ABSTRACT

MONDian dark matter (MDM) is a new form of dark matter quantum that naturally accounts for Milgrom’s scaling, usually associated with modified Newtonian dynamics (MOND), and theoretically behaves like cold dark matter (CDM) at cluster and cosmic scales. In this paper, we provide the first observational test of MDM by fitting rotation curves to a sample of 30 local spiral galaxies ($z \approx 0.003$). For comparison, we also fit the galactic rotation curves using MOND and CDM. We find that all three models fit the data well. The rotation curves predicted by MDM and MOND are virtually indistinguishable over the range of observed radii ($\sim$1 to 30 kpc). The best-fit MDM and CDM density profiles are compared. We also compare with MDM the dark matter density profiles arising from MOND if Milgrom’s formula is interpreted as Newtonian gravity with an extra source term instead of as a modification of inertia. We find that discrepancies between MDM and MOND will occur near the center of a typical spiral galaxy. In these regions, instead of continuing to rise sharply, the MDM mass density turns over and drops as we approach the center of the galaxy. Our results show that MDM, which restricts the nature of the dark matter quantum by accounting for Milgrom’s scaling, accurately reproduces observed rotation curves.

1. INTRODUCTION

The cold dark matter (CDM) model (e.g., Bertone et al. 2005) successfully explains several astrophysical phenomena. These include flat galactic rotation curves (e.g., Rubin et al. 1980), gravitational lensing (e.g., Clowe et al. 2004), and the power spectrum of cosmic microwave background (CMB) anisotropies (e.g., Lineweaver et al. 1997; Planck 2013). This consistency has led to the widespread acceptance of the $\Lambda$CDM paradigm, in which the universe also exhibits a cosmological constant $\Lambda$. CDM does, however, have remaining tensions with observations, especially on $\lesssim$Mpc scales. These include inconsistency with the observed asymptotic velocity-mass ($v^4 \propto M$) scaling in the Tully–Fisher relation (Tully & Fisher 1977; Gentile et al. 2007; McGaugh et al. 2000, 2010), and the over-prediction of the number of satellite galaxies (Cen 2001).

Efforts have been made to construct theories that better match observations on galactic length scales than CDM. The most prominent of these is modified Newtonian dynamics (MOND; Milgrom 1983; Bekenstein 2004; Famaey & McGaugh 2012). In MOND, Newton’s equation of motion $F = ma$ is modified to

$$F = \begin{cases} ma & \text{for } a \gg a_c \\ ma^2/a_c & \text{for } a \ll a_c \end{cases}$$

(1)

where $a_c$ is the critical acceleration, which separates the two regions of different behavior. For a given source mass $M$, we have $F = m(GM/r^2) \equiv ma_N$, where $a_N$ is the usual Newtonian acceleration without dark matter. Thus, $a = a_N = GM/r^2$ when $a \gg a_c$, while $a = \sqrt{a_c a_N}$ when $a \ll a_c$. On the outer edges of a galaxy of mass $M$ where gravity is weak, we can therefore expect

$$v^2 = ra \xrightarrow{r \to \infty} r \sqrt{a_c a_N} = \sqrt{a_N GM} \equiv v_{\infty}^2,$$

leading to asymptotically flat rotation curves, and $v^4 \propto M$, the Tully–Fisher relation (Milgrom 2009).

The two regions of acceleration, $a \gg a_c$ and $a \ll a_c$, are connected by a smooth interpolating function $\mu(x) \equiv a/a_c$ such that

$$\mu(x) = \begin{cases} 1 & \text{for } x \gg 1 \\ x & \text{for } x \ll 1 \end{cases}$$

(3)

and the MOND equation of motion is $F = ma\mu(x)$. The choice for $\mu(x)$ is not unique. For example, some possible choices are

$$\mu(x) = \frac{x}{(1 + x^2)^{1/2}} \left[ 1 - \frac{1}{x} \left( \frac{1}{x^2} + 1 - \frac{1}{2} \right) \right].$$

(4)

Milgrom’s original choice was the first expression with $n = 2$. The formula with $n = 1$ was adopted by Famaey & Binney (2005), while the second expression in Equation (4) was studied by Milgrom (1999). Fitting galactic rotation curves with MOND by tuning the critical acceleration yields consistent values for $a_c$ (Begeman et al. 1991), found to be numerically related to the speed of light $c$ and the Hubble parameter $H$ as $a_c \approx c H/(2 \pi) \sim 10^{-8}$ cm s$^{-2}$.

