Abstract

We report a measurement of the first and second moment of the hadronic mass distribution $M_X$ in $B \to X_c \ell \nu$ decays for lepton threshold momenta ranging from 0.9 to 1.6 GeV/c in the center of mass frame. The measurement uses $B \bar{B}$ events in which the hadronic decay of one $B$ meson is fully reconstructed and a charged lepton from the decay of the other $B$ meson is identified. These results are obtained from a 140 fb$^{-1}$ data sample collected near the $\Upsilon(4S)$ resonance with the Belle detector at the KEKB asymmetric energy $e^+e^-$ collider.

PACS numbers: 13.20.He,14.40.Nd
The heavy quark effective theory (HQET) combined with the operator product expansion provides a framework in which inclusive $B$ decay properties can be calculated. In particular, the moments of various inclusive quantities in $B \rightarrow X_c \ell \nu$ decays, such as the lepton momentum $p_\ell$, the 4-momentum transfer squared $q^2$ and the hadronic recoil mass $M_X$, can be related to the non-perturbative parameters that also appear in calculations of the semileptonic decay rate (see Ref. [1, 2, 3] for calculations of the moments of $M_X$). Measurements of these moments can thus improve calculations of the semileptonic $B$ decay rate and lead to a more precise determination of the magnitude of the Cabibbo-Kobayashi-Maskawa (CKM) matrix element $V_{cb}$ [4]. In this paper, we present a measurement of the first and second moment of $M_X$, $\langle M_X \rangle$ and $\langle M_X^2 \rangle$, for lepton momentum thresholds ranging from 0.9 to 1.6 GeV/c in the center-of-mass (c.m.) frame.

The analysis is based on the data recorded with the Belle detector [5] at the asymmetric energy $e^+e^-$ collider KEKB [6], operating at a c.m. energy near the $\Upsilon(4S)$ resonance. KEKB consists of a low energy ring (LER) of 3.5 GeV positrons and a high energy ring (HER) of 8 GeV electrons. The Belle detector is a large-solid-angle magnetic spectrometer consisting of a three-layer silicon vertex detector (SVD), a 50-layer central drift chamber (CDC), an array of aerogel threshold Čerenkov counters (ACC), a barrel-like arrangement of time-of-flight scintillation counters (TOF), and an electromagnetic calorimeter comprised of CsI(Tl) crystals (ECL) located inside a super-conducting solenoid coil that provides a 1.5 T magnetic field. The responses of the ECL, CDC ($dE/dx$) and ACC detectors are combined to provide clean electron identification. Muons are identified in the instrumented iron flux-return (KLM) located outside of the coil. Charged hadron identification relies on the information from the CDC, ACC and TOF sub-detectors.

The $\Upsilon(4S)$ dataset used for this study corresponds to an integrated luminosity of 140 fb\(^{-1}\), or about 152 million $B\bar{B}$ events. Another 15 fb\(^{-1}\) taken 60 MeV below the resonance are used to subtract the non-$B\bar{B}$ background. Full detector simulation based on GEANT [7] is applied to Monte Carlo (MC) simulated events. The size of the MC samples is equivalent to about three times the integrated luminosity. The decay $B \rightarrow D^*\ell\nu$ is simulated using a HQET-based model [8]. The ISGW2 model [9] is used for the decays $B \rightarrow D\ell\nu$ and $B \rightarrow D^{*\ast}\ell\nu$. The non-resonant $B \rightarrow D^{(*)}\pi\ell\nu$ component is generated according to the model of Goity and Roberts [10].

