Visual Abstract

Significance Statement

Transcranial direct current stimulation (tDCS) is a neuromodulation procedure in which a weak electric direct current is delivered through the brain for tens of minutes. Despite reported positive effects, the mechanisms of tDCS stimulation are not yet well understood. Here, we examined microglial morphology in the mouse cortex after tDCS. We find that the morphology and morphologic dynamics of microglia are altered by tDCS in a manner dependent on adrenergic receptors, supporting the notion that (nor)adrenergic signaling is involved in tDCS.
Transcranial direct current stimulation (tDCS) has been reported for its beneficial effects on memory formation and various brain disorders. While the electrophysiological readout of tDCS effects is subtle, astrocytes have been demonstrated to elicit Ca\(^{2+}\) elevations during tDCS in a rodent model. This study aimed to elucidate the effects of tDCS on another major glial cell type, microglia, by histology and \textit{in vivo} imaging. tDCS performed in awake conditions induced a significant change in the pixel intensity distribution of Iba-1 immunohistochemistry, and microglial somata were enlarged when examined 3 h after tDCS. These effects were blocked by adrenergic receptor antagonists or in IP\(_3\)R2 (inositol trisphosphate receptor type 2)-deficient mice, which lack large cytosolic Ca\(^{2+}\) elevations in astrocytes. No obvious changes were observed in isoflurane-anesthetized mice. Furthermore, \textit{in vivo} two-photon imaging of microglia showed a reduction of motility that was blocked by a \(\beta_2\)-adrenergic receptor antagonist. Our observations add support for the influence of noradrenaline in tDCS and suggest possible interactions between microglia and astrocytes to express functional changes associated with tDCS.

\section*{Introduction}
Noninvasive neuromodulation is a subject of intense research because of its potential for treating patients with neuropsychiatric and neurologic conditions. Transcranial direct current stimulation (tDCS) is the application of a constant and weak electric current to the brain through the skull. Typical parameters applied in humans are 1 mA over \texttilde{}30 cm\(^2\) for 10–30 min (Bikson et al., 2016). A fair sized body of published literature suggests that tDCS has positive effects on cognitive abilities and could be an alternative treatment for various brain disorders (Fregni and Pascual-Leone, 2007; Nitsche et al., 2008, 2009; Brunoni et al., 2012; Dedoncker et al., 2016). On the other hand, there is a notable degree of skepticism due to mixed outcomes of tDCS experiments (Horvath et al., 2015a,b; Jalali et al., 2017; Medina and Cason, 2017; Kunzelmann et al., 2018; Turkakin et al., 2018). The skepticism has been, in part, strengthened by a recent study that suggested negligible tDCS-induced membrane potential changes in cerebral cortical neurons (Vöröslakos et al., 2018), implying limited involvement of neuronal discharge as the prevalent mechanism of tDCS.

The circuit and cellular mechanisms for tDCS remain to be understood. Glial cells represent electrically nonexcitable cells in the nervous system. They have been regarded as “support cells” for the normal function of neurons. Among glial cell types, astrocytes and microglia maintain the extracellular milieu by ion homeostasis and phagocytosis, respectively. Additionally, astrocytes and microglia have been reported to interact with neuronal synapses (Wake et al., 2013; Araque et al., 2014). We recently reported that astrocytic Ca\(^{2+}\) surges occur during tDCS in mice. Moreover, tDCS-induced astrocytic Ca\(^{2+}\) surges were shown to promote cortical plasticity and have beneficial effects in a mouse model of depression (Monai et al., 2016; Monai and Hirase, 2016, 2018). The recruitment of Ca\(^{2+}\) activities in astrocytes has prompted us to investigate another major glial cell type, microglia.

Microglia are sensitive to brain tissue damage and transform to reactive microglia on inflammation. Iba1 (ionized calcium binding adaptor molecule 1) immunohistochemistry (IHC) visualizes the morphology of microglia, which is profoundly altered in reactive microglia. Following the published observation that reported the lack of pronounced microglial reactivity after tDCS (Monai et al., 2016), here we investigated Iba1 IHC in detail by digital image analysis. We report subtle, but significant effects of tDCS in an awake condition, but not under anesthesia, that depended on adrenergic receptors. Subsequently, we examined microglial motility by \textit{in vivo} two-photon imaging and found that tDCS reduces microglial motility.