As mentioned above, MOND naturally explains both the observed non-Keplerian galactic rotation curves and the
Tully-Fisher relation (Milgrom 2009). MOND, however, struggles to reproduce observations at cluster and cosmological length scales (Clowe et al. 2004; Angus et al. 2007; Planck 2013). Hence, CDM is usually preferred over MOND, with efforts ongoing to reconcile CDM with observations on \( \lesssim \) Mpc scales (e.g., Swaters et al. 2003; Frenk & White 2012; Strigari 2013).

While CDM and MOND are often viewed as competing theories, it is notable that they actually complement each other, one being phenomenologically successful on length scales where the other is less so. This complementarity motivated three of us (Ho, Minic, and Ng) to combine the salient successful features of both CDM and MOND into a unified scheme, MONDian dark matter (MDM; Ho et al. 2010, 2011, 2012), which is a dark matter model that behaves like CDM at cluster and cosmological scales while reproducing MOND at galactic scales. This also provides an astrophysically motivated restriction on the nature of the dark matter quantum.

There has been an attempt (Kaplinghat & Turner 2002) to theoretically explain the Milgrom (MOND) scaling from the standard CDM scenario. However, such an explanation has turned out to be quite complicated (Kaplinghat & Turner 2002). A more astrophysical attempt, which required some fine-tuning, was conducted in van den Bosch & Dalcanton (2001). Other approaches that try to unite MOND’s successes at galaxy scales to cosmology include Blanchet & Le Tiec (2009) and Klinkhamer & Kopp (2011). In Blanchet & Le Tiec (2009), the phenomenology of MOND is explained by the concept of gravitational polarization. In Klinkhamer & Kopp (2011), the MOND-type acceleration is explained by introducing a fundamental minimum temperature. Distinct from the existing approaches, the concept of MDM realizes a deep duality\(^9\) between MOND and dark matter. For MDM, the appearance of Milgrom’s scaling is simple, but it has profound consequences on the properties of dark matter. Our approach differs from these papers in the crucial fact that it assumes an actual source of dark matter, which, however, is not of a traditional particle type (i.e., it is not described by a local effective quantum field theory). These other approaches to which our approach could be compared do not have this central feature, and they operate with the assumption which amounts to an effective change of either the gravitational equations of motion, or the inertial properties.

In this paper, we provide the first observational test of MDM by comparing predicted rotation curves to those observed for a sample of spiral galaxies. The remainder of the paper is by comparing predicted rotation curves to those observed for a sample of spiral galaxies. The remainder of the paper is

\[^9\] See the last paragraph in Appendix A, right after Equation (A14).

To rewrite MDM in a form resembling MOND would belie the entropic origin of MDM. However, as shown below, we can rewrite MOND as having dark matter and no modification of gravity. This is akin to MDM in a universe where \( A \) vanishes, and allows us to directly compare MOND and MDM. We would also like to compare the CDM mass profiles with the MDM mass profiles on galactic scales.

In this section we will discuss the MDM mass profile and show how it can accommodate Milgrom’s scaling found in a context apparently completely different than that of CDM, viz., the approach of MOND. We assume the dark matter is spherically distributed about the ordinary matter of mass \( M \). Galactic disks would presumably form in a halo of MDM similar to the way they form in simulations using CDM. Investigation of the actual shape of MDM halos is a topic for future works. In the following, the radial dependence of the baryonic mass is implicit unless otherwise stated. In the next section, we will review the CDM mass profiles and then compare the CDM results to the MDM mass profile on the galactic scales.

A dark matter model that naturally reproduces MOND can be constructed in the following way. We take the equation of motion of MOND without dark matter and associate the interpolating function \( \mu(a/a_c) \) with the force term:

\[
\frac{1}{\mu(a/a_c)} F = \frac{1}{\mu(a/a_c)} \left( \frac{G m M}{r^2} \right) = ma. \tag{5}
\]

The usual equation of motion with ordinary matter \( M \) and dark matter \( M'(r) \), enclosed within a sphere of radius \( r \) around \( M \), is

\[
\frac{G m (M + M'(r))}{r^2} = ma, \tag{6}
\]

so both equations will lead to the same prediction for \( a(r) = v^2(r)/r \) if we have an integrated dark matter profile such that

\[
\frac{M'(r)}{M} = \frac{1}{\mu(a(r)/a_c)} - 1, \tag{7}
\]

from which we can infer the dark matter density profile assuming a spherically symmetric distribution:

\[
\rho'(r) = \frac{1}{4\pi r^2} \frac{d}{dr} M'(r). \tag{8}
\]

The required dark matter profile \( \rho'(r) \) can thus be reverse engineered from the required acceleration profile \( a(r) \).

