(Dated: March 24, 2014)

We quantify the non-adiabatic contributions to the vibronic sidebands of equilibrium and explicitly time-resolved non-equilibrium photoelectron spectra for a vibronic model system of Trans-Polyacetylene. Using exact diagonalization, we directly evaluate the sum-over-states expressions for the linear-response photocurrent. We show that spurious peaks appear in the Born-Oppenheimer approximation for the vibronic spectral function, which are not present in the exact spectral function of the system. The effect can be traced back to the factorized nature of the Born-Oppenheimer initial and final photoemission states and also persists when either only initial, or final states are replaced by correlated vibronic states. Only when correlated initial and final vibronic states are taken into account, the spurious spectral weights of the Born-Oppenheimer approximation are suppressed. In the non-equilibrium case, we illustrate for an initial Franck-Condon excitation and an explicit pump-pulse excitation how the vibronic wavepacket motion of the system can be traced in the time-resolved photoelectron spectra as function of the pump-probe delay.

I. INTRODUCTION

Photoelectron spectroscopy is a well-established experimental method to probe the structure of atoms, molecules and solids [1,2]. In comparison to other spectroscopic methods such as optical-absorption spectroscopy, photoelectron spectroscopy is based on non-neutral transitions between many-body states: initial and final states, which have vanishing matrix elements for charge-neutral transitions, might have non-vanishing matrix elements for non-neutral transitions. Hence, photoelectron spectroscopy allows to observe dipole or quadrupole forbidden transitions, which would otherwise not be accessible in optical-absorption spectroscopy.

With the appearance of femtosecond laser pulses [3], which lead to the Nobel prize in chemistry awarded to A. H. Zewail, the field of time-resolved photoelectron spectroscopy has seen tremendous developments in recent years. Femtosecond laser pulses are routinely used to probe a large variety of intra-molecular effects. By combining short pulses with the new possibilities of time-resolved photoelectron spectroscopy, experimentalists are now able to realize femtosecond pump-probe photoelectron spectroscopy: Here, two independent laser pulses are employed to eject photoelectrons. The first pulse is used to excite the sample, followed by a second laser pulse after a finite delay time. The second laser pulse photoexcites the system to emit a photoelectron. The energy and angle resolved distribution of photoelectrons can then be detected by the measurement apparatus. Tuning the delay time allows to monitor dynamical processes in the system. These novel techniques for time-resolved pump-probe photoelectron spectroscopy have already been used to experimentally study and characterize ultrafast photochemical dynamic processes in liquid jets [3], to follow ultrafast electronic relaxation, hydrogen-bond-formation and dissociation dynamics [5], to probe unimolecular and bimolecular reactions in real-time [6], or to investigate multidimensional time-resolved dynamics near conical intersections [7], all on a femtosecond timescale, to mention a few.

Driven by such novel experimental possibilities, there is an ongoing demand to extend and refine existing theory to allow for a first-principles description of time-dependent pump-probe photoelectron experiments and to treat the electronic and ionic responses on an equal footing. Along these lines, first steps have already been taken, which focus on photoelectron spectroscopy in real-time. On the level of time-dependent density functional theory (TDDFT), the first pioneering work to describe photoelectron spectra was based on the momentum distribution of the Kohn-Sham orbitals recorded at a reference point far from the system [8]. More recently a mask technique has been developed [9] and extended to attosecond pump-probe spectroscopy [10]. This approach captures the time-dependent case intrinsically and allows e.g. to directly simulate the photoemission process for given delay times and shapes of pump and probe pulses. However, in this approach, the description is so far limited to classical nuclei. As a result, the vibrational sidebands in time-resolved photoelectron spectra and photoabsorption are not fully captured. Other approaches in similar direction have been realized combining TDDFT and ab-initio molecular dynamics [11], or by using an reduced density matrix description, which also relies on the Born-Oppenheimer approximation [12].

On the other hand, approaches based on the Born-Oppenheimer approximation allow for a detailed analysis of angular resolved photoelectron spectra and for
a reconstruction of molecular orbital densities directly from the spectra [13, 14]. Standard quantum chemical approaches for photoelectron spectroscopy as e.g. the double-harmonic approximation (DHA) [15] allow to capture vibrational sidebands through Franck-Condon factors [16]. Here, the vibronic nature of the involved initial and final states is taken into account within a harmonic approximation of the corresponding Born-Oppenheimer surfaces. Although the vibrational sidebands of photoelectron spectra can be approximately captured in the DHA, such an approach lacks the possibility to describe time-resolved pump-probe experiments explicitly. In this work, we attempt to compare and validate existing computational tools for photoelectron spectroscopy of vibronically coupled systems. We present an approach for time-resolved photoelectron spectra, which explicitly includes the vibronic nature of the involved states and allows to follow the photoemission process in real-time. For a realistic model system of small Trans-Polyacetylene oligomer chains, we investigate time-resolved photoelectron spectra and compare to approaches such as the double-harmonic approximation. Our study is based on exact diagonalization of vibronic Hamiltonians and real-time propagations of the time-dependent Schrödinger equation in the combined electronic and vibrational Fock space of the system. This procedure gives us access to the exact correlated electron-nuclear eigenstates and time-evolved states of the system and enables us to test different levels of approximations against our correlated reference calculations. In particular, we focus on non-adiabatic effects beyond the Born-Oppenheimer approximation.

The paper is organized as follows: In section II, we introduce our employed model for Trans-Polyacetylene oligomers and provide a comparison of the Born-Oppenheimer states of the model to the exact correlated energy eigenstates of the Hamiltonian. Different levels of approximations for the photocurrent are introduced in section III and the relation of photoelectron spectra to the one-body spectral function is discussed. In addition, we focus on time-resolved pump-probe photoemission spectroscopy. In section IV, we apply the theoretical tools of section III to our model system for Trans-Polyacetylene and discuss spurious peaks, which appear in the Born-Oppenheimer approximation for the spectra. To illustrate our approach for explicitly time-resolved spectroscopy, we numerically simulate two pump-probe photoelectron experiments: as first example, we consider a Frank-Condon transition as excitation mechanism and in a second example, we explicitly propagate the system in the presence of a pump pulse. In both cases, photoelectron spectra are recorded and we highlight the underlying nuclear wavepacket motion and the differences to the equilibrium spectra. Finally, in section V we summarize our findings and give an outlook for future work.

FIG. 1. (a) Chemical structure of Trans-Polyacetylene. (b) Model system for SSH-chain: four Trans-Polyacetylene oligomers with clamped ends. The coordinates $u_j$ describe the shift of the oligomers with respect to a perfectly periodic arrangement of lattice spacing $a$. Both, in the exact Born-Oppenheimer and in the exact correlated ground state, the chain favors a dimerized arrangement. Also shown are the optical and acoustic phonon modes of the chain.

