Titania nanosheets (TNSs) are expected to lead to higher photocatalytic performance than bulk TiO₂ because its high reactivity arises from the two-dimensional structure. While their electronic properties are considered to be easily affected by structural vacancies, the effects of vacancies in TNSs on the photocatalytic performance are not clear. In order to study them, we have performed first-principles molecular dynamics simulations for structure models of TNSs with several vacancies. First, we have calculated the electronic density of states and bandgap energies. It has been found that the electronic density of states for TNSs with Ti vacancies are larger than for anatase. This tendency is consistent with the experimentally observed relationship of the Ti vacancy on the electronic structure of TNSs.

I. INTRODUCTION

Titania dioxide (titania, TiO₂) photocatalysts have been intensively researched because they exhibit valuable photocatalytic properties, as typified by the harmful substance decomposition function [1], associated with ultraviolet absorption. While two crystal structures of rutile and anatase have been studied so far, titania nanosheets (TNSs) attract much interest recently. TNSs show high reactivity because their two-dimensional structure has more reactive sites [2]. In addition, TNSs allow us to design new lightweight, flexible and high-performance functional materials because their thinness permits them to be laminated with other films. For example, an enhancement of the photochemical activity of TNSs due to layer-by-layer integration with reduced graphene oxides has been reported [3]. For these reasons, it has been considered that TNSs are a strong candidate for a next-generation photocatalytic material.

The chemical formula of TNS is known to be Ti₉₀.₇₇O₂, which is synthesized by the delamination from a lepidocrocite-type parent layered K₀.₈₇Ti₁.₇₃Li₀.₂₇O₄₂ crystal [4]. Thus, the presence of 13% Ti vacancies is expected. Actually, the Ti vacancies have been directly observed by transmission electron microscopy (TEM) [5]. However, the effects of the Ti vacancies on the photocatalytic activity have not been revealed yet. In order to elucidate them, it is essential to examine the electronic ground and excited states of TNSs with the Ti vacancies.

With regard to atomic structures around the Ti vacancies, it has been suggested that two 1-fold coordinated O atoms around the Ti vacancies tend to be removed [5]. However, the atomic configurations around the Ti vacancies have not been definitely determined yet. In this study, we have performed first-principles molecular dynamics (MD) simulations for several structure models of TNSs with a Ti vacancy, and investigated the effects of the Ti vacancy on the electronic structure of TNSs.

II. COMPUTATIONAL METHODS

A. Numerical details

Adiabatic electronic states were calculated in the framework of the density functional theory (DFT) [6] using the projector-augmented-wave (PAW) method [7], which is an all-electron electronic-structure-calculation method within the frozen-core approximation. The generalized gradient approximation (GGA) was used for the exchange-correlation energy [8]. The plane-wave cutoff energies are 30 and 250 Ry for the electronic pseudowave functions and the pseudo charge density, respectively. The DFT plus Hubbard U model (DFT+U) was employed in our calculations with U_{eff} = 4.2 eV [9]. We used the Γ point for Brillouin zone sampling.

In nonadiabatic MD simulations, electronic transitions were treated by fewest-switches surface-hopping (FSSH) method along with the Kohn-Sham (KS) representation of time dependent DFT (TDDFT). We calculated the time evolution of the density matrix with fixed atomic configuration between MD steps [10]. The elements of the density matrix determine the switching probability between

FIG. 1. Optimized structures in three models. The pink, red, and white spheres represent Ti, O, and H atoms, respectively. (a) Perfect model has no vacancy. In (b) TiV-H model, one Ti atom is removed and four O atoms around the Ti vacancy are terminated by H atoms. In (c) TiO\textsubscript{2}V model, one Ti and two 2-fold coordinated O (O\textsubscript{2-fold}) atoms bonding to the Ti atom are removed.

the adiabatic states that are expressed by a single Slater determinant. To estimate the many-body correction, we used a linear-response TDDFT of Casida [11].