Thus, we can interpret Equation (5) as a modification of inertia or as Newtonian gravity with an additional source term, the dark matter mass \( M' \). This duality was noted in Ho et al. (2010) for MDM, and we show here it extends to (non-relativistic) MOND. Whether such a dark matter profile can be realized dynamically will depend on the detailed nature of the MDM quanta and their interactions with ordinary matter. We have presented several ideas on how this may be arranged in previous publications (Ho et al. 2010, 2011, 2012), but such an endeavor would be pointless if the predicted dark matter profile did not match observations. Thus, in this paper we fit our MDM model to actual galactic data, in the hopes that the model’s predictions can be checked against data from experiments such as Fermi-LAT (Fermi-LAT 2012). If Fermi-LAT is able to map out the dark matter profile from gamma ray observations, we will be

2. THEORETICAL CONSTRUCTS

MDM is a new form of dark matter, and while the equations governing MDM (Equation (A9)) can be mathematically rewritten in a form that is essentially MOND with a particular interpolating function, it is not physically sensible to do so. The form of MDM is rooted in entropic gravity (see Appendix A).
able to compare the observed profile to that predicted by the MDM model.\textsuperscript{10}

The form of the dark matter profile $\rho'(r)$ that reproduces MOND will of course depend on the choice of interpolating function $\mu(a/a_c)$. For instance, if we choose

\begin{equation}
\mu(x) = \frac{1}{x} \left( \sqrt{\frac{1}{4} + x^2} - \frac{1}{2} \right), \quad (9)
\end{equation}

for a point like mass $M$ at the origin MOND will predict

\begin{equation}
v^2(r) = ra(r) = ra_N \sqrt{1 + \frac{a_c}{a_N}} = v_{\infty}^2 \sqrt{1 + \left( \frac{r}{r_c} \right)^2}, \quad (10)
\end{equation}

where $v_{\infty}^2 = \sqrt{a_c GM}$, $r_c = \sqrt{GM/a_c}$, and the corresponding dual dark matter profile will be

\begin{equation}
\frac{M'(r)}{M} = \frac{a_c}{a_N} - 1 = \sqrt{1 + \frac{a_c}{a_N}} - 1 = \sqrt{1 + \left( \frac{r}{r_c} \right)^2} - 1, \quad (11)
\end{equation}

or equivalently

\begin{equation}
\rho'(r) = \frac{M}{4\pi r_c^3} \frac{1}{(r/r_c) \sqrt{1 + (r/r_c)^2}}. \quad (12)
\end{equation}

Alternatively, if we choose the so-called “simple” interpolating function (Famaey & McGaugh 2012)

\begin{equation}
\mu(x) = \frac{x}{1 + x}, \quad (13)
\end{equation}

MOND predicts

\begin{equation}
v^2(r) = ra(r) = ra_N \frac{1 + \sqrt{1 + 4a_c/a_N}}{2}
= v_{\infty}^2 \frac{1 + \sqrt{1 + 4(r/r_c)^2}}{2(r/r_c)^2}. \quad (14)
\end{equation}

\begin{equation}
\frac{M'(r)}{M} = f(r), \quad (17)
\end{equation}

with $f(r)$ given as the solution to

\begin{equation}
\sqrt{\frac{1}{\pi f}} + 1 - 1 = \frac{1}{A} (1 + f), \quad (18)
\end{equation}

with

\begin{equation}
A = \frac{2\pi a_c}{a_N} = \frac{2\pi a_c}{GM} r_c^2 = \frac{2\pi r^2}{r_c^2}. \quad (19)
\end{equation}

The motivation for this equation is explained in Appendix A. Equation (18) is a cubic equation in $f$, and thus has three solutions for each value of $A \geq 0$. Two of these solutions are always negative and converge to $-1$ in the limit $A \rightarrow 0$. The third solution is always positive and vanishes as $A^2/\pi$ as $A \rightarrow 0$. This third solution is the one we need. Thus, for $r \ll r_c$, the MDM model yields $\rho'(r) \sim (M/r_c^3)r$, quite different from what the above two interpolating function choices give. For $A \gg 1$ (i.e., $r \gg r_c$), however, the cubic equation in $f$ becomes a quadratic equation, yielding $f \rightarrow \sqrt{A}/2\pi = r/r_c$ and hence $M' \rightarrow Mr/r_c$. (Ho et al. 2011), i.e., $\rho'(r) \approx (M/4\pi r_c^2)/r^2$, the same as what the above two interpolating functions gave. This difference in behavior for the three different cases is shown in Figure 1 corresponding to a point baryonic mass $M$ at the origin.