\section*{Materials and Methods}
All animal procedures were performed in accordance with the RIKEN animal experimental committee regulations.

\section*{Animals}
Adult C57BL/6J and IP\(_3\)R2 (inositol trisphosphate receptor type 2) knock-out (KO) mice (Futatsugi et al., 2005) were used for immunohistochemical experiments (male, 2–4 months old). BAC-GLT1-G-CaMP7 line 817 mice (male, 2–5 months old; catalog #G7NG817, RIKEN Bioresource Research Center; resource ID: RBRC09650) were used for transcranial macroscopic imaging of neuronal and astrocytic Ca\(^{2+}\) activity (Monai et al., 2016). Iba1-GFP mice (male, 3–10 months old; Hirase et al., 2005) were used for \textit{in vivo} two-photon imaging of microglial morphology.

\section*{Surgical procedures}
Mice were deeply anesthetized with isoflurane (1.5–2.0%), and their scalps were exposed by shaving. Each
mouse was fixed on a stereotaxic apparatus (Narishige) under isoflurane anesthesia. Throughout the surgery and experiments with anesthetized mice, the body temperature was kept at 37°C with a heating blanket (BWT-100A, Bio Research Center). After topical application of xylocaine ointment (2% lidocaine) on the scalp, the skull above the sensory cortex was exposed by incision of the scalp and temporal muscle. A custom-made chamber ring was glued to the skull with cyanoacrylate superglue. After the glue settled, we applied dental cement (Fuji LUTE BC, GC Corporation; Super-Bond C&B, Sun Medical) for reinforcement. For two-photon imaging, the inner cavity of the chamber ring was reinforced with additional dental cement to secure the interface for an objective lens. Once the chamber ring was rigidly attached, the mouse was fixed on a custom-made stage via the chamber ring. Thereafter, a small craniotomy (3 mm, with intact dura) was carefully made using a dental drill.

Habituation to head restraint
The postsurgical recovery period was at least 3 d for IHC experiments and 2 weeks for in vivo two-photon imaging experiments. Following the recovery period, mice were placed on a water restriction schedule and subjected to an acclimatization procedure for head restraint (Fig. 1B). Food was given ad libitum. The acclimatization procedure was performed for 7 d.

On day 1, each mouse was held in the experimenter’s hands and water was given via a syringe (~0.2 ml). During handling, we let the mouse explore until it entered into a body tube similar to the one used with the tDCS apparatus. If the mouse entered the body tube, we repeated the procedure four to five times. The total handling time was 10 min for each mouse. From day 2, the mouse continued to be acclimatized to the experimenter and apparatus with a water reward (0.1–0.2 ml) for each entry to the body tube. At this point, the head of the mouse was quickly (≤10–20 s) fixed to the apparatus via the chamber ring with its body in the tube. Additional water and sunflower seeds were provided during head fixation (10–15 min). The total amount of water given during head fixation was 1.0 ml/d. In some mice, for in vivo two-photon imaging acclimatization was performed for >7 d.
Transcranial DC stimulation

tDCS was applied on mice under anesthesia (2% isoflurane) or in awake conditions. In either condition, the anode (stainless wire, \( \varphi = 350 \mu m \)) was placed on a sodium chloride-based conductive gel interface (Z101BA, NIHON-KODEN) spread over a circular area (\( \varphi = \sim 2 \text{ mm} \)) above the primary visual cortex (anteroposterior, \(-2.9 \text{ mm}; \) mediolateral 2.0 mm). The cathode was connected to the neck skin after topical application of xylocaine ointment. DC (0.1 mA, 10 min) was applied with a custom-made isolated constant-current supply.

Histology

After tDCS application, mice were kept for 30 min or 3 h before they were killed. After deep anesthesia by urethane, they were first perfused with 0.9% NaCl and later before they were killed. After deep anesthesia by urethane the mice were perfused with 0.9% NaCl. Following brain removal and overnight postfixation in the same fixative, coronal slices (60 \( \mu m \)) were prepared using a microslicer (PRO 7, Doshaka). For Iba1 staining, sections were incubated in a buffer containing the primary antibody (Tris-buffered saline with 0.1% Triton X-1000; 1:2000; catalog #019-19741, Wako) overnight. The sections were subsequently washed in PBS and incubated with the Cy3-conjugated secondary antibody (Invitrogen) for 2 h for fluorescent labeling. To evaluate DSP4 [N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine hydrochloride] efficacy, noradrenergic fibers were labeled by anti-tyrosine hydroxylase (TH) antibody (1:1000; catalog #AB152, Millipore) using sagittal slices (60 \( \mu m \)). For positive control of microglial reactivity, Escherichia coli lipopolysaccharide (LPS; 0.5 mg/kg) was administered by intraperitoneal injection 2 d before the mice were killed.

