(\tilde{T}_{\mathbf{In}}) = 0 \). As has been discussed above, the reason for the singularity is that the plane wave representation of solutions of (1) does not exhaust all of them. In order to recover the missing state and to derive the correct form for the transfer matrix we need to analyze closer equation (1) in the case when \( \varepsilon^2 = h_1^2 + h_2^2 \).

Equation (1) can be rewritten as

\[
\alpha_q \mathbf{p}_1 \psi = 2i \hat{\mathbf{P}} \psi, \tag{35}
\]

where \( \hat{P} = (\vec{\sigma} - \gamma \cdot h_{1z})/2 \) and \( h_{1z} = (0, h_{1x}, h_{1z}) \).

We notice that \( \det(2i \hat{\mathbf{P}}) = q^2 \) and, moreover, when \( q = 0 \), one has \( \hat{P} = \mathbf{P} \), thus \( \mathbf{P} \) is a projector. The components of \( h_{1z} \) are real and therefore the eigenstates of \( \hat{P} \) are \( \pm \mathbf{n}_{1z} \), where \( \mathbf{n}_{1z} = h_{1z}/\varepsilon \) and therefore \( \hat{P} = \pm \mathbf{n}_{1z} \mathbf{n}^{(1)}_I \). Taking into account that \( \hat{P} \) can be diagonalized by rotating the coordinate system around the x-axis, we obtain the general solution of equation (35) for the case \( q = 0 \):

\[
|\psi\rangle = |\psi_0\rangle - 2\varepsilon x |\mathbf{n}_{1z}\rangle \langle -\mathbf{n}_{1z}|\psi_0\rangle, \tag{36}
\]

where \( |\psi_0\rangle \) is an arbitrary spin state. The second term in this expression is of secular form and is missed in the representation in terms of plane waves.

Enforcing the continuity at the boundaries of the barrier we find that the transfer matrix through the barrier in the case \( q = 0 \) has the form

\[
\tilde{T}_{\mathbf{In}} = \tilde{\mathbf{I}} - 2\varepsilon d \tilde{M}^{-1} \begin{pmatrix}
0 & 0 \\
\langle -\mathbf{n}_{1z} | \mathbf{p}^{(1)}_1 \rangle & \langle -\mathbf{n}_{1z} | \mathbf{p}^{(2)}_1 \rangle
\end{pmatrix},
\]

where

\[
\tilde{M} = \begin{pmatrix}
\langle -\mathbf{n}_{1z} | \mathbf{p}^{(1)}_1 \rangle & \langle -\mathbf{n}_{1z} | \mathbf{p}^{(2)}_1 \rangle \\
\langle \mathbf{n}_{1z} | \mathbf{p}^{(1)}_1 \rangle & \langle \mathbf{n}_{1z} | \mathbf{p}^{(2)}_1 \rangle
\end{pmatrix}. \tag{38}
\]

Employing the symmetry of involved vectors we obtain

\[
\tilde{T}_{\mathbf{In}} = \tilde{\mathbf{I}} + \frac{d}{\varepsilon} \begin{pmatrix}
-1 & -e^{-i\varphi} \\
1 & 1
\end{pmatrix}, \tag{39}
\]

where \( \varphi = A(-\mathbf{n}_{1z}, \mathbf{n}^{(1)}_I) \) and

\[
d = \frac{1}{\varepsilon} \sqrt{1 + \mathbf{n}_{1z} \cdot \mathbf{n}^{(1)}_I} = \frac{1}{\varepsilon} \tan(\gamma/2), \tag{40}
\]
where \( \gamma \) is the angle between \( \mathbf{n}_{\perp} \) and \( \mathbf{n}_{\perp}^{(1)} \). Using Equation (39) we find
\[
r = -\frac{e^{-i\gamma}}{1 - id/d},
\]
\[
t = \frac{1}{1 + id/d}.
\]
Thus the transition from the over-barrier regime \( (q^2 > 0) \) to canonical tunneling, characterized by exponential decay with the width of the barrier \( (q^2 < 0) \), occurs through the Lorentzian decay with the characteristic length scale \( d_c \).