We use $B\bar{B}$ events in which the hadronic decay of one $B$ meson is fully reconstructed ($B_{\text{tag}}$) and the semileptonic decay of the recoiling $B$ meson ($B_{\text{signal}}$) is inferred from the presence of a charged lepton (electron or muon). After selecting hadronic events [11], we reconstruct $B_{\text{tag}}$ by searching the decay modes $B^+ \rightarrow D^{(*)0}\pi^+, D^{(*)0}\rho^+, D^{(*)0}a_1^+$ and $B^0 \rightarrow D^{(*)-}\pi^+, D^{(*)-}\rho^+, D^{(*)-}a_1^- + [12]$. Pairs of photons satisfying $E_\gamma > 50$ MeV and $117$ MeV/$c^2 < m(\gamma\gamma) < 150$ MeV/$c^2$ are combined to form $\pi^0$ candidates. $K^0_S$ mesons are reconstructed from pairs of oppositely charged tracks with invariant mass within $\pm 30$ MeV/$c^2$ of the $K^0_S$ mass and decay vertex displaced from the interaction point. Candidate $\rho^+$ and $\rho^0$ mesons are reconstructed in the $\pi^+\pi^0$ and $\pi^+\pi^-$ decay modes, requiring their invariant masses to be within $\pm 150$ MeV/$c^2$ of the $\rho$ mass. Candidate $a_1^+$ mesons are obtained by combining a $\rho^0$ candidate with a charged pion and requiring an invariant mass between 1.0 and 1.6 GeV/$c^2$. $D^0$ candidates are searched for in the $K^-\pi^+, K^-\pi^+\pi^0, K^-\pi^+\pi^+\pi^-$, $K^0_S\pi^+\pi^-$ and $K^0_S\pi^0$ decay modes. The $K^-\pi^+\pi^+$ and $K^0_S\pi^+$ modes are used to reconstruct $D^+$ mesons. Charmed mesons are selected in a window corresponding to $\pm 3$ times the mass resolution in the respective decay mode. $D^{*+}$ mesons are reconstructed by pairing a charmed meson with a low momentum pion, $D^{*+} \rightarrow D^0\pi^+, D^+\pi^0$. The decay modes $D^{*0} \rightarrow D^0\pi^0$...
FIG. 1: Reconstruction of the tag-side \( B \) meson. The \( M_{bc} \) distribution after requiring \( \Delta E < 50 \) MeV is shown for fully reconstructed (a) \( B^+ \) (b) \( B^0 \) decays. The fit uses a Gaussian function for the signal and an ARGUS background function \( [14] \) for the combinatorial background.

Semileptonic decays of \( B_{\text{signal}} \) are selected by requiring exactly one identified charged lepton among the particles that are not associated to \( B_{\text{tag}} \). In the lepton momentum range relevant to this analysis, electrons (muons) are selected with an efficiency of 92% (89%) and the probability to misidentify a pion as an electron (a muon) is 0.25% (1.4%) \( [15, 16] \). For \( B^+ \) tags, we require \( Q_\ell \cdot Q_B < 0 \), where \( Q_\ell \) and \( Q_B \) are the charges of the lepton and of \( B_{\text{tag}} \), respectively.

The charged tracks and neutral clusters which are associated neither with \( B_{\text{tag}} \) nor with the charged lepton are assigned to the hadronic \( X \) system. The 4-momenta of the charged particles are calculated with the pion mass except for identified kaons. The missing 4-momentum in the event is calculated,

\[
p_{\text{miss}} = (p_{\text{LER}} + p_{\text{HER}}) - p_{B_{\text{tag}}} - p_\ell - p_X ,
\]

where the indices LER and HER refer to the colliding beams. As only the neutrino in
$$B \to X_c \ell \nu$$ should be missing in the event, we require the missing mass to be consistent with zero, \(|M_{\text{miss}}^2| < 2 \text{ GeV}^2/c^4\).

The neutrino 4-momentum is inferred from the missing momentum, \(p_\nu = (|\vec{p}_{\text{miss}}|, \vec{p}_{\text{miss}})\), and the 4-momentum of the \(X\) system is recalculated,

$$p'_X = (p_{\text{LER}} + p_{\text{HER}}) - p_{\text{B-tag}} - p_\ell - p_\nu.$$  \hspace{1cm} (3)

The \(M_X\) resolution (defined as half width at the half maximum) obtained with this procedure is about 200 MeV/c².