As an example, we consider the Milky Way. We estimate the mass interior to the solar orbit as $10^{11} M_\odot$ (e.g., Sommer-Larsen 2006, and references therein). The dark matter density

\begin{itemize}
\item[$\text{10}$] We note that the signals from Fermi-LAT could also have a regular astrophysical origin such as pulsars (Profumo 2014).
\end{itemize}
profiles diverge around $r/r_c = 0.1$. With $r_c = \sqrt{GM/\alpha}$, these values imply that differences in dark matter distributions between MDM and Equations (12) and (16) will occur at radii $r < 1$ kpc for a Milky-Way-sized disk.

The MDM prediction for the rotation curves is then

$$v^2(r) = \frac{G(M + M'(r))}{r^2} \left( 1 + \frac{M'(r)}{M} \right),$$

where $a_N = GM/r^2$ is the Newtonian acceleration due to ordinary matter only. The baryonic mass $M$ consists of contributions from the stellar disk and the interstellar gas:

$$M = M_{\text{disk}} + M_{\text{gas}}.$$  \hfill (21)

The mass of the interstellar gas can be inferred from 21 cm observations of HI. The mass of the stellar disk must be inferred indirectly from its luminosity $L_{\text{disk}}$.

$$M_{\text{disk}} = \alpha L_{\text{disk}}.$$  \hfill (22)

which introduces an extra free parameter $\alpha$, the stellar mass-to-light ratio ($M/L$), into the fit.

### 3. DATA FITTING

#### 3.1. Sample Selection

In order to test MDM with galactic rotation curves, we fit computed rotation curves to the sample of Ursa Major galaxies given in Sanders & Verheijen (1998). Of the 79 members of the Ursa major cluster identified by Tully et al. (1996), 62 are brighter than $M_B \approx -16.5$. These form a complete optically selected sample and have been imaged in the B, R, I, and $K'$ bands (Tully et al. 1996). Sanders & Verheijen (1998) identify 30 galaxies from this sample that have appropriate LOS inclination angles for kinematic studies while being neither poor in neutral hydrogen nor strongly interacting. These galaxies are listed in Table 1. The sample contains both high surface brightness (HSB) and low surface brightness (LSB) galaxies. LSBs are particularly useful for testing MOND theories of gravity since the acceleration is below $a_c$ at all radii (e.g., Swaters et al. 2010).

In Table 1, LSB galaxies are denoted with an “L” beside the galaxy name. Of the 30 galaxies in our sample, 7 have velocity fields with significant deviation from circular motion (Verheijen 1997) and are marked with an asterisk.

Using the $K'$-band surface photometry of Tully et al. (1996) and the 21 cm line data from Verheijen (1997), Sanders & Verheijen (1998) compared rotation curves predicted by MOND to those observed in the sample listed in Table 1. They used...
a tilted rings fitting procedure (Begeman 1987) to estimate rotation curves from velocity measurements assuming a thin, axisymmetric disk and an adopted distance of 15.5 Mpc for each galaxy in the sample. The dispersion of up to a few megaparsecs in actual galactic distances introduces some error in the data fitting. However, we expect the errors in velocity to be less than about 15 km s$^{-1}$ (e.g., see Figure 2 of Bottema et al. 2002), which is within error for most of the data. Assuming $M/L$ is constant with radius for a given galaxy but allowed to vary between galaxies, they find MOND is in general agreement with the observed rotation curves. After removing the seven galaxies with disturbed velocity fields and one outlier (NGC 3992), they determine a mean $M/L$ ratio in the near-infrared of 0.92 ± 0.25.

3.2. Model Comparisons

In this section, we discuss fits to galactic rotation curves for our sample using CDM, MOND, and MDM. The data fits are shown in Figures 2 and 3, and dark matter density profiles for CDM and MDM are shown in Figures 4 and 5. The physical mechanisms that give rise to the galactic rotation curves for
Each model differ. In the CDM paradigm, accelerations are determined by general relativity and the addition of massive particles that interact only gravitationally, dark matter. In (non-relativistic) MOND, inertia is modified for accelerations near or below the critical acceleration \( (a_c) \), and no non-baryonic particles are introduced. In MDM, the critical acceleration is introduced through the cosmological constant \( \Lambda \), and the dark matter quanta give rise to the observed galactic rotation curves. In essence, CDM and MDM introduce dark matter quanta to explain (nearly) flat galactic rotation curves, while MOND modifies inertia.

