Abstract

Using the large-$N$ limit of the $t$–$J$ model and also allowing for phonons and the electron–phonon interaction, we study the isotope effect $\alpha$ for coupling constants appropriate for YB$_2$C$_3$O$_y$. We find that $\alpha$ has a minimum at optimal doping and increases strongly (slightly) towards the underdoped (overdoped) region. Using values for the electron–phonon interaction from the local density approximation we get good agreement for $\alpha$ as a function of $T_c$ and doping $\delta$ with recent experimental data in YB$_2$C$_3$O$_y$. Our results strongly suggest that the large increase of $\alpha$ in the underdoped region is (a) caused by the shift of electronic spectral density from low to high energies associated with a competing phase (in our case a charge density wave) and the formation of a gap, and (b) compatible with the small electron–phonon coupling constants obtained from the local density approximation. We propose a similar explanation for the anomalous behavior of $\alpha$ in Sr-doped La$_2$CuO$_4$ near the doping 1/8.

Keywords: phonons, cuprates superconductors, pseudogap regime

(Some figures may appear in colour only in the online journal)

1. Introduction

The isotope effect on the superconducting transition temperature $T_c$ is one of the hallmarks of phonon-induced superconductivity in conventional superconductors [1]. Many experiments showed that the measured isotope coefficient $\alpha$ in these systems is near the theoretical value of 1/2, confirming the important role played by phonons [2]. The isotope effect in high-$T_c$ oxides differs from that in conventional superconductors [3, 4]. Similar to $T_c$, $\alpha$ depends strongly on doping in this case. At optimal doping, i.e., where $T_c$ assumes its largest value, $\alpha$ turns out to be very small and of the order of 0.05. Decreasing the doping, $T_c$ decreases and vanishes near the onset of long-range antiferromagnetism. At the same time $\alpha$ increases monotonically, reaching low doping values of about 1. Increasing the doping from its optimal value, $T_c$ decreases monotonically down to zero. The behavior of $\alpha$ in this region is presently not as clear as in the underdoped region but seems to be constant or slightly increasing with doping [3, 4]. The above characterization of $\alpha$ applies in particular to the well-investigated Y- and Bi-based high-$T_c$ oxides. The situation in Sr-doped La$_2$CuO$_4$ (LSCO) is somewhat different. Large values of $\alpha$ occur near the doping 1/8, where $T_c$ is suppressed [5, 6].

A nonzero isotope coefficient proves the involvement of phonons and the electron–phonon (EP) interaction in the superconducting state. Since $\alpha$ assumes values near 1 in high-$T_c$ oxides, i.e., values which are larger than in all conventional superconductors, it has been concluded [3, 7, 8] that phonons...
play an important role in the high-$T_c$ phenomenon. As a result, theories with a strong EP coupling and polarons have been used to explain the observed $\alpha$ [9–11]. On the other hand the experiments show that very large values of $\alpha$ occur in high-$T_c$ oxides if a competing phase with a gap or pseudogap is present [4]. Theories of this kind [12, 13] may explain $\alpha$ without assuming a strong EP coupling. Whether the EP coupling is strong or not in cuprates is of fundamental interest. Angle-resolved photoemission spectra show large electronic self-energies [14, 15], but it is not easy to decide whether they are caused by a strong coupling to phonons [16] or to spin excitations [17]. $\alpha$, however, is only sensitive to phonons and not to spin excitations. A convincing explanation of $\alpha$ thus could also contribute to the presently controversial discussed question of the role played by phonons in high-$T_c$ oxides.

In this paper we show that the theory of [13] may explain the recently reported doping behavior of $\alpha$ in YBa$_2$Cu$_3$O$_y$ (YBCO) [18]. For this aim we review part of our theory and give new expressions and discussions for $\alpha$. In our scenario the large increase in $\alpha$ in the underdoped regime can be explained in the presence of a d charge-density wave (CDW) state using small EP interaction constants, as calculated in the local density approximation (LDA) [19–21].