4. Matrix potential barriers as waveguides

We apply the developed technique to the analysis of the waveguiding properties of the barrier, or, equivalently, of states localized on the barrier. In general the barrier supports two kinds of such states differing by the structure of the fermion state inside the barrier. These are either propagating states, so that \( k_{li,lj}^{(1,2)} = \pm i\kappa_l \) and \( \gamma_l > 0 \), or edge states with \( k_{li,lj}^{(1,2)} = \pm i\kappa_l \) and \( \kappa_l < 0 \).

All localized states are characterized by exponential decay of the wave function away from the barrier with the rate \( \kappa_l = \sqrt{\kappa_x^2 - \gamma^2} \). This implies that at \( x < x_l \) the fermion state is given by \( \mathbf{n}_{l}^{(2)} \), while at \( x > x_l \) the state is \( \mathbf{n}_{l}^{(1)} \). In order to support such localized states the transfer matrix through the barrier should satisfy
\[
\langle \mathbf{n}_{l}^{(2)} | \mathbf{T}_{\text{tot}} | \mathbf{n}_{l}^{(1)} \rangle = 0.
\]
Using equations (18) and (22) this condition can be written as
\[
e^{-2i\gamma d} = \left( \frac{\mathbf{n}_{l}^{(2)}}{\mathbf{n}_{l}^{(1)}} \right)^{-1} \left( \frac{\mathbf{n}_{l}^{(2)}}{\mathbf{n}_{l}^{(1)}} \right)^{+} \frac{\mathbf{n}_{l}^{(2)}}{\mathbf{n}_{l}^{(1)}} \mathbf{n}_{l}^{(1)}.
\]
This expression is valid in both cases, \( q^2 > 0 \) and \( q^2 < 0 \). When \( q^2 > 0 \) it suggests an interesting interpretation: the phase variation inside the barrier should match the geometric phase spanned by the spin states inside and outside: \( \gamma_B = \gamma_l = \pi m \) with integer \( m \), where \( \gamma_B = qd \) and \( \gamma_G = A(\mathbf{n}_{l}^{(1)}, -\mathbf{n}_{l}^{(1)}, -\mathbf{n}_{l}^{(2)}) \).

As we will show, such interpretation in some generalized form is valid also in the case of edge states.

In order to present equation (43) in terms of the parameters of the system it is more convenient to use an alternative representation of the transfer matrix using dilational operators.

First, we consider the case \( q^2 > 0 \). The diagonal form of the transfer matrix inside the regions with the constant potential implies the ‘spectral’ representation
\[
\mathbf{T}_{\text{tot}} = \mathbf{n}_{l}^{(1)} \left( \mathbf{n}_{l}^{(2)} \right)^{-1} e^{ipd} + \mathbf{n}_{l}^{(2)} \left( \mathbf{n}_{l}^{(2)} \right)^{-1} e^{-ipd} \]
with the matrix elements \( (\mathbf{T}_{\text{tot}})_{ij} = \langle \mathbf{n}_{l}^{(2)} | \mathbf{T}_{\text{tot}} | \mathbf{n}_{l}^{(1)} \rangle \).

Taking into account equation (13) and the definition of the dual basis, \( \mathbf{T}_{\text{tot}} \) can be presented as
\[
\mathbf{T}_{\text{tot}} = e^{ipd} \sigma \mathbf{T}_{\text{tot}}^{\text{a}} \sigma e^{-ipd},
\]
where \( \cosh(b h \gamma_{l}) = \frac{e^{i\gamma_{l}}}{q} \) and \( \sinh(b h \gamma_{l}) = h_{l} \mathbf{sign}(\gamma_{l}) q \).