II. MODEL SYSTEM

A. Su-Schrieffer-Heeger-Hamiltonian and exact eigenvalues and eigenfunctions

In this section, we briefly review the Su-Schrieffer-Heeger (SSH) model [17, 18] for Trans-Polyacetylene (PA) and the exact-diagonalization approach. To model PA oligomer chains (Fig. 1(a)), we employ the SSH Hamiltonian to describe $\pi$-electrons in a polymer chain

$$\hat{H}_{ssh} = \hat{H}_\pi + \hat{H}_{ph} + \hat{H}_{\pi-ph}$$  \hspace{1cm} (1)

$$\hat{H}_\pi = -T \sum_{n,\sigma} \hat{c}_{n+1,\sigma}^\dagger \hat{c}_{n,\sigma} + \hat{c}_{n,\sigma}^\dagger \hat{c}_{n+1,\sigma}$$

$$\hat{H}_{ph} = \sum_n \frac{\hat{p}_n^2}{2M} + \frac{K}{2} (\hat{u}_{n+1} - \hat{u}_n)^2$$

$$\hat{H}_{\pi-ph} = \sum_{n,\sigma} \alpha (\hat{u}_{n+1} - \hat{u}_n) \left( \hat{c}_{n+1,\sigma}^\dagger \hat{c}_{n,\sigma} + \hat{c}_{n,\sigma}^\dagger \hat{c}_{n+1,\sigma} \right).$$

With $\hat{c}_{n,\sigma}^\dagger$ and $\hat{c}_{n,\sigma}$, we denote the usual fermionic creation and annihilation operators, which create or destroy $\pi$-electrons with spin $\sigma$ on site $n$ of the chain. The nuclear subsystem in the Hamiltonian is described by the nuclear displacement operators $\hat{u}_n$, and the nuclear momentum operators $\hat{p}_n$. Expectation values of the operator $\hat{u}_n$ measure the displacement of the nuclear positions of site $n$ with respect to an equidistant arrangement of the oligomers in the chain. The displacement and momentum operators obey the usual bosonic commutation relations, $[\hat{p}_i, \hat{p}_j] = 0$, $[\hat{u}_i, \hat{u}_j] = 0$, $[\hat{u}_i, \hat{p}_j] = i\hbar$. For clarification, we always use the hat symbol $\hat{\cdot}$ to distinguish between quantum mechanical operators and classical variables. Throughout the paper, we use the standard set of
parameters for the SSH-Hamiltonian \[ [18] \]: \( \alpha = 4.1 \text{ eV/Å} \),\n\( T = 2.5 \text{ eV} \), \( K = 21 \text{ eV/Å}^2 \), \( M = 1349.14 \text{ eV/Å}^2 \), which leads to a lattice spacing of \( a = 1.22 \text{ Å} \) in the chain. For this set of parameters, the chain energetically favors a dimerized arrangement of the oligomers in the ground-state, leading to a nonvanishing displacement coordinate \( u \neq 0 \). The dimerization is illustrated in Fig. 1. The SSH Hamiltonian has been used in the literature to describe soliton propagation in conjugated polymers \[ [18] \], or to study coupled electron-nuclear dynamics \[ [19-21] \]. The Hamiltonian in Eq. 1 can be divided into three parts: (1) the electronic Hamiltonian \( H_\pi \), which models electron hopping of \( \pi \)-electrons within a tight binding scheme. (2) The nuclear Hamiltonian \( H_{ph} \) describes all nuclei as a chain of coupled quantum harmonic oscillators, and (3) the interaction part in the Hamiltonian \( H_{\pi-ph} \) takes the coupling of electrons and nuclei up to first-order in the nuclear displacement into account. The electron-phonon coupling \( H_{\pi-ph} \) may be combined with the kinetic term \( H_\pi \) of the \( \pi \) electrons. The hopping parameter \(-T\) is then replaced by \(-T + \alpha (\bar{u}_{n+1} - \bar{u}_n)\). Physically speaking, it is more likely for electrons to hop when two nuclear positions approach each other or conversely the effective hopping parameter is decreased when the nuclei are moving apart.

To get access to all eigenvalues and eigenstates of the system, we employ an exact diagonalization technique \[ [22, 23] \]. In the combined electron-nuclear Fock space, we explicitly construct matrix representations for all operators present in Eq. 1. For the photoelectron spectra, we choose to work in Fock space, since here we have directly access to states with different electron number \( N \). The matrix representations for the electronic creation and annihilation operators are constructed in terms of a Jordan-Wigner transformation \[ [24] \] and the nuclear position and momentum operators are represented on a uniform real-space grid applying an 8th-order finite-difference scheme. In the present work, we use a two-dimensional phonon grid with 35x35 grid points. Hence, the total Fock space containing up to eight electrons has the size \( M_{\text{tot}} = 4^3 \times 35 \times 35 = 313600 \). The four (three) electron Hilbert space has a size of \( M_{\text{max}}^{[4][3]} = 70(56) \times 35 \times 35 = 85750(68600) \) basis functions.

The Hamiltonian in Eq. 1 commutes with the spin operators \( \hat{S}_z, \hat{S}_x \), particle number \( N \), and parity \( P \). By exploiting all these symmetries, we first block-diagonalize the Hamiltonian by ordering basis states according to tuples of eigenvalues of all symmetry operators that commute with the Hamiltonian. All remaining blocks in the Hamiltonian are then diagonalized with a dense eigenvalue solver. In contrast to standard sparse diagonalization approaches for exact diagonalization, this procedure gives us access to the full spectrum of all \( M_{\text{tot}} \) eigenvalues and eigenvectors of the static Schrödinger equation

\[
\hat{H}_{ssh} | \Psi_j^{(N)} \rangle = E_j^{(N)} | \Psi_j^{(N)} \rangle.
\] (2)

Here, the eigenstates \( | \Psi_j^{(N)} \rangle \) and eigenvalues \( E_j^{(N)} \) of the SSH Polyacetylene chain refer to the exact correlated stationary states of the combined system of electrons and nuclei in Fock space. To simplify the following discussion of electron removal, we always indicate the number of electrons explicitly with superscript \( N \).

To solve for the time evolution of arbitrary initial states \( | \Phi^{(N)}(0) \rangle \) in the presence of pump and probe pulses, we explicitly propagate the time-dependent Schrödinger equation

\[
i\hbar \frac{\partial}{\partial t} | \Phi^{(N)}(t) \rangle = \hat{H}_{ssh} | \Phi^{(N)}(t) \rangle,
\] (3)

with a Lanczos propagation scheme \[ [25, 26] \]. In the following, the exact diagonalization of the static Schrödinger equation and the time-evolved states of the correlated system serve as exact reference to test the quality and validity of approximate schemes for photoelectron spectra. Due to the exponential scaling of the Fock space size, the calculation of exact eigenstates and time-evolved wavefunctions is limited to small SSH chains (maximum of four oligomers in the present case). Although the exact numerical solutions are only available for small SSH chains, they serve as valuable reference to test approximate schemes, which then can be employed for larger systems.

of the system. Similar to the case of the exact correlated eigenstates $|\Psi_j^{(N)}\rangle$, we here use for electronic Born-Oppenheimer states $|\phi_j^{(N)}\rangle$ a superscript $(N)$ to distinguish between the Hilbert spaces of different electron numbers. In analogy to the exact diagonalization approach for the full Hamiltonian, as discussed in the previous section, we employ here a dense exact diagonalization scheme for the electronic Born-Oppenheimer Hamiltonian. This procedure gives us access to all exact Born-Oppenheimer surfaces and corresponding Born-Oppenheimer states of the SSH chain. In addition to the exact surfaces, we compute the Hessian of the electronic energies with respect to the displacements. By diagonalizing the Hessian, we arrive at the harmonic approximation for the Born-Oppenheimer surfaces. In Fig. 2 we illustrate the exact potential energy surfaces (dashed lines) along the axis of the optical normal mode of the chain and compare to the harmonic approximation of the surfaces (solid lines). As can be seen from the figure, for the Hamiltonian in Eq. 1 the harmonic approximation is very close to the exact surfaces. Overall, the model behaves rather harmonic and only small anharmonicities are present. We emphasize, that the almost harmonic nature of the exact potential energy surfaces originates from the quadratic interaction term in the phonon Hamiltonian $\hat{H}_{ph}$, since already in the exact model Hamiltonian only quadratic nuclear interaction terms are included. The only source of anharmonicity and non-adiabaticity is the electron-phonon coupling term $\hat{H}_{\pi-ph}$ in Eq. 1, which introduces only small anharmonicities and non-adiabatic couplings between different electronic surfaces. For each fixed set of nuclear coordinates $\{u_n\}$, the electronic eigenstates $|\phi_j^{(N)}(\{u_n\})\rangle$ form a complete set in the many-particle Hilbert space of the electrons. For a given set of nuclear displacement coordinates $\{u_n\}$, we can expand the exact many-body wavefunction in terms of the electronic eigenstates $|\phi_j^{(N)}\rangle$ and the nuclear eigenstates $|\chi_{ij}\rangle$ in terms of the Born-Huang expansion [27]:

$$|\Psi_i^{(N)}(\{u\})\rangle = \sum_{j=1}^{\infty} |\chi_{ij}(\{u\})\rangle \otimes |\phi_j^{(N)}(\{u_n\})\rangle$$