2. Derivation of the expression for $\alpha$

Our calculation of $\alpha$ is based on the Hamiltonian $H^{t\rightarrow J} + H^{ep}$, where $H^{t\rightarrow J}$ is the $t$-$J$ model and $H^{ep}$ represents the EP interaction. $H^{t\rightarrow J}$ is given by,

$$H^{t\rightarrow J} = -\sum_{i,j,\sigma} t_{ij} \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} + J \sum_{<i,j>} \left( \hat{S}_i \cdot \hat{S}_j - \frac{1}{4} n_i n_j \right) + V_c \sum_{<i,j>} n_i n_j,
$$

where $t_{ij} = t (t')$ is the hopping integral between the first (second) nearest-neighbor sites on a square lattice; $J$ and $V_c$ are the exchange interaction and the Coulomb repulsion, respectively, between nearest-neighbor sites. $\hat{c}_{i\sigma}^\dagger$ and $\hat{c}_{i\sigma}$ are creation and annihilation operators for electrons with spin $\sigma$. $n_i = \sum_{\sigma} \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma}$ is the electron density and $\hat{S}_i$ the spin operator. $\langle i,j \rangle$ denotes a sum over pairs of sites $i$ and $j$.

In the framework of the large-$N$ expansion, the spin index $\sigma$ in (1) is extended to $N$ components, the coupling constants scaled as $t \rightarrow 2t/N$, $t' \rightarrow 2t'/N$, $J \rightarrow 2J/N$, and $V_c \rightarrow 2V_c/N$, and the large N limit is considered [22]. As a result, the quasiparticle dispersion is given by

$$\epsilon(k) = -2(t\delta + rf)\cos(k_x) + \cos(k_y) - 4t'\delta \cos(k_x)\cos(k_y) - \mu ,$$

where $r = 1/N \sum_q \cos(q_x) f(\epsilon(q))$. $f$ is the Fermi function, $\delta$ the doping away from half-filling, $\mu$ the chemical potential, and $N$ the number of sites. In the following we use the lattice constant $a$ and $t$ as length and energy units, respectively. In addition, we take $t'/t = -0.35$ and $J/t = 0.3$, which are typical values for cuprates.

As discussed previously [22] the above model shows instabilities with respect to a d CDW [23, 24] and a superconducting phase. The corresponding order parameters are

$$i\Phi(k) = -4J_\gamma(k) g_{13}(k', \omega_n) \left( \begin{array}{c} \Delta(k) \\ i\omega_n - \epsilon(k) \\ -\Delta(k) \\ 0 \\ 0 \\ -i\Phi(k) \\ 0 \\ i\Phi(k) - \Delta(k) \\ i\omega_n - \epsilon(k) - \Delta(k) \end{array} \right)$$

and

$$\Delta(k) = -4J_\gamma(k) g_{12}(k', \omega_n).$$

$T$ is the temperature and $i\omega_n$ a fermionic Matsubara frequency. $g_{12}$ and $g_{13}$ are the elements (1,2) and (1,3), respectively, of the $4 \times 4$ Green’s function $g^{-1}(i\omega_n, k)$.

In figure 1 previous results [13] for $\Phi$ and $\Delta$ at $T = 0$, and for $T_c$ and $T^*$, as a function of doping, $T^*$ is the temperature where the CDW phase develops. The phase diagram is qualitatively similar to the experiments; i.e., there is a dome-like behavior for $T_c$ and a superconducting phase with a gap or pseudogap. The phase diagram is qualitatively similar to the experiments; i.e., there is a dome-like behavior for $T_c$ and $T^*$ as a function of doping.
Next we discuss the phonon-induced interaction $H^{\text{pp}}$ between electrons, which can be written in the static limit as,

$$H^{\text{pp}} = -\frac{1}{2} \sum_{k,k'} \gamma(k) \hat{c}_k \hat{c}_{k'} \gamma(k') \hat{c}_{k'} \hat{c}_k.$$  \hspace{1cm} (5)

The prime at the summation sign means that $k - k' + k'' - k'''$ must be equal to a reciprocal lattice vector. In the following the $d$-wave part of $V(k - k')$ will be important. It is obtained by replacing $V(k - k')$ by $4 V^{d}(k) \gamma(k')$ which defines the $d$-wave coupling constant $V$ for a phonon-induced nearest-neighbor interaction.

An expression for $\alpha$ has been given in [13]. There it has also been shown that two simplifications can be made without changing the results much. First, one may neglect the influence of phonons on $T^*$. Secondly, the EP interaction yields a contribution to the pairing but also one to the quasi-particle weight $Z$. If the general question is studied of whether phonons increase or decrease $\alpha$, it is well known that the dimensionless EP coupling constant in the $s$-wave channel, $\gamma_s$, is independent of $M$. The same is then true also for $Z$. Since there is good evidence that the EP coupling in cuprates is rather small [21], we may even use in the following the approximation $Z = 1$.