In particular, the zero of reflectivity corresponds to
\[
\langle \mathbf{n}_{l}^{(2)} | \mathbf{T}_{\text{tot}} | \mathbf{n}_{l}^{(1)} \rangle = 0
\]
and, hence,
\[
-\mathbf{e}_{l} e^{-b h \gamma_{l}^2 / 2 \mathbf{T}_{\text{tot}}^{\text{a}} \sigma e^{b h \gamma_{l}^2 / 2 \mathbf{T}_{\text{tot}} \sigma} | \mathbf{e}_{l} \rangle = 0,
\]
where \( \mathbf{e}_{l} = e^{ih_{l}^2 / 2 \mathbf{T}_{\text{tot}} \sigma} | \mathbf{e}_{l} \rangle \)
and \( \mathbf{h}_{l} = h_{l} \mathbf{sign}(\gamma_{l}) q \).

It can be seen that equation (46) holds when the width of the barrier satisfies \( qd = \pi n \) with integer \( n \) or for an arbitrary width of the barrier when \( h_{l} \mathbf{c} = 0 \) and at the same time \( b_{l} = b_{l} h_{l} \mathbf{c} = 0 \). These conditions are, of course, identical to those discussed above.

For the case \( q = i \kappa_l \) we have
\[
\mathbf{T}_{\text{tot}} = e^{i\gamma_{l} d} \sigma \mathbf{h}_{l} \mathbf{c} e^{-i\gamma_{l} d} \sigma e^{i\gamma_{l} d} \sigma e^{-i\gamma_{l} d} \sigma^{2},
\]
where \( \mathbf{l} = h_{l} \times \mathbf{e}_{l} h_{l} \mathbf{c} \), \( \mathbf{h}(b)h_{l} = \gamma_{l} / \kappa_{l} \mathbf{h}_{l} \mathbf{c} \), and \( \mathbf{c} \).

The convenience of representations (45) and (47) is that in both cases \( q^2 > 0 \) and \( q^2 < 0 \) the transfer matrix takes the same form
\[
\mathbf{T}_{\text{tot}} = e^{i\gamma_{l} d} \sigma \mathbf{h}_{l} \mathbf{c} e^{-i\gamma_{l} d} \sigma \mathbf{h}_{l} \mathbf{c} e^{i\gamma_{l} d} \sigma e^{-i\gamma_{l} d} \sigma^{2},
\]
which allows one to treat bulk and edge states on the same footing.

In order to support the localized state the transfer matrix through the barrier should correspond to rotating vector \( \mathbf{n}_{l}^{(2)} \) so that it is directed along \( \mathbf{n}_{l}^{(1)} \). In the case \( q^2 > 0 \) according to equation (45) this is eventually achieved by the conventional rotation around the \( x \)-axis, which yields the geometric interpretation mentioned above. In the case of edge states the corresponding rotation is hyperbolic as is illustrated by equations (13) and (14). Thus the waveguiding modes supported by the bulk states may occupy multiple bands, while the edge states may support only the single band.

First, we analyze equation (42) for the case of edge states, i.e. when \( \kappa_l > 0 \). Presenting equation (42) as
\[
\langle \mathbf{e}_{l} | e^{-b h \gamma_{l}^2 / 2 \mathbf{T}_{\text{tot}}^{\text{a}} \sigma e^{b h \gamma_{l}^2 / 2 \mathbf{T}_{\text{tot}} \sigma} | \mathbf{e}_{l} \rangle = 0,
\]
where \( \mathbf{h}(b)h_{l} = \gamma_{l} / \kappa_{l} \mathbf{h}_{l} \mathbf{c} \), and \( \mathbf{c} \).

Expanding \( \mathbf{T}_{\text{tot}} \) we obtain the condition of localization in the form
\[
\gamma_{G} = \gamma_{B},
\]
with \( \gamma_{B} = \kappa_{l} d \), and
\[
\tanh(\gamma_{G}) = \frac{\kappa_{l} / \gamma_{B}}{D}.
\]

