Abstract: The pores in rocks are multi-scale and highly complex. Based on complex network theory, the topological properties of a sandstone flow network are studied. The results show that the sandstone pore scale network is a small-world network with an average shortest path of 5.720, and 80% of the network node degree is less than 3. This network structure can improve the security of the network and ensure the permeability of the pores under the action of external forces. In addition, nodes with appropriate degree distribution have a significant influence on permeability. Nodes with a larger degree will significantly reduce the average shortest path of the network, while nodes with a smaller degree will expand the coverage of the seepage network.

Keywords: porous material; complex network; pore throat; the distribution of degree; clustering coefficient

1. Introduction

The pores in a rock reservoir are characterized by a multi-form, multi-scale and complex connection structure. The accurate description and quantitative characterization of the rock pore structure is the key to revealing the mechanism of the seepage phenomenon [1,2]. Further study on the structural characteristics of reservoir rocks has important scientific significance and engineering application value for accurately and quantitatively evaluating the permeability of rocks, improving oil recovery and reducing production costs.

In recent years, many experiments and simulations have been carried out on the statistical properties and evolution of the pore structure in rocks. Based on sandstone’s computed tomography (CT) scan image data of sandstone, Hajizadeh, A. [3] proposed a type of random porous media reconstruction technology by combining continuous, two-dimensional, multi-point statistical simulation with a multi-scale data extraction process using statistical methods. Since the traditional Darcy’s law cannot accurately describe gas flow in tight rock, Civan, F. [4] adopted the revised Darcy’s law to describe the gas density in shale migration law, and the apparent permeability is a function of the internal permeability porosity. Based on the pore network model, Zhang, T.Y. [5] proposed a modeling method based on the pore and throat size and calculated the permeability of different models in combination with seepage theory. Yang, J. [6] applied the fractal control function to characterize the complex shape of a rock’s pore structure and established the fractal reconstruction model of the rock pore structure in combination with the improved simulated annealing algorithm. Shaina, K. [7] used focused ion beam scanning electron
microscopy (FIB-SEM) to obtain the pore structure distribution of shale by the digital core method and compared the result with conventional scanning electron microscopy from the perspective of the organic matter content of the porosity and the pore connectivity.

At present, we mainly adopt the Euler number or average (such as for the average pore size or average pore throat length) from a macro perspective around the rock pore connectivity structure characterization. However, the relationship between the anisotropy degree of pore network clustering, the selection of the seepage path and the macroscopic permeability remains to be studied.

*Nature* and *Science* successively published two pioneering achievements of complex networks and put forward the small world model [8] and scale-free model [9] from 1988 to 1999. These two models form the basic framework of modern complex network theory. In the past 10 years, complex network theory has been widely used in physics, biology, informatics, big data and many other research fields [10–12]. Based on the analysis of network topology and complexity, the theoretical model of a network structure is established, and the internal evolution, robustness and dynamic transmission mechanism of a network are revealed.

Considering a real sandstone pore network and complex network theory, this study analyzes the topological characteristics and correlation properties of the pore network. This provides a new method for revealing the microscopic mechanism of porous seepage and characterizing the pore network structure of a rock.

2. Basic Characteristics of a Sandstone Pore Network

Sandstone in the Tongnan area of China was studied as an example. After the mercury injection experiment, the seepage network of the sandstone was obtained by scanning electron microscopy, as shown in Figure 1.

![Figure 1. Sandstone slice under scanning electron microscope (single polarized × 25).](image)

In the pore network, the pore–throat intersection is defined as the “node”, and the seepage crack is defined as the “edge”. The average shortest path length of the network is expressed as [12]

\[
l = \frac{1}{2N(N-1)} \sum_{i>j} d_{ij}
\]

where \( N \) is the number of nodes and \( d_{ij} \) is the shortest path length from node \( i \) to \( j \). The distribution of the distance \( d \) of the network \( P(d) \) is at its maximum when \( d = 6 \), as shown in Figure 2. \( P(d) \) represents the proportion of the shortest path length in the entire network when the sandstone pore network’s shortest path is \( d \). The average shortest path length of the network was 5.720, and the average shortest path length was 14.
shortest path length of the network was 5.720, and the average shortest path of the network was
1.720, which is 3.170 times the average shortest path of the network. The network clustering
coefficient is used to measure the clustering of network nodes. The clustering coefficient of
every node is the ratio of the number of edges connected to the node to the maximum number of
edges connecting the node to adjacent nodes. Figure 3 shows that 80% of the network nodes had
degrees of 10 or less, and those with degrees equal to 10 accounted for more than 50% of the
total nodes. This indicates that the permeability would be significantly affected only when
the nodal degree distribution value was at a certain intermediate value. The nodes with
a larger degree significantly reduced the average shortest path of the network, while the
nodes with a smaller degree expanded the coverage of the seepage network.

Figure 2. Sandstone pore network’s shortest path distribution.