Introducing a phonon cutoff $\omega_0$ and the cutoff function $\Theta_0(\omega_0 - |\omega_0|)$, the gap equation reads

$$\Delta(\mathbf{k}, i\omega_0) = -4 J \gamma(\mathbf{k}) \int_0^\infty \frac{d\omega}{\omega} \frac{N_0(\omega)}{\omega} \frac{2}{\pi} \tan \left( \frac{\omega}{2T_c} \right) - 4 V \gamma(\mathbf{k}) \Theta_0 \int_0^\infty \frac{d\omega}{\omega} \Theta_0 \gamma(\mathbf{k}') \delta(\mathbf{k}', i\omega_0').$$  \hspace{1cm} (6)

The condition for $T_c$ can be written as,

$$(1 + F_{11})(1 + F_{22}) - F_{12}^2 = 0$$  \hspace{1cm} (7)

where

$$F_{11} = -2J \int_0^\infty d\omega \frac{N_0(\omega)}{\omega} \frac{2}{\pi} \tan \left( \frac{\omega}{2T_c} \right)$$  \hspace{1cm} (8)

$$F_{12} = -2 \sqrt{JV} \int_0^\infty d\omega \frac{N_0(\omega)}{\omega} \frac{2}{\pi} \Im \left[ \psi \left( \frac{1}{2} + \frac{i\omega}{2\pi T_c} \right) - \psi \left( \frac{\omega_0}{2\pi T_c} + 1 + \frac{i\omega}{2\pi T_c} \right) \right].$$  \hspace{1cm} (9)

$$F_{22} = \sqrt{V/J} F_{12},$$

and $\psi$ is the digamma function. The $d$-wave projected density of electronic states is given by

$$N_d(\omega) = \frac{1}{N_0} \sum_k \gamma^2(k) \sum_{\alpha=1}^2 \frac{E_{\alpha}^2(k) - \epsilon^2(k) - \Phi^2(k)}{E_{\alpha}^2(k) - E_{\alpha}^2(k)} \cdot \left( \delta(\omega - E_{\alpha}(k)) + \delta(\omega + E_{\alpha}(k)) \right),$$  \hspace{1cm} (10)

with $\alpha = 3 - \alpha$, and

$$E_{1,2} = \epsilon(\mathbf{k}) \pm \sqrt{\epsilon^2(\mathbf{k}) + \Phi^2(\mathbf{k})},$$

where $E_{1,2}$ is the energy corresponding to the van Hove peak in the normal state.

Thus one expects that $N_d(\omega)$ shows a doublet with a mean energy $\epsilon(\mathbf{k}) + \Phi(\mathbf{k})$ and a splitting energy $2\epsilon^2(\mathbf{k})/\Phi(\mathbf{k})$. With increasing $\Phi$ the splitting decreases in agreement with the curves in figure 2.

The isotope coefficient $\alpha$ is defined by

$$\alpha = \frac{\omega_0}{2T_c} \frac{\partial T_c}{\partial \omega_0}.$$  \hspace{1cm} (13)

From (7) follows then

$$\alpha = -\frac{\omega_0}{2T_c} \frac{\partial T_c}{\partial \omega_0} \cdot \left( 1 + F_{12} \right) + \left( 1 + F_{11} \right) \frac{F'}{2F_{12}}.$$  \hspace{1cm} (14)

with

$$F' = \left( 1 + F_{11} \right) \sqrt{V/J} - 2F_{12}.$$  \hspace{1cm} (15)