The general structure of the spectrum of edge states is determined by the overlap of intervals, where \( k_{i} \) may reside in order to have positive \( \kappa_{l} \), \( \kappa_{l} \) and \( D \), as is illustrated in figure 4. The general form of the spectrum is determined by simple relations between \( V \) and \( U_{i} \). It can be seen that solutions of equation (50) with \( k_{i} > 0 \) and \( k_{i} < 0 \) may exist only when \( V < -U_{i} \) and \( V < U_{i} \), respectively. Thus, for sufficiently deep attracting barriers, \( V < 0 \) and \( |V| > |U_{i}| \), equation (50) may support for the same energy solutions with both \( k_{i} > 0 \) and
When $V$ increases so that $V > U_y$, for a particular energy there may be only one solution and $k_y$ and $U_y$ must be of opposite signs. With a further increase of $V$, in sufficiently strong repulsive potentials do not solutions of equation (50) exist.

We would like to emphasize that the condition of existence of waveguiding modes supported by the edge states, does not require the scalar potential to be attractive nor the presence of the mass gap (i.e. when $U_y < 0$).

In order to avoid overly cumbersome expressions we discuss details of the spectrum in the case when $V = 0$ and we take for definiteness $U_y < 0$, so that only solutions with $k_y > 0$ may exist. As can be seen from figure 4 the maximal energy of the edge states cannot exceed the value determined by the intersection of the curve $\kappa = \varepsilon_k$,0 with either $\gamma = \varepsilon_Dk$,0 (if $V < |U|< |U|$) or with $\varepsilon_k,0$ (if $V > |U|> |U|$):

$$\epsilon < \epsilon_{max} = \max\left((U_y^2 - U_y^2)/2, U_y \sqrt{U_y^2 + U_z^2}\right)/U_y.$$  

In order to find the actual width of the band of edge states we consider the condition of the existence of solutions of equation (50) within the intervals shown in figure 4. Depending on whether $d < d_c$ or $d > d_c$, where $d_c = \text{Re}\left[\sqrt{U_y^2 - U_z^2}/U_z\right]$, the condition has the form $\gamma^2(k_y)\gamma_g(k_y)\gamma_g(k_y)_{k_y = d^{-1}} < 1$ or $\gamma^2(k_y)\gamma_g(k_y)\gamma_g(k_y)_{k_y = d^{-1}} > 1$, respectively. Here

$$\gamma_B = qd$$

$$\tan(\gamma_G) = \frac{\kappa d}{\epsilon - k_y U_y}.$$  

Thus the edge states are massless excitations. Now we turn to the analysis of bulk states, i.e. states localized inside the barrier and characterized by $q^2 > 0$, whose spectrum has a much richer structure. In this case the condition of localization (49) takes the form

$$\gamma_B - \gamma_G = \pi n,$$  

where $\gamma_B = qd$ and

$$\tan(\gamma_G) = \frac{\kappa d}{\epsilon - k_y U_y}.$$  

Figure 4. Characteristic curves on $(k_y, \Delta \epsilon)$-plane, where $\Delta \epsilon = \sqrt{\epsilon^2 - U_z^2}$, determining the structure of the spectrum of edge states: $k(\Delta \epsilon)$ or $\kappa(\epsilon, \Delta \epsilon) = 0$ (solid line), $D(k_y, \Delta \epsilon) = 0$ (dashed line) and $\kappa(\epsilon_0, \Delta \epsilon) = 0$ (dotted line) plotted for the case $U_y < 0$ and intermediate $V$. The edge states may exist only in shaded areas. In the case $V + |U| < |U|$, the edge state can be either in the upper region, $k_y > |U|$ or the lower region depending on the relation between $d$ and $d_c$ (see the main text). When $V + |U| > |U|$ (b) the band edge is determined by $\gamma_B(\epsilon) > 1$.\[53\]
In contrast to the previous case, the phases should match up to multiples of $\pi$. According to equation (45), this corresponds to different numbers of full rotations of the incoming spin state inside the barrier. States corresponding to $n = 0$ constitute the fundamental band and those with $n > 0$ form higher bands.