Confocal imaging

Immunolabeled cortical microglia (V2 area) were examined using a confocal microscope (FV1000, Olympus). Images were acquired with a 60× water-immersion objective (UPlanSApo; numerical aperture, 1.20) at an excitation wavelength of 559 nm. Imaged areas covered 211.761 \( \times \) 211.761 \( \mu m^2 \) (1024 \( \times \) 1024 pixels) with an optical sectioning of 0.5 \( \mu m \). Images were scanned with the one-way mode (8 \( \mu s/pixel\) exposure).

Drug administration

In some experiments, the following drugs were administered before tDCS by intraperitoneal injection: ICI81551 (5 mg/kg body weight, 30 min before; Tocris); and Prazosin (10 mg/kg, 30 min before; Sigma-Aldrich). For the ablation of noradrenergic neurons, DSP4 (Sigma-Aldrich) was injected 11 and 7 d before tDCS application (50 mg/kg, i.p., each time). Drugs were dissolved in 0.9% NaCl.

In vivo imaging of microglial morphology

Adult Iba1-EGFP transgenic mice (Hirasawa et al., 2005), in which EGFP is expressed exclusively in microglia, were used to monitor microglial morphologic dynamics. All mice were habituated to the experimental apparatus for >7 d. On the day of imaging, the mouse was set on a custom-made stage under a two-photon microscope (B-Scope, Thorlabs). Microglia located >50 \( \mu m \) below the pial surface were imaged under awake conditions at a wavelength of 920 nm. The laser power was adjusted to \( \sim 12 \text{ mW} \) at the preparation (Hines et al., 2009; Wake et al., 2009; Pfeiffer et al., 2016). Depth stacks (24–26 slices, 2 \( \mu m \) z interval, 512 \( \times \) 512 pixels corresponding to 101 \( \times \) 101 \( \mu m^2 \) or 201 \( \times \) 201 \( \mu m^2 \)) were acquired every 60 s.

Analysis

Iba1 IHC image analysis

Confocal images were used for pixel intensity analysis. Image stacks extending to 15 \( \mu m \) thickness were collapsed into 2D images by maximum intensity projection. Pixel intensities were converted to z scores, and the cumulative distribution was computed for each collapsed 2D image.

For soma size analysis, confocal image stacks (45–50 \( \mu m \) thickness) were first filtered with a 3 \( \times \) 3 \( \times \) 3 median filter. The resultant image stacks were collapsed into 2D images by maximum intensity projection. To correct for uneven background, the rolling ball method with a radius of 30 pixels was used for background subtraction. Thereafter, the images were subjected to a 3 \( \times \) 3 2D median filter followed by binarization with Yen’s thresholding method (ImageJ, National Institutes of Health) for soma extraction. In some cases, manual adjustments of threshold were needed. Extracted somata were approximated to ellipses. Following these automated procedures in ImageJ, extracted somata were validated by manual inspection. The median of microglial soma size distribution from each mouse was taken as a data point for statistical comparisons.

TH image analysis

The efficacy of DSP4 was evaluated by calculating the mean intensity of posterior cortical layer 1 TH-positive (TH+) innervation using ImageJ. Briefly, sagittal brain section images (60 \( \mu m \) thickness) were acquired by a Keyence microscope (BZ-X710; 0.37 \( \mu m \) pixel size). Ten to 12 contiguous regions of interest (ROIs; 100 \( \times \) 100 \( \mu m \) each) were allocated to occupy layer 1. A background intensity value was calculated from a neighboring parenchymal area that does not contain TH+ axons. The mean TH+ signal intensity of each ROI was computed as the mean pixel intensity minus the background intensity.