The rotation curves predicted by MDM are given by Equation (20). We fit these to the observed rotation curves as determined in Sanders & Verheijen (1998) using a least-squares fitting routine. As in Sanders & Verheijen (1998), \( \alpha = M/L \), which is our only fitting parameter for MDM and MOND, is assumed constant for a given galaxy but allowed to vary between galaxies. Newtonian rotation curves for the stellar disk and the interstellar gas given in Sanders & Verheijen (1998) are used to determine the baryonic mass \( M(\alpha, r) \). We use the value of the critical acceleration determined in Begeman et al. (1991); \( a_c = 1.2 \times 10^{-8} \text{ cm s}^{-1} \). Rotation curves predicted by MDM for each galaxy are shown in Figures 2 and 3 for HSB galaxies and LSB galaxies, respectively. In these figures, observed rotation curves are depicted as filled circles with error bars, and the dotted and dash-dotted lines show the stellar and interstellar gas rotation curves, respectively. The dashed lines are rotation curves predicted by the standard cold dark
mature (CDM) paradigm discussed below. The $M/L$ ratios for MDM, MOND, and CDM predicted by our data fits are given in Table 1. Uncertainties in fitting parameters for each galaxy are determined by randomizing the data within the errors, obtaining fits for 100 randomized data sets, and determining the standard deviation for each parameter. For MOND, we use the interpolation function in Equation (13). The rotation curves for MOND are not shown in the figures since they are virtually indistinguishable from the curves predicted by MDM. We note that different interpolating functions for MOND yield different $M/L$ ratios, but the fits to data are very similar. For comparison, Sanders & Verheijen (1998) present rotation curve fits and $M/L$ ratios using the first interpolating function in Equation (4) with $n = 2$.

Shown in Figures 4 and 5, are dark matter density profiles predicted by MDM (solid lines) and CDM (dashed lines) for HSB and LSB galaxies, respectively. The MDM density is given by

$$\rho'(r) = \left( \frac{a_c}{r} \right)^2 \frac{d}{dr} \left( \frac{M}{a^2} \right).$$  (23)

For the CDM fits, we use the Navarro et al. (1996) density profile:

$$\rho'(r) = \frac{\rho_0}{r_c \left( 1 + \frac{r}{r_c} \right)^2},$$  (24)
in which

\[ r_s = \frac{r_{200}}{c}. \]  

(25)

Here, \( r_{200} \) designates the “edge” of the halo, within which objects are assumed to be virialized, usually taken to be the boundary at which the halo density exceeds 200 times that of the background (Navarro et al. 1996). The parameter \( c \) is a dimensionless number that indicates how centrally concentrated the halo is. The velocity curves are then determined by

\[ v(r) = v_{200} \sqrt{\frac{\ln(1 + cx) - cx/(1 + cx)}{x [\ln(1 + c) - c/(1 + c)]}} \]  

(26)

where \( v_{200} \) is the Newtonian velocity at \( r_{200} \) (Navarro et al. 1996). Equation (26) is fit to the data with \( c, v_{200} \), and \( \alpha = M/L(\geq 0) \) as free parameters. Values of the fitting parameters for each galaxy are given in Table 1. Rotation curves and density profiles for CDM are shown as dashed lines in the figures. For several galaxies, CDM fits predict very small \( M/L \) ratios (formally approaching zero). In nearly a third of the galaxies in our sample, the estimated virial mass of the dark matter halo is too large. For NGC 4389, \( v_{200} \approx 1000 \text{ km s}^{-1} \), leading to a virial mass of \( \approx 5 \times 10^{14} \text{ M}_\odot \). Since rotational velocities in our sample are less than 300 \text{ km s}^{-1}, we expect virial masses \( \sim 10^{12} \text{ M}_\odot \) (Navarro et al. 1996). Furthermore, we note that many of the fits require \( c, v_{200} \) pairs that do not agree with the \( c - v_{200} \) relation
shown in Navarro et al. (1996; see also de Blok & Bosma 2002). The relation between $c$ and $v_{200}$ depends on the cosmology used, and a study by McGaugh et al. (2007) found that dark matter concentrations predicted by the Navarro–Frenk–White profile for a range of measured cosmological parameters disagree with observations over a large range of rotation velocities (see Figure 10 of that paper).

4. SUMMARY AND DISCUSSION

In this paper, we tested the inertial properties of MONDian dark matter (Ho et al. 2010, 2011, 2012) by fitting rotation curves in a sample of 30 local galaxies. We compared rotation curves derived from MDM, MOND, and CDM. All three models fit the data well. While the fits for MDM are indistinguishable from the fits for MOND over the range of observed radii, these models are distinguishable from rotation curves at very small radii, as shown in Figure 1. Both MDM and MOND require a single fitting parameter, the mass-to-luminosity ratio $M/L$. We find that $M/L$ is very similar for both models. We also compared the dark matter profiles for MDM and CDM for each of the galaxies. The profiles differ at small $r$ in the range of observed radii but are quite similar at large $r$. Our results show that MDM is a viable model at the galactic scale. We will study constraints from galaxy clusters and the CMB in forthcoming papers.