The degree distribution of the network nodes is the number of cracks connected to this node. The node degree distribution of the sandstone pore network is shown in Figure 3. \( P(k) \) represents the proportion of all degree distributions in the whole network when the degree distribution is \( k \). Figure 3 shows that 80% of the network nodes had degrees less than or equal to 3, and those with degrees equal to 3 accounted for more than 50% of the total nodes. This indicates that the permeability would be significantly affected only when the nodal degree distribution value was at a certain intermediate value. The nodes with a larger degree significantly reduced the average shortest path of the network, while the nodes with a smaller degree expanded the coverage of the seepage network.

Figure 3. Sandstone pore network’s node degree distribution.

The network clustering coefficient is used to measure the clustering of network nodes. The clustering coefficient of a node is the ratio of the number of edges of the node to the maximum number of edges of adjacent nodes, which can be expressed as

\[
C_i = \frac{2E_i}{k_i(k_i - 1)}
\]

where \( k_i \) is the number of nodes connected node \( i \) and \( E_i \) is the actual number of edges between \( k_i \) nodes. The clustering coefficient of all the network \( C \) is the average of the clustering coefficients of all the nodes \( C = \frac{1}{N} \sum_{i=1}^{N} C_i \).

The distribution of the clustering coefficients is shown in Figure 4. It can be seen from Figure 4 that the percentage of nodes in the penetration network with a clustering coefficient of 1 was greater than 70%, and the average clustering coefficient of the whole network was 0.799. It can be seen from the seepage network that any three intersecting
fractures could form a loop. Obviously, this network was a ring network [11]. It can be seen from the nature of the network structure that the ring network had a high flow point, which means that the network was not easy to disconnect under the action of external forces.

![Figure 4. Distribution of sandstone pore network’s clustering coefficient.](image)

The above study shows that seepage is a small world network. The average distance of the seepage network was small \(d = 5.720\), but the average clustering coefficient was large \(C = 0.799\).

3. Results and Discussion

In order to describe the structure of the network more comprehensively, it is necessary to further study the nodes and the level of the clustering degree. The average degree of all adjacent nodes connected to node \(i\) can be expressed as

\[
k_{nn,i} = \frac{1}{k_i} \sum_{j \in \langle i \rangle} k_j
\]

(3)

Therefore, the average degree of all adjacent nodes connected to the nodes whose degree is \(k\) can be written as

\[
k_{nn}(k) = \frac{1}{N_k} \sum_{k_i = k} k_{nn,i}
\]

(4)

where \(N_k\) is the number of the nodes whose degree is \(k\). The relation of the nodes is their preference of mutually choosing [12]. If \(k_{nn}(k)\) is increasing along with \(k\) (i.e., the nodes with large degrees can connect to other nodes with large degrees too preferentially), then the network has a positive correlation. The Pearson correlation coefficient can be used to quantitatively judge network correlation [13], which can be expressed as

\[
r = \frac{M^{-1} \sum j_i k_i - [M^{-1} \sum \frac{1}{2} (j_i + k_i)]^2}{M^{-1} \sum \frac{1}{2} (j_i^2 + k_i^2) - [M^{-1} \sum \frac{1}{2} (j_i + k_i)]^2}
\]

(5)

where \(j_i\) and \(k_i\) are the degrees of two endpoints of the \(i\) edge, \(i = 1, \cdots, M\), the number of edges in network is \(M\) and \(-1 \leq r \leq 1\). When \(r > 0\), the network has a positive correlation. When \(r < 0\), the network has a negative correlation. When \(r = 0\), the network has no correlation. The Pearson related coefficient of the nodes in network \(r = 0.098\); that is, the seepage network did not show an obvious relationship, as shown in Figure 5.
In this paper, the percolation network was a small network [14] (i.e., the total number of nodes was small), and more than 50% of the nodes’ degrees were equal to 3. The middle interval of degrees had more nodes than other intervals. The nodes with higher degrees and nodes with lower degrees had more connections, depending on the size and characteristics of the network. Different fracture numbers and distributions of the internal rocks would lead to different correlations of the nodes in network. It should be noted that a large amount of empirical data and further studies are needed to determine whether this distinction can characterize the seepage capacities of rocks with different fracture degrees.

The correlation of degree refers to the relationship between the average clustering coefficient and node degree. The research shows that the clustering coefficient of the nodes in the real network presents an obvious power law decreasing trend with the increase in nodes [15], while the clustering coefficient of a certain network presents a certain power law decreasing trend with the increase in the change degree. The relationship between the node clustering coefficient and degree is shown in Figure 6. It can be seen from Figure 6 that the pore network had no obvious correlation.

4. Conclusions

Based on complex network theory, this study analyzed the topological characteristics of a sandstone pore network. The results show that the sandstone pore network, taking the fracture intersection as nodes, was a small world network. It had a shorter average path length and bigger clustering coefficient. This kind of network has higher security and shows that the material under the external force can better ensure the seepage ability. The
clustering coefficient and degree had no obvious correlation. The permeability was mainly determined by nodes of a medium degree, while the nodes of a large degree and small degree had no significant influence on the permeability.