Microglial motility assessment

Quantification of microglial surveillance was performed using custom-written ImageJ and MATLAB programs (MathWorks). The maximum intensity projection image was computed for each time point of xyzt image stack. The resultant xyzt image stack was registered for xy motion correction. Next, each slice of the xyzt stack was processed by the ImageJ “Subtract Background” plugin to subtract smooth continuous background with a ball size of 30 pixels. Thereafter, images were treated with a 2D 3 \( \times \) 3 median filter. After this preprocessing, rectangular areas containing the morphologic extent of single microglia were extracted as separate image stacks. These cellular image stacks were then binarized with a single
threshold determined by Li's Minimum Cross Entropy method (ImageJ). Noise reduction was then performed by a cycle of erosion and dilation. The normalized surveillance area at time $t$ was calculated as the number of pixels that were occupied by the microglia at least once since the beginning of imaging until a given time $t$, divided by the number of pixels occupied by the microglia at the beginning. Normalized surveillance area is therefore a monotonically increasing function of time (see Fig. 6C,D, example). The surveillance index is defined as the ratio of normalized surveillance areas of a microglia in two different sessions [e.g., control (“Before”) vs post-tDCS (“After”).]

Statistical analyses
Statistical analyses were performed using Igor Pro (WaveMetrics). Student’s paired t tests and Wilcoxon-Mann–Whitney rank sum tests were used for the comparison of two sample populations with matched data and unmatched data, respectively, unless otherwise noted. Data are expressed as the mean ± SEM, and $p$ values <0.05 were considered statistically significant. Statistical values are reported in Table 1.

Results
First, we confirmed tDCS-induced cortex-wide Ca$^{2+}$ elevations (Monai et al., 2016) in the present setting using G7NG817 transgenic mice that express the G-CaMP7 Ca$^{2+}$ sensor in astrocytes and a subpopulation of neurons. Mice had been acclimatized to be rigidly fixed to a head-restraint platform, where tDCS (0.1 mA, 10 min) and transcranial fluorescence imaging were performed (Fig. 1A,B; see Materials and Methods). Cortical Ca$^{2+}$ signals elevated immediately after the passage of the DC current. The peak amplitude of the G-CaMP7 response measured ~3 mm anterior to the anodal position was 39.7 ± 4.1% (Fig. 1C; N = 4 mice), showing that tDCS-induced Ca$^{2+}$ elevation is observable with the head-chamber ring configuration. Notably, tDCS-induced Ca$^{2+}$ elevations were not observed in isoflurane-anesthetized mice (Extended Data Fig. 1-1). Having demonstrated the effectiveness of tDCS, we used C57BL/6 mice to investigate microglial morphology after tDCS by Iba1 IHC. Mice were killed either 30 min or 3 h after tDCS for perfusion fixation.

Iba1 IHC patterns are affected by tDCS in awake mice
Iba1 IHC visualized highly ramified microglial morphologies throughout brain slices of sham-operated, LPS-treated, and tDCS mice (Fig. 2A,B,J). To investigate the impact of tDCS on the wide-field appearance of Iba1 IHC, we computed the pixel intensity distribution, which is a proxy of global morphologic changes. We analyzed layer 2 and 3 of the visual cortex located below the anode, since a previous study demonstrated that tDCS-mediated plasticity occurs in these layers (Monai et al., 2016). Pixel intensities were converted to z scores with which the cumulative distributions were plotted. We compared head ring-implanted, unrestrained control mice (Ctl group) with head ring-implanted, acclimatized, 25 min head-restrained mice (Sham group) to evaluate the possible effects of head restraint. In Figure 2C, we demonstrate that cumulative pixel intensity distribution is similar between the Ctl and Sham groups, whereas the pixel intensity distribution shifted significantly in mice with reactive microglia caused by LPS. These results suggest that the head-restraining procedure in acclimatized mice does not cause reactivity in cortical microglia.

Next, we compared tDCS and sham-treated mice. The combination of two conditions [isoflurane-anesthetized (isofl) or awake] and two time points (30 min and 3 h after tDCS) were investigated (Fig. 2D–G). Pixel intensity distribution was similar between sham and tDCS for isofl 30 min, isofl 3 h, and awake 30 min experiments; however, the awake 3 h tDCS data exhibited a visible deviation from the sham group (Fig. 2G). This deviation was caused by a higher proportion of pixels at the high-intensity end. For instance, tDCS had a relatively large presence of pixels that had a z score >0.6 (21.2 ± 1.6% vs 18.2 ± 1.4%; $p = 1.7e-5$, t test). Moreover, a high-intensity cluster that had a z score >2 was apparent in the pixel intensity histogram (Fig. 2H). Consistent with this observation, thresholding with $z > 2$ preserved more microglial structures in awake 3 h tDCS images than the sham counterpart (Fig. 2J). While the cumulative pixel intensity histogram of awake 3 h tDCS deviated in the same direction as LPS, microglial morphology appeared normal with fine ramified processes throughout the extent of the cor-

tex in all tDCS experiments. Thus, tDCS does not appear to cause inflammatory responses.