We have performed simulations for the monolayer TNSs in a supercell of a dimension of 11.4×18.5×10.0 Å\textsuperscript{3}, under periodic boundary conditions. The TNS with no vacancy consists of 36 Ti and 72 O atoms. We introduced a vacuum region in the z direction to avoid an interaction between TNSs. MD simulations were carried out at 300 K, as controlled by a Nosé-Hoover thermostat. The computation times were 1210 fs and 605 fs for adiabatic and non-adiabatic calculations, respectively.

B. Structure models

We have used three models of TNSs as displayed in Fig. 1. Figure 1(a) shows the optimized structure without vacancies (Perfect model). Figures 1(b) and 1(c) show the optimized structures with vacancies. In Fig. 1(b), one Ti atom is removed and four O atoms around the Ti vacancy are terminated by H atoms (TiV-H model). In Fig. 1(c), one Ti atom and two 2-fold coordinated O (O\textsubscript{2-fold}) atoms bonding to the Ti atom are removed (TiO\textsubscript{2}V model). As described in Introduction, the chemical composition of Ti\textsubscript{0.87}O\textsubscript{2} has been expected from the synthesis method. However, we focus on charge neutral systems in this study, as the TEM experiments [5] have suggested that O atoms around a Ti vacancy tend to be removed, which may justify the TiO\textsubscript{2}V model. The charged systems with a deficiency of Ti atoms will be studied in our future work.

In addition, we calculated the electronic states of bulk anatase to compare them with TNSs. The local structures of TNSs and bulk anatase differ from each other in the coordination number of O atoms. In bulk anatase, each O atom is coordinated to three Ti atoms. On the other hand, in TNSs, there are two types of O atoms (see Fig. 1).

One exists at the top or the bottom of a TNS, and is two-fold coordinated to Ti atoms. The other exists in the middle of the TNS, and is four-fold coordinated to Ti atoms. In both TNSs and bulk anatase, all Ti atoms are six-fold coordinated to O atoms.

III. RESULTS AND DISCUSSION

A. Energetic stability

To discuss the physical properties of the structure models, it is important to estimate the relative stability of each model. The defect formation energy $E_d$ for the TiO\textsubscript{2}V model can be estimated by subtracting the energy per formula unit of the Perfect model from that of the TiO\textsubscript{2}V model. The value of $E_d$ was obtained to be 3.6 eV, which confirms that the Perfect model is more stable than the TiO\textsubscript{2}V model, though Ti vacancies are introduced in TNSs due to the synthesis method as observed in the TEM experiments [5]. The comparison of the energetic stability between the TiV-H and TiO\textsubscript{2}V models is also possible by calculating the energy gain or loss of the reaction, in which the TiO\textsubscript{2}V model reacts with two H\textsubscript{2}O molecules to form the TiV-H model. We found that this reaction has the energy gain of 3.0 eV, which indicates that the TiV-H model is more stable than the TiO\textsubscript{2}V model. As explained in Section II.B, the TiO\textsubscript{2}V model seems to be consistent with the observation of the TEM experiments [5]. In our calculations, we did not consider the energy barriers for the reactions, which may be important to discuss which structure actually appears, and will be studied in our future work.
FIG. 2. Electronic density of states. The dotted line indicates the Fermi level.

TABLE I. Calculated bandgap energies $E_g$ in the models studied.

| Model     | $E_g$ (eV) |
|-----------|------------|
| Anatase   | 2.68       |
| Perfect   | 3.36       |
| TiV-H     | 3.38       |
| TiO$_2$V  | 3.07       |

B. Electronic density of states

In order to study the electronic ground states, we have calculated the electronic density of states (EDOS) and bandgap energies $E_g$ for each structure model and bulk anatase. The calculated EDOS and $E_g$ are shown in Fig. 2 and Table I, respectively. The similarity of EDOS and $E_g$ between the TiV-H and Perfect models indicates that the TiV-H model has a similar electronic structure to the Perfect model. This is due to few dangling bonds in the TiV-H model. It has been reported from electrochemical and photochemical measurements that $E_g$ of TNSs (3.8 eV) is larger than anatase (3.2 eV) [2]. We, therefore, conclude that the atomic configurations around the Ti vacancies in both the TiV-H and TiO$_2$V models, as well as the atomic configuration in the Perfect model, are reasonable in the sense that their $E_g$ values are larger than anatase.