The dependence of the spectrum of localized states on the relation between $V$ and $U_y$ is more complex than in the previous case. Let us assume for concreteness that $U_y < 0$. An analysis of conditions $q_y^2 > 0$ and $\kappa_1 > 0$ (see figure 5) shows that there are three possibilities:

(i) $V < |U_y|$. There are no solutions with $k_y < 0$, while states with $k_y > 0$ occupy an infinite band possibly with a gap (see figure 5(a)).

(ii) $|U_y| < V$. The infinite band disappears. A finite band of states with $k_y > 0$ may exist if additionally $V > |U_y|$ (see figure 5(b)). Thus, if $|U_y| < V < |U_y|$ there are no localized states, either bulk or edge.

(iii) $\sqrt{U_y^2 + U_z^2} < V$. If there are solutions, they exist for both $k_y > 0$ and $k_y < 0$ occupying bands of finite size (see figure 5(c)).

Whether there exists a solution of equation (57) at a chosen energy depends on details of the variation of $\gamma_B(k_y)$ and $\gamma_G(k_y)$.

The latter, in turn, depends on the position of the pole of equation (58), depicted by dotted lines in figure 5. This leads to a cumbersome system of conditions and, therefore, we limit ourselves to the case $U_z = 0$ noticing that the main effect of $U_z \neq 0$ is separating regions, where $q_y^2 > 0$ as is demonstrated by figure 5(a).

In the case $V < U_y$, the existence of solutions is determined by the condition $\gamma_B(k_y)\gamma_G(k_y)_{k_y = k_{y>}^+} > 1$, where $k_{y>}^+$ is given by equation (53). This condition is satisfied, when

$$\epsilon > \epsilon_U = V + \frac{|U_y|}{1 + \sqrt{1 + d^2(U_y^2 - V^2)}}$$

and

$$0 < \epsilon < \epsilon_D = V - \frac{|U_y|}{1 + \sqrt{1 + d^2(U_y^2 - V^2)}}$$

These inequalities define two bands formed by bulk states. One band extends to infinity, while another, existing when $V > 1/d$, is finite.

The infinite band consists of an overlapping fundamental band and higher bands. The dispersion law of the fundamental near $\epsilon_U$ is linear, thus the respective excitations are massless.

Figure 5. The structure of the spectrum of localized states propagating across the barrier (bulk modes). In all three panels the localized states may exist only within the shaded regions, dotted lines correspond to $q(k_y, \epsilon) = 0$, i.e. $\epsilon = |k_y|$, the solid lines show $q(k_y, \epsilon) = 0$, i.e. $\epsilon = V \pm \sqrt{(k_y + U_y)^2 + U_z^2}$ for $U_z < 0$. The dashed lines show $D(k_y, \epsilon) = 0$, where $\gamma_Q = \pi/2$. Its position allows one to estimate the variation of the geometric phase along the line connecting the opposite sides of a shaded region at fixed energy and to formulate the condition of the existence of a solution of equation (57). (a) $V < |U_y|$. The case $V > |U_y|$ is shown (more specifically, $|U_y/U_z| = 0.4$ and $V/|U_y| = 0.4$), when the finite band may exist in sufficiently wide barriers. (b) When $V < |U_y|$ the infinite band disappears, while the finite band may exist if $V < |U_y|$. The case $|U_y/U_z| = 0.4$ and $V/|U_y| = 1.04$ is shown. (c) When $V > \sqrt{U_y^2 + U_z^2}$ there may be finite bands corresponding to $k_y$ of both signs. The barrier loses the property of uni-directionality. The case $|U_y/U_z| = 0.4$ and $V/|U_y| = 1.8$ is shown.
The spectrum of higher bands, however, shows an interesting feature. Let us consider the $n$th band with $n > 1$. The form of solutions of equation (57) essentially depends on whether $\epsilon > \epsilon_M$ or $\epsilon < \epsilon_M$, where $\epsilon_M = \frac{1}{2}\text{Vol} + \frac{1}{2}\text{Vol}^2$. In the general case the region of massive bands is given by $\epsilon_M = \frac{1}{2}\text{Vol} + \frac{1}{2}\text{Vol}^2$. Thus, only higher bands with $\epsilon > \epsilon_M$ has the form