The background consists of the following components: combinatorial background in the \(B_{\text{tag}}\) sample, background from secondary or misidentified leptons, and background from non-\(B \bar{B}\) events. The combinatorial background is dominant. Its shape (in \(M_X\) and \(M_{2X}^2\)) is determined from the MC simulation, and the \(M_{\text{bc}}\) side-band region (5.2 GeV/c² < \(M_{\text{bc}}\) < 5.27 GeV/c², \(|\Delta E| < 50\) MeV) is used to determine its normalization, separately for each lepton momentum threshold. The background from secondary or misidentified leptons is significant in the low lepton momentum region. Its shape is estimated from the MC simulation, and the number of well-reconstructed \(B_{\text{tag}}\) candidates is used for its normalization. The magnitude of the background from misidentified leptons is corrected using the pion misidentification rate measured in \(K^0_S \to \pi^+ \pi^-\) decays in hadronic events. The background from non-\(B \bar{B}\) events is smallest, and it is subtracted using the data taken 60 MeV below the \(\Upsilon(4S)\) resonance. Fig. 2 shows the \(M_X\) distributions for different minimum lepton momenta in the c.m. frame, together with the background estimation.

To correct for the distortions caused by finite detector resolution, the background-subtracted \(M_X\) and \(M_{2X}^2\) distributions are unfolded using the Singular Value Decomposition (SVD) algorithm [17]. The approach consists in describing the detector response by a correlation matrix between the true and the reconstructed \(M_X\) (\(M_{2X}^2\)) values which is determined
from the MC simulation. This matrix is decomposed into its eigenvalue components, and only the contributions leading to a statistically stable solution are kept. For the unfolding of the $M_X$ ($M_X^2$) distribution, the measured spectrum is divided into 35 (39) 0.1 GeV/$c^2$ (0.333 GeV/$c^4$) wide bins. For the unfolded distribution, 12 (13) bins are used.

For each minimum lepton momentum, ranging from 0.9 to 1.6 GeV/$c$, the background-subtracted $M_X$ and $M_X^2$ distributions are unfolded, separately for $B^+$ and $B^0$ tags, and for electron and muon events. For each of these four sub-samples, the values of $\langle M_X \rangle$ and $\langle M_X^2 \rangle$ are obtained by calculating the mean values of the unfolded $M_X$ and $M_X^2$ distributions. The results obtained by averaging the four sub-sample results are shown in Fig. 3 and Tables I and II. All results are preliminary. This procedure has been tested on MC simulated events for the full minimum lepton momentum range and no significant bias has been found.

We consider three sources of systematic error, shown separately in columns three to five of Tables I and II: uncertainty related to detector modeling and residual background subtraction, uncertainty related to the unfolding procedure, and uncertainty related to the $X_c$ model in the MC simulation. The total systematic error quoted on the moments corresponds to the quadratic sum of these three components.

The uncertainty related to the detector modeling and to the background subtraction is estimated from the consistency between the four sub-samples, by varying the selections used in the analysis (namely the $B_{\text{tag}}$ signal region and the requirement on $M_{\text{miss}}^2$), and by varying the background normalization. The uncertainty related to the unfolding procedure is estimated by changing the number of eigenvalue components in the unfolding solution. The $X_c$ model uncertainty is obtained by varying the fractions of $B \to D^* \ell \nu$, $B \to D \ell \nu$ and $B \to D^{(*)} / D^{(*)} \pi \ell \nu$ within ±10%, ±10% and ±30%, respectively, and summing the individual variations in quadrature. These ranges of variation roughly correspond to the experimental uncertainties [18] in the isospin averaged branching ratios.

In summary, we have performed a measurement of the first and second moment of the
hadronic mass distribution $M_X$ in $B \to X_c \ell \nu$ decays for minimum lepton momenta ranging from 0.9 to 1.6 GeV/$c$ in the c.m. frame. The results listed in Tables I and II are compatible with recent values from other experiments [20, 21]. It is expected that this measurement (combined with measurements of the semileptonic branching fraction and of the moments of the lepton spectrum in $B \to X_c \ell \nu$) will lead to an improved determination of the CKM matrix element $|V_{cb}|$.