Here, the electronic eigenstates $|\phi_j^{(N)}\rangle$ depend parametrically on the oligomer displacements $\{u_n\}$ and the nuclear eigenstates $|\chi_{ij}\rangle$ are functions of $\{u_n\}$. We solve for the states $|\chi_{ij}(\{u_n\})\rangle$ by diagonalizing the corresponding nuclear Born-Oppenheimer Hamiltonian

$$\hat{H}_{ssh,ph,j} = \hat{H}_{ph,j} + \epsilon_{el,j}(\{u_n\})$$

directly in the real-space representation. In Tab. 1 we compare for the lowest five states and two higher-lying states the exact BO energies $E_{BO}^{exact}$ and the BO energies in harmonic approximation $E_{BO}^{harmonic}$ to the exact

**FIG. 2.** Exact Born-Oppenheimer surfaces and harmonic approximation for a Trans-Polyacetylene oligomer: In the panel on the left-hand side, an one-dimensional cut along the optical axis of the exact potential energy surfaces is shown in dashed lines. The harmonic approximations to the exact BO surfaces are shown in solid lines, where black lines refer to $N-1$ electron states and the red line corresponds to the $N$-electron ground state. In the panel on the right hand side, the corresponding photoelectron spectrum in double-harmonic approximation is shown.

**B. Born-Oppenheimer approximation for the Su-Schrieffer-Heeger-Hamiltonian**

To introduce the required notation for the following sections and to illustrate the exact potential energy surfaces, we briefly discuss the Born-Oppenheimer approximation for the SSH model. By setting the nuclear kinetic energy in Eq. 1 to zero, the nuclear displacements become classical parameters and we arrive at the electronic Born-Oppenheimer Hamiltonian for the SSH chain

$$\hat{H}_{ssh,el} = \hat{H}_{\pi,el} + \hat{H}_{\pi-ph,el}$$

$$\hat{H}_{\pi,el} = -T \sum_{n,\sigma} \hat{c}_{n+1,\sigma}^\dagger \hat{c}_{n,\sigma} + \hat{c}_{n,\sigma}^\dagger \hat{c}_{n+1,\sigma}$$

$$\hat{H}_{\pi-ph,el} = \sum_{n,\sigma} \alpha (u_{n+1} - u_n) \left( \hat{c}_{n+1,\sigma}^\dagger \hat{c}_{n,\sigma} + \hat{c}_{n,\sigma}^\dagger \hat{c}_{n+1,\sigma} \right)$$

with the corresponding eigenvalue problem

$$\hat{H}_{ssh,el}(\{u_n\}) |\phi_j^{(N)}(\{u_n\})\rangle = \epsilon_{el,j}(\{u_n\}) |\phi_j^{(N)}(\{u_n\})\rangle$$

The eigenvalues $\epsilon_{el,j}(\{u_n\})$ as function of the classical coordinates $\{u_n\}$ denote the Born-Oppenheimer surfaces

$$|\Psi_i^{(N)}(\{u\})\rangle = \sum_{j=1}^{\infty} |\chi_{ij}(\{u\})\rangle \otimes |\phi_j^{(N)}(\{u_n\})\rangle$$

$|\Psi_i^{(N)}(\{u\})\rangle = \sum_{j=1}^{\infty} |\chi_{ij}(\{u\})\rangle \otimes |\phi_j^{(N)}(\{u_n\})\rangle$$

$|\Psi_i^{(N)}(\{u\})\rangle = \sum_{j=1}^{\infty} |\chi_{ij}(\{u\})\rangle \otimes |\phi_j^{(N)}(\{u_n\})\rangle$.
many-body energies of the correlated system $E_{\text{exact}}$. In addition, we give the overlaps of Born-Oppenheimer and exact states. For the present model, low lying Born-Oppenheimer states in harmonic approximation and exact Born-Oppenheimer states are both very good approximations to the exact correlated states. In particular, the exact BO ground state has an overlap of 99.86% with the exact correlated ground state. For higher-lying states, the harmonic approximation of the potential energy surfaces yields states with less accurate energies and overlaps compared to the exact BO states. Despite the good agreement for the low lying states, we demonstrate in section IV that the differences between exact and harmonic BO and exact correlated states for higher-lying levels cause sizeable deviations between the exact and the corresponding exact or harmonic BO photoelectron spectra. In particular, the BO photoelectron spectra acquire spurious peak amplitudes that are not present in the exact correlated spectrum.

III. THEORY OF STATIC AND TIME-DEPENDENT PHOTOELECTRON SPECTROSCOPY

In this section, we briefly review the connection between photoelectron spectra and the one-body spectral function known from literature [28, 31] and extend the discussion to vibronic states. For later purposes, we discuss the equilibrium and nonequilibrium spectral functions. Since our emphasis in the present work is on pump-probe photoelectron experiments for vibronic systems, we keep an explicit focus on the reference-state dependence of the vibronic one-body spectral function and we discuss how the photocurrent can be expressed in a real-time evolution.

In terms of Fermi’s Golden Rule, we can formulate the exact expression for the photocurrent $J_k(\omega)$ in first order perturbation theory [2, 28, 32] as

$$J_k(\omega) = \frac{2\pi}{\hbar} \sum_j |\langle \Psi_{j,k}^{(N)} | \hat{\Delta} | \Psi_j^{(N)} \rangle|^2 \delta(E_k - E_j - \hbar \omega). \tag{8}$$

Here, $|\Psi_{j,k}^{(N)}\rangle$ denotes the final state, where the emitted photoelectron with momentum $k$ and energy $E_k$ is typically assumed to be in a scattering state (distorted plane wave, or time-inverted scattering/LEED state, see e.g. Ref. [1] and references therein). The remaining part of the system is left in the excited state $j$ with energy $E_j$ carrying $N - 1$ electrons. Both subsystems, the emitted electron and the remaining photofragment, are in general still correlated in the combined state $|\Psi_{j,k}^{(N)}\rangle$. The wavefunction $|\Psi_{j,k}^{(N)}\rangle$ represents an initial state of the many-body system from where the photoelectron will be emitted. The above form of Fermi’s Golden rule is strictly valid only for pure states as initial and final states. In these cases, usually the $N$-electron ground state is considered, but also excited eigenstates or superposition states are allowed. For many experimental setups it is not justified to consider the ground state as initial state for the photoemission process. In particular, in pump-probe photoelectron spectroscopy, the system is typically not in the ground state when the photoelectron is removed from the system. We illustrate the effect of different initial states for the photoemission process in detail in section IV and later in this section.