$$\epsilon_{\mu}^{(n)} = \epsilon^{(n)} + \Delta^{(n)}$$

where $\Delta^{(n)} = \pi n \hbar d$. The dispersion law of the $n$th band near $\epsilon^{(n)}$ has the form

$$\frac{(k_y - |U_y|)^2}{2\mu^{(n)}} = \epsilon - \epsilon^{(n)}$$

where $\mu^{(n)} = \pi(n + 1/2)\hbar d/2\pi$, thus, only higher bands with numbers $n \leq n_M = \left\lfloor \frac{1}{2}|U_y| \hbar d/2\pi \right\rfloor$, where $\lfloor \text{ } \rfloor$ denotes taking the integer part, are massive.

The finite band occupying $0 < \epsilon < \epsilon_D$ is also formed by overlapping the fundamental band with a finite number (possibly zero) of higher bands. The position of the top of the $n$th band is $\epsilon^{(n)} = V - \epsilon^{(n)}$. Thus the number of higher bands contained in the low-energy finite band is $N = |dV/\pi\hbar|$

The interesting feature of the finite band is that excitations near the top of all higher bands bands are massive and their masses match masses of the respective excitations in the infinite bands but are negative. The dispersion laws are of the form

$$(k_y - |U_y|)^2/2\mu^{(n)} = \epsilon^{(n)} - \epsilon.$$ (62)

Only when $V > \sqrt{U_{y}^2 + U_{z}^2}$, the barrier may admit localized bulk states with $k_y$ of the same sign as $U_y$. The bands occupied by states with $k_y < 0$ and $k_y < 0$ are, however, of different size, but contain approximately the same number of bands. For a given energy $\epsilon$ states with positive and negative $k_y$ are inside intervals $(\epsilon, k_{*}^{+})$ and $(k_{*}^{-}, -\epsilon)$, respectively, where $k_{*}^{\pm}$ are given by equation (53). In order to estimate the position of the $n$th band, with $n = 0, 1, \ldots$, we approximate $\gamma_G \approx \pi$, which is a good approximation when $V$ significantly exceeds $\sqrt{U_{y}^2 + U_{z}^2}$ and $\epsilon$ is not too close to zero. Thus for $k_y < 0$ we find

$$\epsilon^{(n)} = \frac{1}{2}(V - |U_y|) - \left( \frac{\pi(n + 1)}{d} \right)^2 \frac{1}{2(V + |U_y|)}.$$ (63)

Within the adopted approximation for $\gamma_G$ the dispersion laws of the bands are approximately linear, implying massless excitations. This approximation, however, breaks in the immediate vicinity of the top points of the bands.

The same approximation can be used for studying states with positive $k_y$ yielding for the top of the $n$th band

$$\epsilon^{(n)} = \frac{1}{2}(V + |U_y|) - \left( \frac{\pi(n + 1)}{d} \right)^2 \frac{1}{2(V - |U_y|)}.$$ (64)

It should be noted that equations (63) and (64) predict the same number of bands with positive and negative $k_y$. While this result is obtained using a crude approximation $\gamma_G \approx \pi$, it breaks only in barriers with carefully chosen parameters, in which states with negative $k_y$ may have one band less than the states with $k_y > 0$. Equations (63) and (64) also correctly predict that not all barriers with strong $V$ may support localized states. More accurate estimates for parameters of the barrier allowing at least a fundamental band can be obtained as $\gamma_G(\epsilon = 0, k_y = 0) > \pi/2$ yielding $V^2 - U_y^2 - U_z^2 > (\pi/2d)^2$.