**tDCS enlarges microglial somata in awake mice**

While the z score-based pixel intensity distribution analysis detected changes in the global appearance of images, it falls short of providing information on specific aspects of morphologic alterations. Microglial soma size has been reported to be sensitive to brain environmental changes (Kongsui et al., 2015). Therefore, we measured microglial soma size from Iba1 IHC images (Fig. 3A–C; see Materials and Methods). First, we compared the median microglial soma size of individual animals (43 cells per mouse on average) for unrestrained control and head-restrained sham groups as we did in Figure 2C. Figure 3D indicates that microglia soma sizes are similar between AwakeSham and Isofl 3hrs conditions, perfused at 30 min or 3 h after sham/tDCS. H, In awake mice, the pixel intensity histogram indicates that there is a cluster at z score > 2 (i.e., mean ± 2 SDs) region in the tDCS group (dotted red square). I, J, Representative images from a sham-treated mouse and a tDCS-treated mouse. Images in the red squares correspond to the thresholded images on the left at the mean ± 2 SDs. Red scale bars, 20 μm. **p < 0.01, ***p < 0.001.

**Figure 2.** Intensity analysis of microglial confocal images. A, B, Representative images of Cy3-labeled Iba1 IHC by maximum intensity projection obtained in Sham- and LPS-treated mice. Yellow scale bars: A, left, 100 μm; A, right, B, 20 μm. C, Cumulative pixel intensity distributions from unrestrained Ctl and head-restrained Sham groups were similar and distinct from the LPS-treated group. D–G, Intensity was compared between tDCS- and Sham-treated groups under the isoflurane-anesthetized (D, E) or awake (F, G) conditions, perfused at 30 min or 3 h after sham/tDCS. H, In awake mice, the pixel intensity histogram indicates that there is a cluster at z score > 2 (i.e., mean ± 2 SDs) region in the tDCS group (dotted red square). I, J, Representative images from a sham-treated mouse and a tDCS-treated mouse. Images in the red squares correspond to the thresholded images on the left at the mean ± 2 SDs. E, Comparison of microglial soma size in awake mice with/without tDCS treatment at different time points (30 min or 3 h) after tDCS. Microglial soma size was larger in the tDCS group in the awake 3 h experiment (p = 0.017c, Mann–Whitney Wilcoxon rank sum test). F, Microglial soma size comparison in isoflurane-anesthetized mice (Isofl-3hr). ***p < 0.03, N.S. not significant.

**tDCS-induced microglial soma enlargement is dependent on adrenergic receptors**

Recent human and animal studies have implicated the involvement of noradrenaline in tDCS (Monai et al., 2016;
To examine the possible contribution of noradrenaline to tDCS-induced microglia soma size, we ablated noradrenergic cells in the locus ceruleus using the neurotoxin DSP4 (Bekar et al., 2008), which was confirmed by TH staining in the sensory cortex (Fig. 4A,B). Following noradrenergic neuron ablation, we performed tDCS using the awake 3 h protocol. As a result, DSP4-treated mice did not show a microglial soma enlargement after tDCS (Fig. 4C; Sham group: 47.3 ± 0.6 μm², 7 mice; tDCS group: 44.5 ± 1.1 μm², 7 mice; p = 0.073). Since astrocytes exhibit profound \( \alpha_1 \)-adrenergic receptor (A1AR)-mediated \( \text{Ca}^{2+} \) elevations by tDCS (Monai et al., 2016), astrocytic \( \text{Ca}^{2+} \) signaling possibly plays a role in the microglial soma enlargement via an intercellular communication. To examine this possibility, we used IP3R2 knock-out mice in which Gq GPCR (e.g., A1AR)-activated intracellular \( \text{Ca}^{2+} \) elevation is diminished in astrocytes. Awake 3 h tDCS did not result in significant microglial soma size changes in IP3R2 KO mice (p = 0.73); Sham group: 44.6 ± 1.4 μm², 6 mice; tDCS group: 44.4 ± 0.56 μm², 7 mice; Fig. 5A). We next examined the involvement of A1AR using the specific antagonist prazosin in wild-type C57BL/6J mice. Similar to IP3R2 KO mice, prazosin-treated mice did not display tDCS-induced microglial soma enlargement compared with the Sham control group that also received the antagonist pretreatment (p = 0.8 × g; Sham group: 42.6 ± 0.9 μm², 7 mice; tDCS group: 42.3 ± 0.7 μm², 7 mice; Fig. 5B). These results suggest that tDCS-triggered noradrenaline release affects microglial soma enlargement via A1AR activation and the downstream astrocytic IP3R2-dependent \( \text{Ca}^{2+} \) signaling pathway.