Generally, the coupling element $\hat{\Delta}$ between initial and final states can be written in second quantization as

$$\hat{\Delta} = \sum_{lm,\sigma} \Delta_{lm,\sigma} \gamma_l^\dagger \gamma_{m,\sigma}, \tag{9}$$

where $\Delta_{lm,\sigma} = \langle \phi_{l,\sigma}^{(1)} | \hat{O} | \phi_{m,\sigma}^{(1)} \rangle$. The coupling to the pump and probe laser pulses is usually considered in the dipole approximation with length gauge: $\hat{O} \propto \mathbf{r} \cdot \mathbf{E}(r, t)$ or velocity gauge: $\hat{O} \propto \dot{\mathbf{r}} \cdot \mathbf{A}(r, t)$ (without treating multiphoton processes). $\mathbf{E}$ and $\mathbf{A}$ refer to the electric field and the electromagnetic vector potential, respectively. In the framework of second quantization, the wave functions $|\phi_{l,\sigma}^{(1)}\rangle$ form a complete set of one-body states. With no external magnetic field applied to the system, the matrix element is diagonal in spin, since the operator does not act on the spin part of the wave function. The sudden approximation [29, 30] allows to decouple the final state

$$|\Psi_{j,k}^{(N)}\rangle \approx \gamma_k^\dagger |\Psi_{j,k}^{(N-1)}\rangle. \tag{10}$$

This approximation implies that the final state is a product state between a plane-wave like state for the emitted electron and the remaining $N - 1$ electron many-body state $|\Psi_{j}^{(N-1)}\rangle$. At this point, we emphasize that the original matrix elements, which contribute to the photocurrent in Eq. [8], only contain states with fixed electron number $N$. Therefore, photoemission has to be regarded as a charge neutral excitation process induced by the presence of a laser field. Only when the excited photoelectron is starting to spatially separate from the remaining photo-fragment, the system is left in a charged $N - 1$ electron state. This spatial separation is also the basis of the mask approach of Ref. [2]. In general, the emitted photoelectron can still be entangled with the remaining photofragment, for instance in strong coupling situations. However, for weak coupling situation encountered in the range of the validity of the Fermi’s Golden Rule expression for the photocurrent in Eq. [8], this entanglement is often neglected. If no entanglement of the emitted photoelectron and the remaining photofragment remains when the charges separate, then the state $|\Psi_{j,k}^{(N)}\rangle$ can be factorized. This is the basic assumption of the sudden approximation in Eq. [10]. As a result, in the matrix elements of the photocurrent in Eq. [8], the neutral $N$ electron state can be replaced by an ionic $N - 1$ electron state. Only in this sense, we can talk about non-neutral excitations in a photoemission experiment, albeit initially a neutral excitation has taken place. In terms of the usual fermionic anti-commutation rela-
tion, we can write
\[ \{ \hat{c}_k, \hat{c}_m^\dagger \} = \delta_{kl}, \quad \hat{c}_k \hat{c}_m^\dagger \hat{c}_m = \hat{c}_m \delta_{kl} - \hat{c}_k^\dagger \hat{c}_m \hat{c}_k, \]
and since the state |k⟩ of the ejected photoelectron is an energetically high-lying state, virtual fluctuations in the reference state can be neglected. Following this argument, the last term in Eq. 11 can be set to zero [28] and this allows to write approximately
\[ \hat{c}_k \hat{c}_m^\dagger \hat{c}_m \approx \hat{c}_m \delta_{kl}. \] (12)

Using Eqsns. 9 and 10 and the approximation in Eq. 12 to evaluate the matrix elements in Eq. 8 we arrive at
\[ \langle \Psi_j^{(N)} | \hat{A} | \Psi_i^{(N)} \rangle = \sum_{lm,\sigma} \langle \Psi_j^{(N-1)} | \hat{c}_k \Delta_{lm,\sigma} \hat{c}_l^\dagger \hat{c}_m \cdot | \Psi_i^{(N)} \rangle \]
\[ \approx \sum_{m,\sigma} \Delta_{km,\sigma} \langle \Psi_j^{(N-1)} | \hat{c}_m \cdot | \Psi_i^{(N)} \rangle. \] (13)

In practical applications, the matrix element \( \Delta_{lm,\sigma} \) in Eq. 3 is often regarded to be constant over the investigated energy range [1, 2]. This assumption is only perfectly justified in the high-energy limit (X-ray spectroscopy). In this limit, the photoelectron spectrum is directly proportional to the spectral function. The sum-over-states expression for the photocurrent in the sudden approximation (SA) is then found to take the form
\[ J_k^{SA}(\omega) \approx \frac{2\pi}{\hbar} \sum_{lm,\sigma} \Delta_{kl,\sigma} A_{lm,\sigma}(E_k - \hbar \omega) \Delta_{m,\sigma,kl}, \] (14)
where we have introduced the one-body spectral function \( A_{lm,\sigma}(E_k - \hbar \omega) \). In the following, we discuss this quantity for equilibrium and nonequilibrium situations.

A. Spectral function: Sum over states and time-domain formulation

In this section, we state and define the equilibrium and nonequilibrium spectral function. The derivation of these quantities is given in more detail in the appendix.

1. Equilibrium spectral function

For the present study, it is important to distinguish between equilibrium and nonequilibrium situations. In equilibrium, \(| \Psi_i^{(N)} \rangle \) is a eigenstate of the full vibronic Hamiltonian. The time evolution according to the time-dependent Schrödinger equation in Eq. 3 is in these cases trivial, since eigenstates are time-invariant up to a phase. In ground-state photoemission spectroscopy, one encounters this situation, if the sample is in its ground-state before it is hit by the photoemission pulse. The equilibrium spectral function is defined as
\[ A_{lm,\sigma}^{SA}(\omega) = \sum_j \langle \Psi_0^{(N)} | \hat{c}_j^\dagger \cdot | \Psi_j^{(N-1)} \rangle \times \langle \Psi_j^{(N-1)} | \hat{c}_m,\sigma \cdot | \Psi_0^{(N)} \rangle \delta(\hbar \omega - E_j). \]

Further, in equilibrium situations only diagonal terms of the spectral function (\( l = m \)) need to be considered [33]. Eq. 15 can also be formulated in terms of overlaps of time-evolved states. Using this approach, the calculation of the spectral function does not rely on a sum-over-states expression. Rather, it can be computed from an explicit time propagation
\[ A_{lm,\sigma}^{SA}(t) = \langle \Psi_{m,\sigma}^{(N)}(t) | \hat{c}_m,\sigma \cdot | \Psi_0^{(N)}(t) \rangle, \]
with the kicked initial state \( | \Psi_j^{(N-1)}(t_0) \rangle = \hat{c}_t \cdot | \Psi_0^{(N)}(t_0) \rangle \). Depending on the size of the Hilbert space, either Eq. 15 or Eq. 16 are more efficient to evaluate. In our case, we choose to directly evaluate Eq. 15 using all eigenstates from our exact diagonalization procedure. However, for larger systems, where a direct diagonalization of the system Hamiltonian is computationally not feasible anymore, Eq. 16 provides an alternative scheme to obtain the spectral function.

A useful relation is the sum rule [34] that is obeyed by the equilibrium spectral function
\[ S = \sum_{l} \int d\omega A_{l,\sigma}(\omega) = \sum_{l} \langle \Psi_0^{(N)} | \hat{c}_l^\dagger \cdot \hat{c}_l,\sigma \cdot | \Psi_0^{(N)} \rangle, \] (17)
where the value \( S \) gives the total number of electrons \( N \) in the state \(| \Psi_0^{(N)} \rangle \). When computing an explicit sum-over-states summation, the limit \( S = N \) is only reached, if a complete set of states with a full resolution of the identity, \( \sum_{m} | \Psi_m^{(N-1)} \rangle \langle \Psi_m^{(N-1)} | = 1 \), is inserted in Eq. 17. For an incomplete basis of states the sum rule deviates from \( N \). Depending on the orthogonality and completeness of the employed states, \( S \) can then be lower or higher than the total number of electrons in the state \(| \Psi_0^{(N)} \rangle \). Therefore, in practical calculations this sum rule can be exploited to test convergence and the completeness of the employed basis set.