The interpretation of the above data is unique from the point of view of MDM. On one hand, we have one parameter fits to
the galactic rotation curves that cannot be distinguished from the MOND fits. However, the MDM rotation curves arise from the distribution of dark matter, unlike those in MOND, which does not include dark matter, but modifies inertia instead. The force given in Equation (A9) arising from our MDM mass profile (Equation (A8)) can also be interpreted as a modification of inertia (Ho et al. 2010). However, consistency with the holographic formulation of gravity requires the dark matter interpretation (Ho et al. 2010). Furthermore, the success of CDM at large scales (e.g., galaxy clusters and the CMB) suggests that the dark matter interpretation is a better choice for explaining astronomical data at all scales.

On the other hand, our dark matter candidate is not the standard CDM candidate. An essential difference between the dark matter in MDM and the various proposals for the CDM particle is that, while the latter presumably obeys the ordinary statistics (i.e., either Bose or Fermi statistics), the former has been proposed (Ho et al. 2012) to obey the infinite statistics (Doplicher et al. 1971, 1974; Govorkov 1983; Greenberg 1990), also known as the quantum Boltzmann statistics. This is the only known consistent statistics in greater than two space dimensions without the Gibbs factor, as described by the Cuntz algebra. If MDM quanta obey infinite statistics (in some sense a middle quantum statistics between the usual Bose–Einstein and Fermi–Dirac statistics),
they should not be described by a local quantum field theory of particles.

Besides obeying different statistics, MDM has some unusual inertial properties (see Equation (A9)). This provides a natural explanation for the measured underdensity of dark matter in the solar system (e.g., Moni Bidin et al. 2011; but see Bovy & Tremaine 2012 who find a density consistent with standard expectations). The so-called “External Field Effect” (e.g., Milgrom 1983; Blanchet & Novak 2011) is built into the inertial properties of MDM, so we do not expect to see dark matter effects in the Solar system.

We thank the referee for many useful comments that have greatly improved the presentation of the material in this paper. We also thank Philip Mannheim and Louie Strigari for illuminating discussions. APPENDIX A

ENTROPIC GRAVITY AND MONDian DARK MATTER

Our original proposal (Ho et al. 2010) is based on the intriguing relationship between gravity and thermodynamics.
(Verlinde 2011; Jacobson 1995; Padmanabhan 2010; Smolin 2010). Inspired by this relationship, Verlinde (Verlinde 2011) recently showed that the canonical Newton’s laws could be derived from the point of view of holography (Hawking 1975; ’t Hooft 1993; Susskind 1995; Aharony et al. 2000). Verlinde invoked the first law of thermodynamics and proposed the concept of entropic force

\[ F_{\text{entropic}} = T \frac{\Delta S}{\Delta x}, \]  

(A1)

where \( \Delta x \) is an infinitesimal spatial displacement of a particle with mass \( m \) from the heat bath with temperature \( T \). Incorporating Bekenstein’s original arguments for the entropy \( S \) of black holes (Bekenstein 1973), Verlinde demands that \( \Delta S = 2\pi k_B (m c/\hbar) \Delta x \). Together with the Unruh temperature formula, \( k_B T = \hbar a/(2\pi c) \), associated with a uniformly accelerating (Rindler) observer (Unruh 1976; Davies 1975), this leads to Newton’s second law \( F_{\text{entropic}} = T \nabla_x S = ma \).

To determine the expression for \( a \), Verlinde considered an imaginary quasi-local (spherical) holographic screen of area \( A = 4\pi r^2 \) with temperature \( T \). He then assumed the equipartition of energy \( E = (1/2) N k_B T \) with \( N \) being the total number of degrees of freedom (bits) on the screen given by \( N = A c^3/(G\hbar) \). Using the energy relation \( E = M c^2 \), Verlinde obtained \( 2\pi k_B T = GM/r^2 \), and with the help of the Unruh temperature formula, recovered exactly the non-relativistic Newton’s law of gravity, namely \( a = GM/r^2 \).