For a weak EP coupling constant $V$, $\alpha$ reduces to

$$\alpha = \frac{\omega_0}{T_c} \frac{F_{12}}{\partial \omega_0},$$

in agreement with (18) of [13].
3. Results and discussion

3.1. YBCO

Figures 3 and 4 show $\alpha$ versus $T_c$ and $\delta$, respectively, for $V = 0.06$ and $V = 0.10$, and two phonon frequencies. $\omega_0 = 0.1$ and 0.2 corresponds to the buckling and half-breathing phonon modes in YBCO. The solid points are experimental results from [18]. They all lie in the region between the curves calculated with parameter values representative for cuprates. The above choice of parameter values for phonons is, of course, unproblematic. More controversial may be the employed values for the EP coupling constants. First principles calculations of total EP constants have been described in [21]. The results are given in terms of dimensionless coupling constants $\lambda_s$ and $\lambda_d$ for the $s$- and $d$-wave channel, respectively. For each channel, $\lambda$ and $V$ are related by $\lambda = VN(0)$, where $N(0)$ is the density of electronic states at the Fermi energy in the corresponding symmetry channel. LDA calculations yield for YBa$_2$Cu$_3$O$_7$ $\lambda_s \sim 0.24$ and $\lambda_d \sim 0.022$ [21]. These values are rather small, particularly, the value for $\lambda_d$. On the other hand there is good evidence from several experiments that such small values are not unreasonable: Angle-resolved photoemission data in LSCO [15, 28] yielded $\lambda_s \sim 0.4$. Similarly, superconductivity-induced shifts of zone center phonons are in good agreement with calculated LDA values [29, 30] and therefore with such small EP coupling constants. In figures 3 and 4 only EP coupling constants in the $d$-wave channel enter, for which we used $V = 0.06$ and 0.10, which are slightly larger than the LDA values. They describe the experimental points somewhat better than the bare LDA values. One should keep in mind that such adjustments (from $\lambda_d \sim 0.02$ to $\lambda_d \sim 0.04$) should be considered as minor, because we always stay in the region of very small EP couplings.

It is worth remarking that the observed increase of $\alpha$ in the underdoped region of YBCO can be quantitatively explained not only by employing such small values for the EP coupling constants but by noting that a reasonable agreement between experiment and theory requires them. As discussed above the large isotope effect found in underdoped cuprates has been interpreted as evidence for a strong EP coupling in these systems. From the above analysis the conclusion is quite different: The large observed isotope shifts in underdoped cuprates are the result of a competition of superconductivity with another ground state which produces the pseudogap. They can be explained using the small $d$-wave EP coupling constant obtained in the LDA calculations. Figures 3 and 4 demonstrate this for the case of a $d$-CDW state as a competing state, but we expect similar results for other ground states, as long as they are associated with a gap or a pseudogap.

The above calculations indicate that a pseudogap and the associated shift of the density of states from low to high energies are responsible for the strong increase of $\alpha$ in the underdoped regime. It is, however, clear that a reduction of $N_d(0)$ alone cannot increase $\alpha$ as long as $N_d(\omega)$ is constant on the scale of $\omega_0$. It is therefore interesting to analyze the above equations in more detail and to find out what exactly causes the increase in $\alpha$. For the following analytical results we will assume that the density of states $N_d(\omega)$ can be considered either as constant or that $T_c$ is sufficiently low; i.e., we will consider the overdoped or the strongly underdoped regions. It also will be sufficient to consider the expression (16) for $\alpha$, which is valid for a weak EP coupling.

The derivative in the denominator of (16) may be approximated as

$$\frac{\partial F_{11}}{\partial T_c} = \frac{J}{T_c} \int_0^\infty \frac{d\epsilon N_d(2\epsilon T_c)}{\cosh^2(\epsilon)} \approx \frac{J}{T_c} N_d(0).$$

The term $F_{12}$ can be written as

$$F_{12} = -2\sqrt{VJ} \int_0^\infty d\epsilon N_d(\epsilon) \left[ T_c \sum_{\nu} \frac{1}{\omega_\nu^2 + \epsilon^2} \right]$$

$$= T_c \sum_{\nu} \frac{1}{\omega_\nu^2 + \epsilon^2}$$

$$- T_c \sum_{\nu} \frac{1}{\omega_\nu^2} \omega_\nu^2 + \epsilon^2.$$

\[ (17) \]
Let us write $F_{12}$ as

$$F_{12} = \sqrt{V J \left( F_{12}^{(1)} + F_{12}^{(2)} \right)}, \quad (19)$$

with

$$F_{12}^{(1)} = \int_0^\omega 0 d\epsilon \frac{N_\delta (\epsilon)}{\epsilon} \tanh \left( \frac{\epsilon}{2T_c} \right), \quad (20)$$

$$F_{12}^{(2)} = \int_0^\infty d\epsilon \frac{N_\delta (\epsilon)}{\epsilon} \tanh \left( \frac{\epsilon}{2T_c} \right) - \int_0^\infty \frac{N_\delta (\epsilon)}{\omega_0} \arctan \left( \frac{\omega_0}{\epsilon} \right). \quad (21)$$