2. Nonequilibrium spectral function

From the expression for the photocurrent in sudden approximation, Eq. 14 the dependence of the photoelectron spectrum on the reference-state \(| \Psi_0^{(N)} \rangle \) becomes apparent. As mentioned before, in most cases the system is assumed to be in the ground state. However, in a pump-probe experiment this assumption is not justified anymore. As we demonstrate in section 17, quite sizable changes arise in the photoelectron spectrum when the photoelectron is ejected from a time-evolving state.
The expression for the one-body spectral function in Eq. (15) is still formulated in terms of correlated energy eigenstates of the full vibronic Hamiltonian. Therefore, the direct evaluation of this expression is usually a formidable task. For vibronic systems, the most straightforward approximation is to replace the correlated vibronic initial and final states by factorized Born-Oppenheimer states.

For the following discussion in section IV we define as single-harmonic approximation (SHA) the case where only the initial state is replaced by the corresponding factorized Born-Oppenheimer state in harmonic approximation $|\chi_{00}\phi_{0}^{(N)}\rangle$ and all final states are retained as correlated vibronic $N-1$ electron states. In this case, the spectral function takes the form

$$A_{lm,\sigma}^{SA,SHA}(\omega) = \sum_{j} \langle \chi_{00}\phi_{0}^{(N)} | \hat{c}_{l,\sigma}^{\dagger} | \Psi_{j}^{(N-1)} \rangle \times \langle \Psi_{j}^{(N-1)} | \hat{c}_{m,\sigma} | \chi_{00}\phi_{0}^{(N)} \rangle \delta(\hbar\omega - E_{j}).$$

(20)

Interestingly, since the Born-Oppenheimer ground state is by construction not an eigenstate of the full many-body Hamiltonian, already at the level of the SHA the expression in Eq. (18) has to be applied.

As further simplification, we can consider a harmonic approximation for both, the involved initial and final potential energy surfaces and replace the remaining $N-1$ electron states by Born-Oppenheimer states in harmonic approximation. This leads to the double-harmonic approximation (DHA) for the spectral function

$$A_{lm,\sigma}^{SA,DHA}(\omega) = \sum_{n,j} \langle \chi_{nj}\chi_{00} | \hat{c}_{l,\sigma}^{\dagger} | \phi_{0}^{(N)} \rangle \langle \phi_{0}^{(N)} | \hat{c}_{m,\sigma}^{\dagger} | \phi_{j}^{(N-1)} \rangle \delta(\hbar\omega - \epsilon_{j}).$$

(21)

In particular, the expression for the DHA shows that the peak-heights in the photoelectron-spectrum are modulated by Franck-Condon factors. Although this simplifies practical computations considerably, we show in section IV that spurious peaks appear in the DHA of the spectral function, which are not present in the exact spectral function, Eq. (15).

IV. RESULTS

A. Comparison of BO and exact ground-state photoelectron spectra

In this section, we illustrate the different theory levels that we introduced in the previous section for the calculation of vibronic photoelectron spectra. Due to the dense diagonalization that we can perform for our model system of Trans-Polyacetylene, we have all correlated states and all required Born-Oppenheimer states available to perform the explicit sums over states that arise in the definition of the different spectral functions in Eqs. (15) [20] and [21]. In the following, we restrict ourselves only to the ground state as initial state for the photoemission process. We term these spectra ground-state photoelectron spectra. Later, we lift this restriction to also consider pump pulses and time-evolving reference states explicitly.

In Fig. 3 we illustrate spectral functions of the SSH chain for three different cases: In case (a), the spectral function has been calculated in the double-harmonic approximation using Eq. (21). Spectrum (b) shows the spectrum calculated in the single-harmonic approximation,
Intensity in arb.u.

Intensity in arb.u.

FIG. 3. Calculated Photoelectron spectra for Trans-Polyacetylene: (a) The ground-state spectrum in double-harmonic approximation (DHA), (b) the ground-state spectrum in single-harmonic approximation (SHA) (c) the exact ground-state spectrum from the full-quantum calculation. With $S$ we refer to the value of the sum rule for the spectral function as defined in Eq. [17]. For a complete set of states this corresponds to the total number of electrons. Restricted summations of the sum rule in the energy range above $-5$ eV and below $-5$ eV are given by $S_{< -5eV}$ and $S_{> -5eV}$, respectively.

where Eq. 20 has been employed and in spectrum (c), we show the exact correlated ground-state spectrum computed from Eq. 15. In the figure, the different peaks are labeled according to their corresponding quantum numbers (quantum numbers of electronic state, optical mode and acoustical mode are shown). In experiment, the spectra are typically plotted as function of the positive binding energy (see e.g., Fig. 4 in Ref. [2]). To connect the plots of the present work to this convention, the absolute value of the x-axis has to be considered to arrive at positive values for the binding energy. Furthermore, for all spectra a Lorentzian broadening of the form

$$f(E; E_0, \gamma) = \frac{1}{\pi} \frac{\gamma}{(E - E_0)^2 + \gamma^2}. \quad (22)$$

with $\gamma = 0.002$ eV has been used. Note, that a conventional broadening of 0.1 eV that is employed frequently for purely electronic Green’s functions would completely wash out the vibrational side bands. To resolve here the vibrational side-bands of the photoelectron spectrum a much smaller broadening of 0.002 eV has to be employed. Note, that this broadening is also about an order of magnitude smaller than 1/40 eV, which gives a typical energy scale for vibronic motion at room temperature. In experiment, the vibrational sidebands are hence only clearly visible in a low temperature limit.

In comparison to the exact spectrum in (c), we conclude from Fig. 3 that DHA and SHA, both accurately predict the peak positions corresponding to the optical phonon mode in the energy range of the spectrum from -10 eV to -5 eV, but the spectra reveal clear differences in the energy range from -5 eV up to 0 eV. The accurate location of the peaks is in accord with the quality of the approximate energy values shown in Tab. I. On the other hand, peak heights in the DHA are not accurate: peaks, which correspond to the optical phonon mode are most dominant in the spectrum and their broadening overlaps and even hides peaks, which correspond to mixed or acoustical phonon modes.

As additional information, we also show in Fig. 3 the sum rule calculated with Eq. 17 for each spectrum. The DHA spectrum violates the sum rule due to the non-completeness of the approximation, as discussed in Sec. III. In all three spectra, most of the spectral amplitude is located in energy areas below -5 eV, while only less than two percent of the spectral weight is located in the energy range above -5 eV in the DHA and SHA spectra. The most prominent feature between the different spectra is that in the DHA and SHA spectra spurious peaks appear above -5 eV that are not present in the exact correlated ground-state spectrum. We discuss the origin of this artefact of the DHA and SHA in detail in the next section.
Overlap (log) in arb.u.

Fig. 3. Double portant contributions: As indicated by the name correlated spectrum shown in Fig. 3 have two equally important contributions: the differences between the SHA spectrum in Fig. 3 (b) and the exact spectrum in Fig. 3 (c), is caused by the factorized Born-Oppenheimer initial state in the SHA. The remaining spurious amplitude, and hence the spurious peaks is reduced from 1.6% in DHA to 0.2% in SHA. The magnitude for the different expansion coefficients \(a_n\) is shown in Fig. 4 (a) in logarithmic scale. As expected, the highest overlap is found between the Born-Oppenheimer ground state and the exact correlated ground state. For the present system, this overlap is equal to 0.9986 (see Tab. 1) and is marked as a black dot in the graph. The following corrections are orders of magnitudes smaller. In Fig. 4 (a), we illustrate with different colors the overlaps \(a_n\) for \(n_{\text{max}} \geq 1\) with magnitude larger than \(10^{-13}\). The overlaps can be grouped in different sets, which allow to identify different PES in terms of Fig. 2. In Fig. 4 (b), we show the SHA spectral function for different upper limits of summation \(n_{\text{max}}\) in the expansion of the Born-Oppenheimer initial state. If only the coefficient \(a_1 = 0.9986\) with the highest overlap is included, we recover the exact correlated ground-state spectrum. This is shown in the upper spectrum in Fig. 4 (b). Note, that we are not renormalizing the state in Eq. 23 after truncation, so that the sum rule corresponds for \(n_{\text{max}} = 1\) to \(S = 4 \cdot a_1^2 = 3.9888\). When more and more expansion coefficients \(a_n\) with \(n > 1\) are included in the expansion, the artificial peaks shown in Fig. 4 in the range from -5 eV to 0 eV start to emerge. This is illustrated in the sequence of spectra in Fig. 4.