5. Application for topological insulators

The results of the previous sections can be directly applied for a description of electrons moving along the surface of a topological insulator. In order to do this, two important circumstances should be taken into account. First, the Hamiltonian of a free electron in this case is usually taken in the Rashba form $H_0 = \epsilon \sigma \cdot (\sigma \times p)$, which is different from the electron Hamiltonian in graphene: $H_0 = \epsilon \sigma \cdot p$. Hamiltonians $H_R$ and $H_W$, however, are equivalent up to different choices of the $\sigma$-matrices, generators of the $su(2)$ algebra. Second, a consistent treatment of the matrix potential requires taking into account the following circumstance. If, for instance, the matrix potential is implemented by a vector potential, there is a strong magnetic field at the points of strong variation of the vector potential. The Zeeman interaction of the electron spin with this magnetic field cannot be neglected and has to be taken into account.

In order to keep the general character of the consideration and to distinguish the effect of the Zeeman interaction, we formally distinguish the contribution of the matrix and vector potentials and, thus, consider the equation of motion of the form

$$[\epsilon \sigma \cdot (\sigma \times (p - eA)] + \hat{U}\psi = \epsilon \psi,$$ (65)

where $A$ is the vector potential. The matrix potential $\hat{U}$ can be presented in terms of $\sigma_{x,y,z}$

$$\hat{U} = V\hat{1} + U'\sigma,$$ (66)

with $U' = U + gB - \nabla \times A$ is the magnetic field and $g$ is the gyromagnetic ratio. In order to show the equivalence of equation (65) and (1) we introduce $\sigma_z = -\sigma_0$ and $\sigma_0 = \sigma_z$, which correspond to the representation $\sigma_x = \sigma_y \times (\sigma_x \sigma_x + \sigma_0 \sigma_0)$. It can be easily checked that $\sigma_x, \sigma_y, \sigma_z$ satisfy the same commutation relations as $\sigma_x, \sigma_y, \sigma_z$. In terms of $\hat{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ equation (65) is written as

$$\hat{\sigma} \cdot (p + \hat{U})\psi = (\epsilon - V)\psi,$$ (67)

with $\hat{U} = -eA + \hat{U}_0 + Ue_y$ and $\hat{U}_0 = e_z \times U$. Equation (67) has the same form as equation (1) but with vectors and spin states rotated by $\pi/2$ around the $z$-axis. Thus the consideration of section 2 can be simply repeated in the present case. In order to restore the directions of the effective fields and spin states for the electron in a topological insulator one only needs to perform the inverse rotation, i.e. rotate the respective vectors by $-\pi/2$ around the $z$-axis. Having this relation established we will omit tilde while writing the components of the effective matrix potential.

In order to obtain the transfer matrix, however, it is necessary to account for the effect of the Zeeman term. We introduce $f(x) = \theta(x - x_0)\theta(x_0 - x)$, where $\theta(x)$ is the Heaviside
function, and denote \( A(\alpha) = A f(\alpha) \), so that \( B(\alpha) = \nabla f \times A \). In the immediate vicinity of the boundary of the barrier one can neglect non-singular contributions in equation (67) thus obtaining

\[
\sigma \psi - \frac{\partial}{\partial x}(\sigma_2 A_y + \sigma_3 A_z) \psi = 0. \tag{68}
\]

The solution of this equation can be written as

\[
\psi(x) = \exp\{g(\sigma_2 A_y - i\sigma_3 A_z)(f(x) - f(x_0))\} \psi(x_0). \tag{69}
\]

It is seen that at \( x = x_L \) and \( x_R \) the spin experiences discontinuity described by the dilation operators \( e^{\sigma_y A_y} \) and \( e^{-\sigma_y A_y} \), respectively. These jumps are conveniently accounted for in the representation of the transfer matrix through the barrier, \( \tilde{T}_{\text{tot}} \), in terms of dilation operators:

\[
\tilde{T}_{\text{tot}} = e^{-g\delta A_y i\sigma_2 - g\delta A_z i\sigma_3} \sigma_2 g\delta A_y. \tag{70}
\]

Comparing with expressions for matrix elements of \( \tilde{T}_{\text{tot}} \), see e.g. equations (46) and (49), it can be seen that the effect of the spin jump reduces to a straightforward modification of the dilation operator determining the incoming spin state: \( b_1 \rightarrow b_1 = b_1 + 2gA_y \). This allows us to apply directly the results of the previous sections.