In the last term in (21) the zero-temperature limit has been taken. The derivative $\frac{\partial F_{12}^{(2)}}{\partial \omega_0}$ acts only on the last term in $F_{12}^{(2)}$, yielding

$$\frac{\partial F_{12}^{(2)}}{\partial \omega_0} = -\int_0^\infty d\epsilon \frac{N_\delta (\epsilon)}{\epsilon} \frac{\omega_0}{\omega_0^2 + \epsilon^2}. \quad (22)$$

Inserting the above results into (16) gives

$$\alpha = -\frac{\omega_0 V}{N_\delta (0)} \frac{F_{12}}{\sqrt{V J}} \int_0^\infty d\epsilon \frac{N_\delta (\epsilon)}{\omega_0 + \epsilon^2}. \quad (23)$$

Numerical evaluation of (18) shows that $F_{12}$ is practically constant as a function of doping above optimal doping and only very slowly increasing towards lower dopings. Thus we may consider $F_{12}$ in (23) as a constant. As a result we obtain for the increase of $\alpha$ relative to its value $\alpha_0$ at optimal doping, i.e., at the onset of the CDW,

$$\alpha/\alpha_0 = \frac{2}{\pi} \int_0^\infty d\epsilon \frac{\omega_0}{\omega_0^2 + \epsilon^2} \frac{N_\delta (\epsilon)}{N_\delta (0)}. \quad (24)$$

The above formula allows us to understand the large increase of $\alpha$ in the underdoped regime. Near optimal doping $N (\epsilon)$ depends only weakly on frequency so that the density ratio $N_\delta (\omega)/N_\delta (0)$ and, therefore, also $\alpha/\alpha_0$ is near 1. Below optimal doping the spectral weight is shifted from low to high frequencies, which produces the pseudogap. As a result the ratio $N_\delta (\omega)/N_\delta (0)$ is large around the pseudogap, leading to large values for $\alpha/\alpha_0$. Since $N_\delta (0)$ is roughly proportional to $\delta$, $\alpha/\alpha_0$ increases monotonically with decreasing doping, yielding values which may exceed by far the canonical BCS value of 1/2. Taking the limit $\omega_0 \to 0$ in (24), the first factor under the integral becomes a delta function, and we obtain $\alpha/\alpha_0 = 1$. The absence of an enhancement of $\alpha$ for small $\omega_0$ can easily be understood: The main part in the integral in (24) comes from the region of small $\epsilon$, well below the pseudogap, where $N_\delta (0)$ is small. The contribution from electronic spectral density shifted to the frequency region around the gap is missing, and no substantial enhancement of $\alpha$ can occur. This case also shows that the reduction of $N_\delta (0)$ due to the formation of the gap does not cause an increase of $\alpha$ by itself. Instead the shift of spectral weight from low to high frequencies near the pseudogap is responsible for the increase of $\alpha$. For large phonon frequencies, $\alpha/\alpha_0$ decreases with increasing $\omega_0$. Thus one expects that $\alpha/\alpha_0$ as a function of $\omega_0$ first increases, passes then through a maximum, and finally decreases. The curves in figure 5, calculated with the full expressions for the functions $F$, illustrate nicely this behavior.

In the overdoped region one may assume that the density of states $N_\delta (\epsilon)$ is constant. The approximations leading to (24) imply then $\alpha = \alpha_0$ throughout the overdoped region. A better approximation in this region is obtained by using $\omega_0$ as the cutoff in the energy integration in $F_{12}$. The two terms in $F_{12}^{(2)}$ cancel then exactly, and $F_{12}^{(1)}$ can be evaluated as in the usual BCS theory, yielding

$$\alpha = \frac{\pi \lambda_d}{2} \log \left( \frac{1.14 \omega_0}{T_c} \right). \quad (25)$$

A similar result has been first derived in [31]. For optimal doping where $T_c$ is highest, $\alpha$ shows a minimum with a value which for $T_c > 1.14 \omega_0$ is weakly negative. For more realistic parameter values the logarithmic factor is about 1, and thus $\alpha \approx \lambda_d$. The observed small values $\alpha_0 \sim 0.05$ in cuprates with the highest $T_c$ do require similar values for $\lambda_d$ in good agreement with the values obtained from the LDA calculations. Our analytical expressions for $\alpha$ in the under- and overdoped region used $\omega_0$ as a cutoff, but one time along the imaginary and one time along the real axis. Taking the cutoff always along the real axis is not suitable in the underdoped region, because if the density peak in $N_\delta (\omega)$ coincides with the phonon frequency, one obtains a spurious peak in the curve $\alpha$ versus $\delta$. Using the cutoff along the imaginary axis we never found such an artifact and therefore used this choice of cutoff in all our numerical calculations.