**B. Non-adiabaticity in ground-state photoelectron spectroscopy**

The prominent differences in the energy range from -5 eV to 0 eV between the DHA spectrum and the exact correlated spectrum shown in Fig. 3 have two equally important contributions: As indicated by the name double-harmonic approximation, one performs two harmonic approximations in the DHA. It turns out that both harmonic approximations contribute independently to the spurious peaks in the spectrum. We can isolate the effect of each of the two harmonic approximations by comparing to the single-harmonic approximation. Since according to our definition in Eq. 20, we use correlated final states in the SHA, the only remaining approximation in the SHA is the factorized and harmonic Born-Oppenheimer initial state. Comparing the sum rules for the spectral function of the DHA with the spectral function of the SHA in Fig. 3 for the upper part of the spectrum (-5 eV to 0 eV) shows that the spectral weight of the spurious peaks is reduced from 1.6% in DHA to 0.2% in SHA. The remaining spurious amplitude, and hence the differences between the SHA spectrum in Fig. 3 (b) and the exact spectrum in Fig. 3 (c), is caused by the factorized Born-Oppenheimer initial state in the SHA. To illustrate this further, we expand the Born-Oppenheimer ground state in the complete set of correlated eigenstates of the full many-body Hamiltonian from Eq. 2

\[
|\chi_{00} \phi_0^{(N)}\rangle = \sum_{n=1}^{n_{\text{max}}} \langle \psi_n^{(N)} | \chi_{00} \phi_0^{(N)} \rangle |\psi_n^{(N)}\rangle \quad (23)
\]

\[
S_{\text{max}} = (3.988,3.988,0.000)
\]

\[
S_{\text{max}} = (3.999,3.999,0.000)
\]

\[
S_{\text{max}} = (3.996,3.999,0.000)
\]

\[
S_{\text{max}} = (1.000,3.992,0.008)
\]

\[
S_{\text{max}} = (1.000,3.992,0.008)
\]

\[
S_{\text{max}} = (4.000,3.992,0.008)
\]

\[
S_{\text{max}} = (4.000,3.992,0.008)
\]

\[
S_{\text{max}} = (4.000,3.992,0.008)
\]

\[
S_{\text{max}} = (4.000,3.992,0.008)
\]

\[
S_{\text{max}} = (4.000,3.992,0.008)
\]

FIG. 4. Non-adiabatic contribution to the BO ground state of the Trans-Polyacetylene chain: (a) Projection of the BO ground state onto correlated eigenstates. (b) SHA spectra depending on expansion coefficients. Here, \(S = (S, S_{\leq-5eV}, S_{\geq-5eV})\), as in Fig. 3.
FIG. 5. (a) Illustration of Frank-Condon transition: The excited $N$-electron initial state propagates on the Born-Oppenheimer surface of the first excited electronic state. $N$-electron potential-energy surfaces are shown in red, $N-1$-electron potential-energy surfaces in blue. The oscillation spread of the center of the wavepacket is indicated by a yellow background. The different wavepacket shapes indicate the squeezing of the vibronic state. (b) Spectra at different time-steps (the first spectrum at $t_0$ corresponds to spectrum (b) in Fig. 3); (c) All obtained spectra plotted time-resolved, the color code refers to high intensity in red and low intensity in blue color. The dashed black line shows the motion of the center of the nuclear wavepacket as function of pump-probe delay. The color code refers to high intensity in red and low intensity in blue color.

(b). When the expansion of Eq. 23 is inserted in Eq. 20, the spurious peaks arise due to additional cross and diagonal terms in the spectral function, which involve excited correlated eigenstates. Hence, we conclude that the artificial peaks are due to the factorized nature of the Born-Oppenheimer ground state. We emphasize, that the spurious spectral weight appears, both for the Born-Oppenheimer ground state in harmonic approximation, as well as for the exact Born-Oppenheimer ground state without the harmonic approximation. In both cases, the expansion in Eq. 23 in terms of correlated vibronic eigenstates has in general more than one term ($n_{\text{max}} > 1$) and hence additional cross and diagonal terms in the spectral function necessarily appear. As we have demonstrated in Tab. 4 for the present model of Trans-Polyacetylene the overlap between exact Born-Oppenheimer, harmonic Born-Oppenheimer, and exact correlated ground state is very high due to the rather harmonic nature of the Su-Schrieffer-Heeger model. Nevertheless, the spurious spectral weights already have a magnitude of about 1.6% in DHA. For any molecular system, which is less harmonic than our model, a larger contribution to the spurious spectral peaks is expected, since in the expansion more terms with a larger weight of expansion coefficients $a_n$ contribute. In this sense, the present system can be regarded as best-case scenario and in general the spurious spectral peaks are more pronounced. However, in the limit of large nuclear masses, the Born-Oppenheimer approximation becomes more accurate. In this limit, the Born-Oppenheimer ground state of the system becomes identical to the correlated ground state, hence leading to identical spectra.

One way to correctly incorporate nonadiabatic effects could be the inclusion of non-adiabatic couplings in the Born-Huang expansion (Eq. 6). Other alternatives could rely on an explicitly correlated ansatz for the combined electron nuclear wavefunction, as e.g. in an electron-nuclear coupled cluster approach [35], or in a multi-component density functional theory approach for electrons and nuclei [36].

C. Time-resolved pump-probe photoelectron spectra

So far, we have considered the ground state as the reference state for the calculation of the spectral function. In this section, we turn our attention to explicitly time-resolved vibronic photoelectron spectra. All calculations for the remaining part of the paper are done with the exact Hamiltonian and are based on the exact time-evolution of the correlated time-dependent Schrödinger equation. To illustrate pump-probe photoelectron spectra for vibronic systems, we consider two different examples. In example (1), we initially excite our system with a Franck-Condon transition, while in example (2),
we explicitly include a short femtosecond laser pulse with Gaussian envelope in our real-time propagations to simulate the pump pulse. We start in the present section with example (1).

1. Time-resolved photoelectron spectra with initial Frank-Condon excitation

In our first example, we excite the SSH chain from the Born-Oppenheimer ground state to the first excited charge neutral $N$ electron state $\phi_1^{(N)}$, while the vibrational state remains in the ground state configuration $\chi_0\phi$. After excitation, the initial state for the time-propagation is still a factorized Born-Oppenheimer state of the form

$$|\Psi(t = t_0)\rangle = |\chi_0 \phi_1^{(N)}\rangle. \quad (24)$$

This type of Franck-Condon transition takes here the role of the pump pulse and is illustrated in Fig. 3 (a) in the left panel. The initial state in Eq. 24 is then propagated in real-time with the full correlated Hamiltonian in the combined electronic and vibrational Fock space of the model. Since the factorized excited Franck-Condon state is not an eigenstate of the correlated many-body Hamiltonian, a wave-packet propagation is launched with this initial state, which resembles predominantly the motion of a Born-Oppenheimer state in the first excited potential-energy surface. We propagate from $t_0 = 0$ fs to a final time of $t_f = 110$ fs, which corresponds to about $9/4$ of the oscillation period of the nuclear wavepacket in the excited state. The oscillation spread of the center of the nuclear wavepacket is indicated by a yellow background in Fig. 3 (a).