C. Recombination time

A recombination time of a hole and an excited electron is known as an indicator to evaluate the photocatalytic activity. We have estimated the recombination time $\tau$ from the Fermi’s golden rule as:

$$\tau = \left\{ \frac{2\pi}{\hbar} |\langle \psi_h |H'| \psi_e \rangle|^2 \delta (E_h - E_e) \right\}^{-1},$$

where $\hbar$ is the Planck’s constant, $H'$ is a non-time-dependent perturbation, and $\psi_e$ and $\psi_h$ are the electronic wave functions of the excited electron and the hole, respectively. $E_e$ and $E_h$ are the energy eigenvalues corresponding to $\psi_e$ and $\psi_h$, respectively.

Table II shows that $\tau$ of the TiO$_2$V model is the longest, and $\tau$ of the Perfect model is the shortest. It would be considered that $\tau$ of TNSs with vacancies would be shorter than the Perfect model because the vacancies might be recombination sites. However, our results are different from this consideration. In order to clarify the difference, we have investigated the spatial distribution of the hole and the excited electron.

D. Inverse participation ratio

To evaluate the localization of the hole and the excited electron, we have calculated inverse participation ratio (IPR) [12], which is given by the following equation:

$$\text{IPR}(n) = \sum_{i=1}^{N} q_i(n)^2 , \quad (n = \text{hole, electron}),$$

where $N$ is the number of atoms, and $q_i$(hole) and $q_i$(electron) are Mulliken charges at an atomic site $i$ obtained from the wave functions of the hole and the excited electron, respectively. IPR = 1 and IPR = 1/N represent perfectly localized and uniformly extended states, respectively. The calculated IPR values are listed in Table III.

Additionally, we have visualized the wave functions of the hole and the excited electron to clarify their spatial distribution, as shown in Table III. We see, from Table III, that the hole and the excited electron in the TiO$_2$V model are the most localized, and those in the Perfect model are the most delocalized. This order is the same as the recombination time. The localized hole and electron in the TiO$_2$V model are trapped at the atoms around the Ti vacancy and spatially separated. Consequently, it is considered that the recombination time of TNSs with vacancies becomes longer than the Perfect model.

IV. CONCLUSION

In this study, the electronic structures of TNSs with vacancies have been investigated based on first-principles MD simulations. The obtained results are the following.

1. The TiV-H model has similar electronic structure to...
TABLE III. Calculated IPR(hole) and IPR(electron) for each model. In snapshots, the isosurfaces ($\pm 0.01$ a.u.) of wave functions of the hole and the electron are shown in yellow and blue, respectively.

|            | Perfect | TiV-H  | TiO$_2$V |
|------------|---------|--------|----------|
| IPR(hole)  | 0.22    | 0.26   | 0.24     |
| IPR(electron) | 0.09    | 0.10   | 0.27     |

the Perfect model in the ground state. (2) The TiV-H and the TiO$_2$V models have larger bandgap energies than bulk anatase, which is consistent with the experimental observation. (3) The existence of the Ti vacancies causes the spatial charge separation and leads to the longer recombination time.

ACKNOWLEDGMENTS

The present study is financially supported by KAKENHI [16K05478]. We would like to thank the Supercomputer Center, Institute for Solid State Physics, University of Tokyo for the use of facilities. The computations were also carried out the computer facilities at the Research Institute for Information Technology, Kyushu University.