First we consider the modification of the KT condition. It has the same form as equation (46), which results in

\[
\sinh(2gA_y) [\epsilon \tilde{\epsilon} - k_y(k_y + U_y)] - \cosh(2gA_y) [k_y V + U_y \epsilon] = 0. \tag{71}
\]

We briefly analyze this result assuming for concreteness that \( A_y > 0 \).

In the case \( \epsilon < V \) the effect of the spin discontinuity is a modification of the dependence of the KT direction on the relation between \( U_y \) and \( V \) as is illustrated in figure 6(a). Additionally the KT direction becomes energy dependent (see figure 6(b)). At the same time the condition for the KT to exist remains the same as in the case of continuous spin distribution, \( |U_y| < V \).

When \( \epsilon > V \), however, new features appear. First of all, when \( |U_y| > V \) the KT is no longer suppressed but rather appears at high energies,

\[
\epsilon > \frac{1}{2}(V + U_y \coth(2gA_y)) + \frac{1}{2\sinh(2gA_y)} \sqrt{U_y^2 - V^2}. \tag{73}
\]

Moreover, if \( \epsilon > V/(1 - e^{-4gA_y}) \) there are two distinct KT directions.

In a similar way the effect of the spin discontinuity on localized modes can be studied. Using equation (70) in localization
condition (49) we find that the spin jump leads to modification of the geometric phase only

$$\tanh(\gamma G) = \frac{\gamma \psi}{D T}.$$  (74)

where

$$D T = \epsilon \left[ e \cosh(2g A_1) + k_x \sinh(2g A_1) \right] - \left( k_x + U_j \right) [k_y \cosh(2g A_1) + e \sinh(2g A_1)].$$  (75)

The equation for localized states \(\tanh(\gamma_0) = \tanh(\gamma G)\) can be analyzed using the same approach as in the previous section. The effect of the spin discontinuity can be seen to be less significant than for the KT. The main conditions for the existence of localized states and the boundary between massive and massless modes remain the same as in the case of continuous spin. The exact positions of the band edges and masses are modified. The explicit expressions, however, are too cumbersome and we do not provide them here.

6. Conclusion

We present a detailed consideration of the propagation of a 2D Dirac electron in the presence of a rectangular matrix potential barrier. We describe scattering with the help of spinor transfer matrices, which relate the orientation of the electron spin state at different points of the system given in terms of superposition of eigen spin coherent states. We show that the Klein tunneling is suppressed in the presence of the mass term, \(\propto \sigma_\tau\). In the absence of such contribution, the Klein tunneling is not suppressed but is observed at an oblique direction with the angle of incidence determined by the ratio between the scalar and vector components of the matrix potential.

The analysis of scattering is applied for studying waveguiding properties of the matrix potential barrier. Depending on the electron energy and parameters of the barrier, it may support states localized near the boundaries (edge states) or penetrating the interior (bulk states). We describe the general properties of the waveguiding modes, determine the widths of the bands and obtain the dispersion laws of the low-energy excitations. We show that both kinds of waveguiding modes, supported by edge and bulk states, may demonstrate the property of uni-directionality when the barrier admits only waveguiding modes with \(k_x U_j < 0\). We obtain general conditions governing the general form of the spectrum of waveguiding modes. In particular, we show that in barriers with sufficiently strong attractive scalar potential, the waveguiding modes supported by the bulk states may demonstrate a gapped spectrum in wide barriers. When the scalar potential increases, the bottom of the infinite band raises and in sufficiently strong repulsive scalar potential only the finite band remains, which serves as the precursor to loosing the uni-directionality property.

While the waveguiding modes supported by the edge states are massless, those supported by the bulk states have both massive and massless bands. We find the energy region, where the massive bands are located, and find their number.

In addition to the case when the electron is characterized by the pseudospin, we consider the case where the spin is real and thus is sensitive due to the Zeeman effect to the magnetic field at the boundaries of the barrier. Its most significant manifestation is the appearance at sufficiently high energies of two distinct directions corresponding to the Klein tunneling.