Furthermore, we asked whether activation of \( \beta \)-adrenergic receptors is also involved. In particular, microglia are known for high levels of \( \beta_2 \)-adrenergic receptor (B2AR) expression (Tanaka et al., 2002; Gynøe and Traynelis, 2013). Accordingly, mice were pretreated with ICI181551, a selective B2AR blocker, and soma sizes were compared. In the ICI181551 group, tDCS-induced soma size enlargement was not observed (p = 0.48); Sham group: 45.9 ± 0.8 μm², 6 mice; tDCS group: 45.2 ± 1.7 μm², 6 mice; Fig. 5C). These results are indicative of noradrenergic involvement in tDCS-induced microglial changes and suggest that both A1ARs and B2BRs are involved in tDCS-induced microglial soma enlargement.

tDCS decreases microglial surveillance area in vivo

Kuo et al., 2017; Monai and Hirase, 2018; Souza et al., 2018. To examine the possible contribution of noradrenaline to tDCS-induced microglia soma size, we ablated noradrenergic cells in the locus ceruleus using the neurotoxin DSP4 (Bekar et al., 2008), which was confirmed by TH staining in the sensory cortex (Fig. 4A,B). Following noradrenergic neuron ablation, we performed tDCS using the awake 3 h protocol. As a result, DSP4-treated mice did not show a microglial soma enlargement after tDCS (Fig. 4C; Sham group: 47.3 ± 0.6 μm², 7 mice; tDCS group: 44.5 ± 1.1 μm², 7 mice; p = 0.073). Since astrocytes exhibit profound \( \alpha_1 \)-adrenergic receptor (A1AR)-mediated \( \text{Ca}^{2+} \) elevations by tDCS (Monai et al., 2016), astrocytic \( \text{Ca}^{2+} \) signaling possibly plays a role in the microglial soma enlargement via an intercellular communication. To examine this possibility, we used IP3R2 knock-out mice in which Gq GPCR (e.g., A1AR)-activated intracellular \( \text{Ca}^{2+} \) elevation is diminished in astrocytes. Awake 3 h tDCS did not result in significant microglial soma size changes in IP3R2 KO mice (p = 0.73); Sham group: 44.6 ± 1.4 μm², 6 mice; tDCS group: 44.4 ± 0.56 μm², 7 mice; Fig. 5A). We next examined the involvement of A1AR using the specific antagonist prazosin in wild-type C57BL/6J mice. Similar to IP3R2 KO mice, prazosin-treated mice did not display tDCS-induced microglial soma enlargement compared with the Sham control group that also received the antagonist pretreatment (p = 0.8 × g; Sham group: 42.6 ± 0.9 μm², 7 mice; tDCS group: 42.3 ± 0.7 μm², 7 mice; Fig. 5B). These results suggest that tDCS-triggered noradrenaline release affects microglial soma enlargement via A1AR activation and the downstream astrocytic IP3R2-dependent \( \text{Ca}^{2+} \) signaling pathway.

Furthermore, we asked whether activation of \( \beta \)-adrenergic receptors is also involved. In particular, microglia are known for high levels of \( \beta_2 \)-adrenergic receptor (B2AR) expression (Tanaka et al., 2002; Gynøe and Traynelis, 2013). Accordingly, mice were pretreated with ICI181551, a selective B2AR blocker, and soma sizes were compared. In the ICI181551 group, tDCS-induced soma size enlargement was not observed (p = 0.48); Sham group: 45.9 ± 0.8 μm², 6 mice; tDCS group: 45.2 ± 1.7 μm², 6 mice; Fig. 5C). These results are indicative of noradrenergic involvement in tDCS-induced microglial changes and suggest that both A1ARs and B2BRs are involved in tDCS-induced microglial soma enlargement.