Since we live in an accelerating universe (in accordance with the ΛCDM model), it is well-motivated to generalize Verlinde’s
proposal to de Sitter (dS) space. This was precisely the starting point of our derivation in Ho et al. (2010). For convenience, we set $\bar{h} = c = 1$ henceforth. First of all, the Unruh temperature, as measured by an inertial observer in de Sitter space with a positive cosmological constant $\Lambda$, is given by $T_{dS} = a_0/(2\pi k_B)$ where $a_0 = \sqrt{\Lambda/3}$ (Hawking 1975). Note that $\Lambda$ is related to the Hubble scale $H$ through $\Lambda \sim 3 H^2$. Numerically, it turns out that $a_0$ is related to Milgrom’s critical acceleration as

$$a_0 \approx 2\pi a_c,$$  \hspace{1cm} (A2)

and so we set $a_c = a_0/(2\pi)$ for simplicity. The corresponding Unruh temperature as measured by a non-inertial observer with acceleration $a$ is (Deser & Levin 1997; Jacobson 1998)

$$T_{dS+a} = \frac{1}{2\pi k_B} \sqrt{a^2 + a_0^2}. \hspace{1cm} (A3)$$

Consequently, we can define the net temperature as measured by a non-inertial observer (due to some matter sources that cause the acceleration $a$) to be

$$\tilde{T} \equiv T_{dS+a} - T_{dS} = \frac{1}{2\pi k_B} \left(\sqrt{a^2 + a_0^2} - a_0\right). \hspace{1cm} (A4)$$

Milgrom has suggested that the difference between the Unruh temperatures as measured by non-inertial and inertial observers in de Sitter space, namely $2\pi k_B \Delta T = \sqrt{a^2 + a_0^2} - a_0$, might...
give the correct behaviors of the interpolating function for the Newtonian acceleration and his modified acceleration at very small accelerations (Milgrom 1999). As we will see, adopting Verlinde’s entropic force point of view allows us to justify his intuition naturally.

Following Verlinde’s entropic approach, the force acting on the test mass $m$ with acceleration $a$ in de Sitter space is given by

$$F_{\text{entropic}} = \tilde{T} \nabla_x S = m \left( \sqrt{a^2 + a_0^2} - a_0 \right). \quad (A5)$$

In order to derive an explicit form for $a$, we apply Verlinde’s holographic approach by invoking an imaginary holographic screen of radius $r$. Then, using Equation (A4), we can write

$$\sqrt{a^2 + a_0^2} - a_0 = 2\pi k_B \tilde{T} = 2\pi k_B \left( \frac{2\tilde{E}}{N k_B} \right)$$

$$= 4\pi \left( \frac{\tilde{M}}{A/G} \right) = \frac{G\tilde{M}}{r^2}. \quad (A6)$$

where $\tilde{M}$ represents the total mass enclosed within the volume $V = 4\pi r^3/3$.

A necessary step is to determine $\tilde{M}$. In Ho et al. (2010), we proposed that $\tilde{M} = M + M'$, where $M'$ is some unknown mass in addition to the ordinary mass $M$ enclosed within the volume.
V = 4πr³/3. We interpret M' to be the total dark matter mass within the volume. We thus have

\[ \sqrt{a^2 + a_0^2} - a_0 = \frac{G(M + M')}{r^2}. \]  

(A7)

We also proposed a profile for the dark matter mass:11

\[ M' = \frac{1}{\pi} \left( \frac{a_0}{a} \right)^2 M. \]  

(A8)

As a result, using Equations (A7) and (A8), the entropic force is given by

\[ F_{\text{entropic}} = ma \left( \sqrt{a^2 + a_0^2} - a_0 \right) = ma_N \left[ 1 + \frac{1}{\pi} \left( \frac{a_0}{a} \right)^2 \right]. \]  

(A9)

By solving the above cubic equation, we can obtain a general solution for a as a function of r. One could also find a general solution of (a₀/a)² and substitute it into Equation (A8) to obtain M' as a function of r. We have used Equation (A9) to determine galactic rotation curves in Section 3. Before doing so, it is informative to state some general theoretical expectations of galactic rotation curves in Section 3. Before doing so, it is informative to state some general theoretical expectations of our approach.