The inset of figure 5 shows $\alpha$ versus $\delta$, calculated without approximations, over a large doping region. In the overdoped region this function increases roughly as predicted by (25). A closer look reveals, however, that both the analytic expressions (24) for the underdoped regime and, to a lesser degree, (25) for the overdoped regime do not well agree with the numerically evaluated curves. One reason is that our model $N_\delta (\omega)$ in equation (17) varies in the energy interval $[0, 2T_c]$ considerably so that the approximation proposed in that equation is problematic. Band structure effects thus play a role in our model, even at low energies, producing...
fluctuations in the curve \( \alpha \) versus \( \delta \) if calculated with (24). In the numerically exact calculated curves in figures 3–5, such fluctuations are absent due to a properly carried out energy integration in (17). Though (24) and (25) are thus not suitable to obtain accurate values, they nevertheless explain correctly the curves \( \alpha \) versus \( \delta \) at low and high dopings.

3.2. La- and Ba-doped \( \LaCuO \)

Our theory can also be applied to Sr- and Ba-doped \( \LaCuO \). \( \LaCuO \) shows a variety of phase transitions near the doping \( \delta = 1/8 \) [32]. \( T_c \) exhibits a dip between \( \delta_1 = 0.155 \) and \( \delta_2 = 0.095 \), which nearly touches zero at \( \delta = 0.125 \) [32, 33]. Between these limiting dopings a leading-phase CO with charge stripe order extends towards higher temperatures above the superconducting phase in a domelike manner, touching \( T_c \) at the end points. There are additional phases of spin stripe order or of orthorhombic or tetragonal symmetry present, which will be disregarded in the following. Above \( \delta_1 \) or below \( \delta_2 \), \( T_c \) is decreasing with increasing distance from these points, reaching very small values near \( \delta = 0.25 \) and 0.05, respectively. The phase diagram of the sister compound LSCO does not contain long-ranged phases around the doping 1/8. Nevertheless it is probable that superconductivity competes with phases in the particle–hole channel near this doping, because \( T_c \) shows a pronounced dip in this region [5, 6]. Also angle resolved photoemission experiments find in LSCO a pseudogap that sets in at around \( \delta = 0.20 \), and exists and increases in magnitude towards lower dopings. The isotope coefficient in LSCO (see figure 6) is very small at the large doping value of 0.20, where the pseudogap forms. With decreasing \( \delta \), \( \alpha \) first increases slightly and then very rapidly, reaching a maximum near the doping 1/8 with a value of about 1. Decreasing \( \delta \) further, \( \alpha \) decreases but settles down in the region of about 0.5.