tDCS decreases microglial surveillance area in vivo

One of the striking features of microglia is the motility of their ramified processes. Here, we directly examined the...
morphologic dynamics of individual microglia in the cortex of awake mice using a two-photon microscope (Fig. 6A). We used the Iba1-EGFP mouse, in which EGFP is exclusively expressed in microglia (Hirasawa et al., 2005). We confirmed that microglia showed surveillance activities by continual extension and retraction of their processes in all directions (Davalos et al., 2005; Nimmerjahn et al., 2005). For example, the overlay of 60 min imaging resulted in an extensive coverage of the area within ~60 μm from the soma, while the soma position remained unmoved (Fig. 6C). We defined normalized surveillance area as the proportion of cumulative microglia-occupied area at a given time relative to a start time (Fig. 6D). To check whether laser scanning has an impact on microglial morphology, we compared the occupied area of each monitored microglia at the beginnings of Before and After imaging sessions of the Sham-treated group (Fig. 6E). We found no significant difference, suggesting that the effect of laser irradiation on microglial morphologic dynamics is negligible.

While the evolution of a normalized surveillance area varied considerably among individual microglia, the average trace converged to a gradually decelerating curve (Fig. 6F). The mean surveillance area after 60 min did not differ significantly between before and after sham stimulation. Remarkably, the mean surveillance area index curve of tDCS mice (i.e., After session) is plotted lower than the control condition (i.e., Before session). We assessed the surveillance area change of individual microglia by taking the ratio of the surveillance area indices during Before and After sessions, demonstrating a significant decrease of surveillance area by tDCS (t = 40 min, p = 0.014, paired t test; Fig. 6G).

Furthermore, we addressed whether noradrenergic signaling is involved in this tDCS-induced microglial surveillance reduction by prazosin or ICI181551 pretreatment in
awake mice (Fig. 7A). As a reference, we computed the surveillance index comparing Before and After sessions at 40 min after the start of respective sessions. As expected from the previous analysis (Fig. 6D), the surveillance index of tDCS experiments was significantly reduced (Fig. 7A). Prazosin-treated mice showed a similar significant reduction of surveillance index after tDCS (Fig. 7A). By contrast, ICI181551 treatment abolished tDCS-induced reduction of microglia surveillance, and a trend for increased surveillance was apparent (Fig. 7C). These results point to a significant role of the B2AR in the inhibition of microglial surveillance activity after tDCS.

**Discussion**

The present experiments report that tDCS induces subtle, but significant, alterations of Iba1 distribution and microglial motility in the cerebral cortex in awake mice. Furthermore, these alterations were dependent on (nor-)adrenergic receptors, which is in line with the results of an earlier study that described tDCS-induced A1AR-dependent astrocytic Ca$^{2+}$ surges (Monai et al., 2016). Notably, while astrocytic Ca$^{2+}$ responses occur during tDCS, morphologic alterations of microglia occurred after a few hours.

We demonstrated that the microglial soma is enlarged after tDCS. Remarkably, the soma enlargement occurs only in awake mice. It is well established that microglial morphology is radically altered by LPS-induced inflammation (Kondo et al., 2011; Kozlowski and Weimer, 2012; Kongsgui et al., 2015). LPS-induced microglial alterations are obvious even with a low dosage of 100 μg/kg, whereby ~20% soma enlargement has been reported in the prefrontal cortex (Kongsgui et al., 2015). The tDCS-induced microglial soma enlargement of a mere several percentage points in the current study is relatively modest. Moreover, no obvious change was detected in ramiﬁed processes. As general anesthesia compromises astrocytic Ca$^{2+}$ activation, in particular noradrenergically driven large-scale and synchronized Ca$^{2+}$ surges (Thrané et al., 2012; Ding et al., 2013), microglial changes by tDCS conceivably depend on the elevated noradrenergic tone during awake states. On the other hand, some studies have reported significant changes in anesthetized mice that underwent tDCS. For instance, one study reported that enhancements of GFAP and brain-derived neurotrophic factor (BDNF) in anesthesia changed gene expression (de Souza Nicolau et al., 2018). Another study showed long-lasting antidepressive behavioral effects (Peanlikhit et al., 2017). However, these studies used stronger stimulation in terms of stimulus current, duration, and/or frequency. Moreover, the anesthesia condition used in the current study is deeper than that in the study by Peanlikhit et al. (2017). Considering the lack of astrocytic Ca$^{2+}$ surges in this condition (Extended Data Fig. 1-1), our results support the involvement of volume-transmitted neuromodulators in tDCS.