After a certain delay time $\tau$ we simulate a probe pulse by recording the photoelectron spectrum in terms of the spectral function. This amounts to replacing the reference state $|\Psi_0^{(N)}\rangle$ in Eq. 15 with the time-evolved state $|\Psi^{(N)}(\tau)\rangle$ at the pump-probe delay time $\tau$

$$A^{SA}_{lm,\sigma}(\tau, \omega) = \int_{t_1}^{t_f} A^{SA}_{lm,\sigma}(\tau, \omega) d\tau \quad (26)$$

and that can be viewed as an average of the 2D contour data of Fig. 3 (c) along the axis of the delay time $\tau$. The average spectrum is useful in determining in which spectral regions the emitted photoelectrons can be found over certain oscillation periods.

2. Time-resolved photoelectron spectra with explicit pump pulse

In our second example, we investigate an explicit simulation of a pump-probe experiment in real-time. Compared to the Franck-Condon excitation, which was based only on the selection of a specific excited initial state, a more appropriate description of the excitation of the system can be realized by explicitly including the pump pulse into the time-propagation. For the following discussion, we therefore add a dipole-coupling term to the Hamiltonian in Eq. 1

$$\hat{H}_{ssh}(t) = \hat{H}_s + \hat{H}_{ph} + \hat{H}_{\tau-ph} + \hat{H}_{\tau,E}(t)$$

$$\hat{H}_{\tau,E}(t) = -e \sum_{n,\sigma} x_n \hat{c}_{n,\sigma}^\dagger \hat{c}_{n,\sigma} \cdot E(t),$$

$$\hat{H}_{ph,E}(t) = \sum_n q_n x_n \cdot E(t),$$

$$E(t) = E_0 \exp \left(-\frac{(t - t_0)^2}{\sigma^2}\right) \sin \omega t.$$ 

Here, $x_n$ refers to the real-space position of site $n$, $e$ to the elementary electric charge and $q_n$ to the charge of the nuclei $n$ (in the present case, we choose $q_n = e$). Note, that
the laser pulse couples to both, to the dipole moment of the electrons and to the nuclear dipole. For the electric field of the pump pulse \( E(t) \) we use a Gaussian envelope with midpoint \( t_0 = -6 \) fs, maximum envelope \( E_0 = 0.85 \) V/Å and variance \( \sigma = 1.5 \) fs. As carrier wave, we choose a sine function with frequency \( \omega_1 = \Delta E/h = 6.20 \) fs\(^{-1}\). The frequency of the laser pulse is chosen to be resonant for a Frank-Condon like transition with \( \Delta E \) that corresponds to the example in Sec. [IV C](1). For the time-propagation with the time-dependent Hamiltonian \( \hat{H}_{\text{ssh}}(t) \), we use as before a Lanczos propagator, but in addition we employ an exponential midpoint scheme \cite{37} to account for the time-dependence of the Hamiltonian.

For the propagation, we choose the exact correlated vibrionic ground state as initial state. This state is then propagated with fully correlated many-body Hamiltonian including the dipole coupling to the pump laser as given in Eq. [4].

In Fig. 6 (a), we show the amplitude of the external laser pulse. The pulse starts at \( t_0 = -10 \) fs and is switched off at \( t_1 = 0 \) fs. As the state evolves, we compute the overlaps with the Born-Oppenheimer states as function of time. In Fig. 6 (b) we show, which states are populated during the propagation. While at the initial time almost the full population is in the BO ground state \( |\chi_{00} \phi_0^{(N)} \rangle \), the population moves within the first 10 fs to the state \( |\chi_{00} \phi_1^{(N)} \rangle \), i.e. the state, which corresponds to a Frank-Condon transition out of state \( |\chi_{00} \phi_0^{(N)} \rangle \). After the first initial population of \( |\chi_{00} \phi_1^{(N)} \rangle \), the populations indicate two competing processes: First, the pump laser pulse transfers population from \( |\chi_{00} \phi_0^{(N)} \rangle \) to \( |\chi_{00} \phi_1^{(N)} \rangle \), since this transition is resonant. Second, once population occurs in \( |\chi_{00} \phi_1^{(N)} \rangle \), this population induces a wavepacket motion on the first excited potential-energy surface, as seen in Sec. [IV C](1). Therefore, the system never reaches a situation, where only two states are present in the system \( |\chi_{00} \phi_0^{(N)} \rangle \) and \( |\chi_{00} \phi_1^{(N)} \rangle \), as it would be in a Franck-Condon picture of the excitation process. After the end of the pump pulse at \( t = 0 \) fs, the projection of the time-evolving state on the correlated vibrionic ground state is constant in time and the ground state maintains a population of about 50%. In contrast, the projection of the correlated time-evolving state on the BO ground state exhibits small oscillations which is shown in the inset of Fig. (b) and which arise due to the small deviations between the BO ground state and the exact correlated ground state. As in the example before, we record photoelectron spectra as function of pump and probe delay. The photoelectron spectrum at time \( t = t_0 = -10 \) fs is given in red color in Fig. 6 (c). This spectrum is identical to the spectral also shown in Fig. 3 (c). The spectra after the pulse has been switched off are shown in green color and correspond to delay times of \( t = 0 \) fs and \( t = 110 \) fs. As before, we also show the time-averaged spectrum in blue color. In contrast to the Franck-Condon excitation in example (1), the photoelectron spectra in this case show a pronounced large peak at about \(-7.5 \) eV. This peak arises due to the remaining population of the Born-Oppenheimer ground state \( |\chi_{00} \phi_0^{(N)} \rangle \). In Fig. 6 (d), we show similar to Fig. 5 (c) the spectral func-

FIG. 6. Time-dependent pump-probe photoelectron spectroscopy: (a) Amplitude of laser-pulse as given in Eq. [9] (b) overlaps of time-evolved state with electronic ground and first excited Born-Oppenheimer states and the exact correlated ground state, (c) spectra at different time-steps (the first spectrum at \( t_0 \) corresponds to spectrum (c) in Fig. 3). (d) all obtained spectra plotted time-resolved, the color code refers to high intensity in red and low intensity in blue color.
tion $A^{SA,\sigma}_{lm,\sigma}(\tau,\omega)$ as function of the pump-probe delay $\tau$. As before in the Franck-Condon case, also with an explicit pump pulse, we can trace the nuclear wavepacket dynamics in the photoelectron spectrum. Overall, the time-evolution of the Franck-Condon excitation captures large parts of the exact vibronic spectrum of example (2). The notable differences in the explicitly time-dependent and fully correlated vibronic case in Fig. 6(c) are the additional population of the Born-Oppenheimer ground state which maintains a large spectral weight at about $-7.5$ eV also for different delay times and some small non-adiabatic contributions to the spectrum in the energy range from $-4$ eV to $-2$ eV.

V. CONCLUSION

In summary, we have analyzed and quantified non-adiabatic contributions to the equilibrium and nonequilibrium photoelectron spectra in a model system for Trans-Polyacetylene. We find that for low-lying states the harmonic Born-Oppenheimer photoelectron spectrum acquires in comparison to the exact photoelectron spectrum spurious spectral weight, which also persists when either the initial state of the photoemission process or the final state is replaced by correlated vibronic states. The origin of this behavior can be traced back to the factorized nature of the involved initial or final Born-Oppenheimer states. Only when both, initial and final photoemission states, are taken as correlated vibronic states the spurious spectral peaks are suppressed. We analyze this in detail by expanding the Born-Oppenheimer ground state in the complete set of correlated vibronic eigenstates of the full Hamiltonian. Inserting this expansion into the equilibrium form of the spectral function shows that additional cross and diagonal terms, which involve excited correlated eigenstates, are responsible for the spurious spectral weight.