In view of the above phase diagrams and the behavior of \( \alpha \) in LSCO, it is natural to assume that the doping dependence of \( T_c \) and \( \alpha \) are caused by gaps or pseudogaps similar to those in YBCO. In order to transfer our results from YBCO to \( \LaCuO \) and LSCO, we consider the calculated \( \alpha \) in YBCO as a function of \( T_c/T_{c,0} \), where \( T_{c,0} \) is the optimal \( T_c \) for a doping near the onset of the pseudogap. Treating first \( \LaCuO \), we can read off from figure 2 of [33] the doping as a function of \( T_c/T_{c,0} \), where \( T_{c,0} \) is the value of \( T_c \) near the dopings \( \delta_1 \) or \( \delta_2 \). Identifying the two ratios for the reduction of \( T_c \), one obtains \( \alpha \) as a function of doping in \( \LaCuO \). The same procedure can be applied to LSCO. From figure 3 in [6] one can read off \( \alpha \) as a function of \( T_c/T_{c,0} \), where \( T_{c,0} \) is the largest transition temperature near \( \delta = 0.15 \). Comparing this reduction ratio with the case of YBCO, one finds the doping dependence of \( \alpha \) in LSCO. Figure 6 contains the obtained curves, calculated for \( V = 0.1 \) and \( \omega_0 = 0.1 \), together with experimental values for LSCO from [5]. Our calculation suggests the following interpretation of the experimental \( \alpha \) in LSCO. One has to distinguish between two pseudogaps in LSCO. The first one is the usual pseudogap, which is observed by angle-resolved photoemission and which exists below \( \delta \approx 0.20 \) [34]. This pseudogap corresponds to that occurring in underdoped cuprates and develops at \( T^* \). At low doping, superconductivity competes with the phase underlying the pseudogap, leading to the overall decrease of \( T_c \) down to very low values near \( \delta = 0.05 \). At the same time this decrease of \( T_c \) is associated with a monotonic increase of \( \alpha \) similar to that in YBCO. The second pseudogap is located between \( \delta = 0.10 \) and \( \delta = 0.15 \) and is due to static (in \( \LaCuO \)) or fluctuating (in LSCO) stripes. As a result \( T_c \) is strongly (in \( \LaCuO \)) or slightly (in LSCO) suppressed. Correspondingly, the increase of \( \alpha \) in figure 6 is large for the Ba- and small for the Sr- doped systems. It is interesting to see that the calculated curve for LSCO shows only a small peak at doping 1/8, quite in contrast to the experimental curve. The reason for this is that the employed experimental \( T_c \) curve exhibits only a small dip near the doping 1/8. One prediction of our calculation is that \( \alpha \) in \( \LaCuO \) should show a large peak near doping 1/8. Though our calculation for \( \alpha \) in LSCO is not able to get quantitative agreement with experiment, we think that the shift of the spectral weight from low to higher energies associated with the formation of the pseudogap plays also a role in LSCO.

Finally we would like to mention that strong renormalizations (softenings and broadenings) of phonons have been observed in underdoped cuprates (see [35] and references therein). These anomalies occur for wave vectors along the crystalline axis with a length of about 0.3 and are seen both in acoustical [36] and optical bond-stretching phonons [37]. They are probably related to the recently observed charge order in these systems [36]. On the other hand, extensive LDA calculations, performed for \( \text{YBa}_2\text{Cu}_3\text{O}_y \), did not yield unusual softenings [21, 38] and cannot explain these phonon anomalies. However, our main result is independent of the validity of the LDA in cuprates and shows only that the observed large values of \( \alpha \) in underdoped cuprates are at least compatible with the LDA values for the EP coupling constants. The existence of the above phonon anomalies suggests
that it is not possible to conclude quite generally from these and other successful LDA results [29, 30] that the EP coupling is necessarily small in the cuprates. Thus, the correct explanation of the phonon anomalies is presently an open problem and beyond the scope of our paper, similarly to their influence on \( T_c \).

4. Conclusions

In summary, our calculations of the isotope coefficient \( \alpha \) were based on a mean-field, like treatment of the \( t-J \) model, where optimal doping coincides with the onset of a CDW, which competes with superconductivity in the underdoped regime and suppresses \( T_c \) there. Adding phonons and the EP coupling, our model can explain the strong experimental increase of \( \alpha \) in the underdoped region, using at the same time the small EP coupling constants from the LDA. Thus we conclude that the large values for \( \alpha \) in the underdoped regime give no evidence for a large EP coupling in these systems but are compatible with the small LDA values once the competing phase is taken into account. Large enhancements of \( \alpha \) are found if the phonon energy \( \omega_{\text{ph}} \) and the gap \( \Phi \) are comparable in magnitude and are absent for very small or large ratios \( \omega_{\text{ph}}/\Phi \). Our explanation of the behavior of \( \alpha \) is supported by several experimental facts: \( \alpha \) assumes its minimum at optimal doping, where the competing phase sets in, and strongly increases towards lower dopings in the presence of the competing phase; in this region superconductivity forms from a state where the density of electronic states varies strongly over the scale of phonon energies, which is quite different from the normal state. All these features make, in our opinion, explanations very improbable that are based on a strong EP interaction, polarons, or anharmonic mechanisms.

Acknowledgments

The authors thank P Horsch and M Bejas for a critical reading of the manuscript. R Z and A G are grateful to the Instituto de Física (Rosario) and the MPI-FKF (Stuttgart), respectively, for hospitality and financial support. The authors are in particular grateful to the late Manuel Cardona for many enlightening and stimulating discussions on high-\( T_c \) superconductors.