A few studies have examined cortical microglia after tDCS. For instance, Rueger et al. (2012) reported that multisession tDCS of 5–10 d induced a mild sign of microglial activation as observed by an upregulation of Iba1 immunohistochemical signals. The current density used in the study by Rueger et al. (2012) was ~150 A/m$^2$, whereas that used in the current study is <30 A/m$^2$. Considering the study by Gellner et al. (2016), which reported a microglial activation threshold of 30–50 A/m$^2$ with light isoflurane anesthesia, it is conceivable that our experiments were performed in near-threshold conditions. The tDCS-induced microglial soma enlargement and Iba1 signal intensity distribution shift are different from the microglial morphologic alterations reported in a rodent model of electroconvulsive therapy (ECT), in which obvious reductions in process ramification and Iba1 expression occur (Jinno and Kosaka, 2008). The pronounced alterations of microglia by ECT are most likely caused by the high-intensity electric stimulation that induces seizures. By contrast, cortical neuronal discharge activity remains undisturbed by tDCS (Monai et al., 2016; Vöröslakos et al., 2018).

We find that tDCS-induced soma enlargement is dependent on noradrenergic signaling. Moreover, the prazosin and IP$$_3$$R2-KO mouse (which lacks astrocytic Ca$^{2+}$ surges) experiments suggest a key mechanism linked to A1AR activation. The previous reports of relative abundance of A1ARs in astrocytes over microglia (Hertz et al., 2010; Zhang et al., 2014) and A1AR-dependent tDCS-

B, Surveillance index comparison in prazosin pretreated mice (Sham group: 9 cells from 2 mice; tDCS group: 11 cells from 3 mice; p = 0.015). C, Surveillance index comparison in ICI181551-pretreated mice (Sham group: 9 cells from 3 mice; tDCS group: 12 cells from 3 mice; p = 0.023) Mann–Whitney Wilcoxon rank sum test. ***p < 0.001; **p < 0.01; *p < 0.05; tDCS vs. sham; ***p < 0.001; **p < 0.01; *p < 0.05; tDCS vs. sham.
induced astrocytic Ca\(^{2+}\) surges (Monai et al., 2016) support the idea that astrocytic activation exerts effects on microglia. While this is intriguing, neither the prazosin nor the IP\(_{3}R2\) KO mouse experiment is cell type-specific; therefore, it is possible that direct noradrenergic activation of microglia causes soma enlargement. Indeed, B2AR inhibition by IC181551 also disrupted microglial somatic enlargement. Functional and transcriptomic evidence underwrites the enriched expression of B2ARs in microglia (Tanaka et al., 2002; Gyoneva and Traynelis, 2013; Zhang et al., 2014).

By imaging microglial morphology in awake mice, we found that tDCS attenuates microglial motility. This effect was also dependent on B2ARs, but not on A1ARs. The inhibitory effect of microglial B2ARs on motility is consistent with the \textit{in vitro} observation by Gyoneva and Traynelis (2013) and recent \textit{in vivo} observations in awake mice (Liu et al., 2019; Stowell et al., 2019). It is tempting to speculate that the brake on microglial surveillance creates an opportunity for relevant synapses to establish an initial stage of synaptic plasticity. Microglia have been demonstrated to be a functional component of the tDCS mechanism via adrenergic receptor activation.

One of the limitations of the current study is the lack of microglia-specific molecular manipulations. While it remains undetermined whether the microglial changes observed in this study have causal roles for positive outcomes of tDCS, several groups have consistently reported inflammation-associated microglial soma enlargement (Chen et al., 2012; Kozlowski et al., 2012; Kongsui et al., 2015). Brain inflammation activates microglia and leads to the production of proinflammatory molecules such as TNF-\(\alpha\), IL-1\(\beta\), and IL-6 (Hanjisch, 2002). It is possible that these cytokines are involved in the synaptic plasticity induced by tDCS. For instance, it has been demonstrated that the glial TNF-\(\alpha\) has a pivotal role in the regulation of homeostatic synaptic plasticity (Stellwagen and Malenka, 2006). Future studies should address the causal relationship, for instance by microglial B2AR knock-out mice combined with tDCS and behavioral performance.