For a ≫ a₀, we have F_{\text{entropic}} \approx ma ≈ ma_N, and hence a ≈ a_N = GM/r², which is the usual Newtonian acceleration without dark matter. For a ≪ a₀, we have F_{\text{entropic}} ≈ ma²/(2a₀) ≈ ma_N (1/π)(a₀/a)². Solving for a, we get

\[ a = (2a_N a_0^3/\pi)^{1/4}, \quad \text{for } a ≪ a_0. \]  

(A10)

In order to fit the galactic rotation curves well, Milgrom requires the force in the regime a ≪ a₀ to be

\[ F_{\text{Milgrom}} = ma_N a_0 = \sqrt{a_N a_0^3/\pi}. \]  

(A11)

But we recall that for a ≪ a₀, our scheme predicts F_{\text{entropic}} ≈ m(a²/2a₀). Substituting a = (2a_N a₀³/π)¹/⁴ into this expression leads to

\[ F_{\text{entropic}} \approx \frac{ma^2}{2a_0} = m \sqrt{a_N a_0^3/2\pi} = F_{\text{Milgrom}}. \]  

(A12)

In conclusion, if we take the total mass of dark matter enclosed by the volume V = 4πr³/3 to be given by Equation (A8) we can actually derive MOND, even though we have a non-trivial mass profile.

To study the rotation curves, we note that our scheme requires F_{\text{centripetal}} = ma²/(2a₀) for a ≪ a₀. The terminal velocity v is then determined from m v²/r = F_{\text{centripetal}} = ma²/(2a₀) with a given by Equation (A10). Note that in this region, the acceleration a is not related to the velocity v in the usual fashion as a = v²/r. That is, a is not the time derivative of v. This leads to

\[ v = \left( \frac{GM a_0}{2\pi} \right)^{1/4} = v_\infty M^{1/4}. \]  

(A13)

Therefore, we predict flat rotation curves and the Tully–Fisher relation.

\[ M'/M = [\lambda(a_0/a) + (1/\pi)(a_0/a)]^2, \]  

where \( \lambda \) is a constant, is a more general expression that gives the correct asymptotic behavior.

---

**Figure 6.** Comparison of the effective interpolating functions \( \mu(x) \) for two MOND models and MDM.

(A color version of this figure is available in the online journal.)

In retrospect, we see that with Equation (A8), we can write the entropic force in the following two apparently different forms:

\[ \frac{G(M + M')m}{r^2} = \frac{GMm}{r^2} \left[ 1 + \frac{1}{\pi} \left( \frac{a_0}{a} \right)^2 \right]. \]  

(A14)

Interestingly, the LHS of Equation (A14) implies that there is no modification of gravity but there is dark matter, while the RHS implies that there is no dark matter but that there is modification of gravity. Therefore, according to our scheme, dark matter and modification of gravity could just be two different manifestations of the same physics at the galactic scale. We interpret this as a CDM-MOND duality at the galactic scale—i.e., dark matter with the profile given by Equation (A8) could behave as if there existed a modification of gravity but no dark matter. We thus call our proposal “MONDian dark matter.”

**APPENDIX B**

**COMPARISON OF INTERPOLATING FUNCTIONS FOR MOND AND MDM**

As we have argued in the main text, with \( x = a_{\text{obs}}/a_c \), where \( a_{\text{obs}} \) is the observed acceleration, the predictions of MOND with interpolating function \( \mu(x) \) that enters into \( F = m a_{\text{obs}} \mu(x) \) can be reproduced exactly using the dark matter profile \( M'(r) \) calculated from Equation (7). Conversely, we can take any dark matter profile and invert Equation (7) to calculate the corresponding interpolating function in MOND. For MDM, the dark matter profile is determined from Equation (18), where \( f(r) = M'(r)/M \) as defined in Equation (17). The corresponding interpolating function is

\[ \mu_{\text{MDM}}(a/a_c) = \frac{1}{1 + f(r)}. \]  

(B1)

Using the dark matter profile given in Equation (A8), we obtain

\[ \mu_{\text{MDM}}(a/a_c) = \left[ 1 + 4\pi \left( \frac{a_c}{a} \right)^2 \right]^{-1}, \]  

(B2)

where we have used \( a_0 = 2\pi a_c \). As mentioned in Appendix A, the acceleration parameter a in the MDM mass profile is not the observed acceleration. In order to properly compare the interpolating functions, we write Equation (B2) in terms
of the observed acceleration. From Equations (20) and (A7), we have
\[ a_{\text{obs}} = \frac{v^2}{r} = \sqrt{a^2 + a_0^2} - a_0, \]
which implies that \[ a^2 = a_{\text{obs}}^2 + 2a_0a_{\text{obs}}. \] Substituting this expression for \( a \) into Equation (B2) yields
\[ \mu_{\text{MDM}}(x) = \left( 1 + \frac{4\pi}{x^2 + 4\pi x} \right)^{-1}. \quad (B3) \]
This function is plotted in Figure 6 along with the interpolating functions for the two MOND cases discussed in the main text. Just as in MOND, \( \mu(x) \approx 1 \) in the range \( x \gg 1 \), and \( \mu(x) \approx x \) in the range \( x \ll 1 \) for MDM, as expected.