For the example of an initial Franck-Condon transition and for an explicit pump-pulse excitation we have demonstrated with explicit real-time propagations of the coupled Polyacetylene chain how the vibronic wavepacket evolution can be traced in the photoelectron spectrum as function of pump-probe delay. Prospects for future work include the study of temperature and pressure dependence of the photoelectron spectrum as well as an extension of the present femtosecond laser excitation to ultrafast photoelectron spectroscopy with attosecond laser pulses in real nanostructured and extended systems. Another line of research is linked to the development of xc functionals for TDDFT capturing the effects discussed in this work, e.g. based on electron-nuclear multicomponent density functional theory.

Appendix: Appendix

1. Spectral function

The one-body spectral function is defined as follows

$$A_{ij}(t, t') = \langle \Psi_0 | \hat{c}_i(t) \hat{c}_j(t') | \Psi_0 \rangle$$

with $t' > t$. The operators $\hat{c}$ and $\hat{c}^\dagger$ are here written in the Heisenberg picture. The index refers to a combined index $i = (n, \sigma)$ and $j = (m, \sigma')$, where $n$ and $m$ refer to the site number and $\sigma$ and $\sigma'$ refer to spin up or spin down.

In this work, we only consider the first part of the commutator $A_{ij}(t, t')$, since we are only interested in photoemission spectra. The second term $A_{ij}^\dagger(t, t')$ leads to inverse photoemission spectra. In the following discussion, we distinguish two cases: 1. if $|\Psi_0\rangle$ is an eigenstate of the system Hamiltonian, we work in an equilibrium framework, 2. if $|\Psi_0\rangle$ is not an eigenstate of the system Hamiltonian, we have to work in a nonequilibrium framework.

2. Equilibrium spectral function

The equilibrium spectral function applies for situations, where $|\Psi_0\rangle$ is an eigenstate of the corresponding many-body Hamiltonian $H$ of the system. Hence, we can write Eq. (A.1) in terms of an time-correlation function

$$A_{ij}(t, t') = \langle \Psi_0 | \hat{c}_j(t') \hat{c}_i(t) | \Psi_0 \rangle$$

$$= \langle \Psi_0 | e^{-iH(t'/\hbar)} \hat{c}_j e^{-iH(t'/\hbar)} \hat{c}_i e^{-iH(t'/\hbar)} | \Psi_0 \rangle$$

$$= \langle \Psi_0 | e^{-iH(t'-t'/\hbar)} \hat{c}_i \hat{c}_j | \Psi_0 \rangle e^{i E_0 (t'-t)/\hbar}$$

$$= \langle \Psi_0(\tau) | \hat{c}_j | \Psi(\tau) \rangle$$

with $\tau = t' - t$ and the initial condition $|\Psi(\tau = \tau_0)\rangle = \hat{c}_i |\Psi_0\rangle$. 

13
Eq. [A.1] can be reformulated to get a sum-over-states expression. This is accomplished by the insertion of an complete set of states \( \sum_m |\Psi_m \rangle \langle \Psi_m| = 1 \) and a Fourier transform with respect to the time-difference \( \tau = t' - t \)

\[
A_{ij}^{\omega}(t,t') = \langle \Psi_0 | c_j^\dagger(t') \hat{c}_i(t) | \Psi_0 \rangle
\]

\[
= \langle \Psi_0 | e^{iHt'/\hbar} \hat{c}_j e^{-iHt'/\hbar} e^{iHt/\hbar} \delta_{ij} \hat{c}_i e^{-iHt/\hbar} | \Psi_0 \rangle
\]

\[
= \sum_m \langle \Psi_0 | c_j^\dagger | \Psi_m \rangle \langle \Psi_m | \hat{c}_i | \Psi_0 \rangle e^{i(E_m-E_0)(t'-t)/\hbar}
\]

\[
A_{ij}^{\omega}(\omega) = \int \frac{dt}{2\pi} \sum_m \langle \Psi_0 | c_j^\dagger | \Psi_m \rangle \langle \Psi_m | \hat{c}_i | \Psi_0 \rangle e^{i(E_m-E_0)\omega + it/\hbar}
\]

\[
= \sum_m |\langle \Psi_0 | c_j^\dagger | \Psi_m \rangle|^2 \delta(E_m-E_0 - \hbar\omega)
\]

3. Nonequilibrium spectral function

In nonequilibrium situations, \( |\Psi_0 \rangle \) is not an eigenstate of the many-body Hamiltonian \( H \). Nevertheless, it is also possible to formulate the spectral function in Eq. [A.4] as time-correlation function involving propagated states

\[
A_{ij}^{\omega}(t,t') = \langle \Psi_0 | c_j^\dagger(t') \hat{c}_i(t) | \Psi_0 \rangle
\]

\[
= \langle \Psi_0 | e^{iHt'/\hbar} \hat{c}_j e^{-iHt'/\hbar} e^{iHt/\hbar} \delta_{ij} \hat{c}_i e^{-iHt/\hbar} | \Psi_0 \rangle
\]

\[
= \langle \Psi_0(t') | c_j^\dagger e^{-iH(t'-t)/\hbar} \hat{c}_i | \Psi_0(t) \rangle
\]

\[
A_{ij}^{\omega}(t,\tau) = \langle \Psi_0(\tau + t) | c_j^\dagger | \Psi(\tau + t, t) \rangle
\]

We introduce the relative time \( \tau = t' - t \), as in Sec. [2] while \( t \) keeps its initial denotation. The state \( \Psi(\tau + t, t) = e^{-iH\tau/\hbar} \hat{c}_i | \Psi_0(t) \rangle \), meaning the kick \( \hat{c}_i \) on the wavefunction acts at time \( t \) during the time propagation. A Fourier transform with respect to the relative time \( \tau \) yields the general expression for the sum-over-states expression

\[
A_{ij}^{\omega}(t,\tau) = \langle \Psi_0 | c_j^\dagger \hat{c}_i | \Psi_0 \rangle
\]

\[
= \sum_{n,n',m} e^{i\tau/h(E_{n'}-E_m)+it/h(E_{n'}-E_n)}
\]

\[
\times \langle \Psi_0 | \Psi_{n'} \rangle \langle \Psi_{n'} | c_j^\dagger | \Psi_m \rangle \langle \Psi_m | \hat{c}_i | \Psi_{n} \rangle \langle \Psi_{n} | \Psi_0 \rangle
\]

\[
A_{ij}^{\omega}(\tau,\omega) = \int \frac{dt}{2\pi} \sum_{n,n',m} e^{i\tau/h(E_{n'}-E_m)+it/h(E_{n'}-E_n)}
\]

\[
\times \langle \Psi_0 | \Psi_{n'} \rangle \langle \Psi_{n'} | c_j^\dagger | \Psi_m \rangle \langle \Psi_m | \hat{c}_i | \Psi_{n} \rangle \langle \Psi_{n} | \Psi_0 \rangle
\]

In our simulations, we neglect the energy dependence of the delta function in the last equation. Hence, we replace the term \( E_{n'} \) by the energy \( E_0 \) of the state \( \Psi_0 \). This leads to

\[
A_{ij}^{\omega}(\tau,\omega) = \sum_{n,n',m} e^{it/h(E_{n'}-E_m)} \delta(E_0 - E_m - \hbar\omega)
\]

\[
\times \langle \Psi_0 | \Psi_{n'} \rangle \langle \Psi_{n'} | c_j^\dagger | \Psi_m \rangle \langle \Psi_m | \hat{c}_i | \Psi_{n} \rangle \langle \Psi_{n} | \Psi_0 \rangle
\]

\[
= \sum_m \langle \Psi_0(T) | c_j^\dagger | \Psi_0(T) \rangle \langle \Psi_0(T) | \hat{c}_i | \Psi_0(T) \rangle
\]

\[
\times \delta(E_0 - E_m - \hbar\omega)
\]

\[
A_{ij}^{\omega}(\omega) = \sum_m \langle \Psi_0(T) | c_j^\dagger | \Psi_0(T) \rangle^2 \delta(E_0 - E_m - \hbar\omega)
\]
