An excellent description of both spin-independent and spin-dependent quark distributions and structure functions has been obtained with a modified Nambu–Jona-Lasinio model, which is free of unphysical thresholds for nucleon decay into quarks – hence incorporating an important aspect of confinement. We utilize this model to investigate nuclear medium modifications to structure functions and find that we are readily able to reproduce both nuclear matter saturation and the experimental $F_{2N}^2/F_{2N}$ ratio, that is, the EMC effect. Applying this framework to determine $g_{1p}$, we find that the ratio $g_{1p}^N/g_{1p}^p$ differs significantly from 1, with the quenching caused by the nuclear medium being about twice that of the spin-independent case. This represents an exciting result, which if confirmed experimentally, will reveal much about the quark structure of nuclear matter.

The discovery in the early 80’s by the European Muon Collaboration (EMC) that nuclear structure functions differ substantially from those of free nucleons [1–3] caused a shock in the nuclear community. Despite many attempts to understand this effect in terms of binding corrections it has become clear that one cannot understand it without a change in the structure of the nucleon-like quark clusters in matter [4–6]. Mean-field models of nuclear structure built at the quark level, which have been developed over the past 15 years, are yielding a quantitative description of the EMC effect. Most recently it has been demonstrated that at least one of these models leads naturally to a Skyrme-type force, with parameters in agreement with those found phenomenologically to describe a vast amount of nuclear data [7].

A second major discovery by the EMC concerned the so-called “spin crisis”[8], which corresponds to the discovery that the fraction of the spin of the proton carried by its quarks is unexpectedly small. This has led to major new insights into the famous $U(1)$ axial anomaly, prompting many new experiments. With this background, it is astonishing that, in the 17 years since the discovery of the spin crisis, there has been no experimental investigation of the spin-dependent structure functions of atomic nuclei. Of course, such experiments are more difficult because the nuclear spin is usually carried by just a single nucleon and hence the spin dependence is an $O(1/A)$ effect. Nevertheless, as we shall see, such measurements promise another major surprise, with at least one model – which reproduces the EMC effect in nuclear matter – suggesting a modification of the spin structure function of a bound proton in nuclear matter roughly twice as large as the change in the spin-independent structure function.

Models of nuclear structure like the quark meson coupling (QMC) model, achieve saturation through the self-consistent change in the quark structure of the colorless, nucleon-like constituents – in particular, through its scalar polarizability [7, 9]. Physically the idea is extremely simple, light quarks respond rapidly to oppose an applied scalar field. Specifically, the lower components of the valence quark wave functions are enhanced and this in turn reduces the effective $\sigma N$ coupling. The fact that changes in the structure of bound nucleons are so difficult to find appears to be a result of this mechanism being extremely efficient and hence yielding only a small change in the dominant upper components of the valence quark wave functions.

On the other hand, the spin structure functions are particularly sensitive to the lower components and this is why the measurement of the spin-dependent EMC effect is so promising. Our calculations are made within the framework developed by Bentz, Thomas and collaborators [10, 11], in which proper-time regularization [12–14] is applied to the NJL model in order to simulate the effects of confinement. This model exhibits similar properties to the QMC model with the advantage that it is covariant. Once we include both scalar and axial-vector diquarks, it readily describes nuclear saturation at the correct energy and density. Moreover it yields PDFs for the free nucleon [15] which are in excellent agreement with existing experimental data.

We write the spin-dependent light-cone quark distribution of a nucleus with mass number $A$ and helicity $H$ as the convolution

$$\Delta f_{q/A}^{(H)}(x_A) = \int dy_A \int dx \delta(x_A - y_A x) \Delta f_{q/N}(x) \Delta f_{N/A}^{(H)}(y_A),$$

where $\Delta f_{q/N}(x)$ is the spin-dependent quark light-cone momentum distribution in the bound nucleon, $\Delta f_{N/A}^{(H)}(y_A)$ the light-cone momentum distribution of the nucleon in the nucleus and $x_A \in [0, A]$ is the Bjorken scaling variable for the nucleus. There have been numerous
investigations of $\Delta f_{q/N_A}(y_A)$ [16] and it is straightforward to calculate for any particular nucleus. Examples of greatest experimental interest would be single proton particle or hole states like $^7$Li, $^{11}$B and $^{15}$N. In this analysis, as our primary focus is the change in $\Delta f_{q/N}$ in-medium, we incorporate the Fermi motion effects on the bound proton structure function by replacing $f_{q/N_A}(y_A)$ with the spin-independent distribution $f_{N/A}(y_A)$, calculated in infinite nuclear matter [11].

To calculate $\Delta f_{q/N}(x)$ in our model, it is convenient to express it in the form [17, 18]

$$\Delta f_{q/N}(x) = -i \int \frac{d^4k}{(2\pi)^4} \delta \left( z - \frac{k_0}{p^} \right) \text{Tr} \left( \gamma^+ \gamma_5 M(p,k) \right),$$

where $M(p,k)$ is the quark two-point function in the nucleon. Within any model that describes the nucleon as a bound state of quarks, this distribution function can be associated with a straightforward Feynman diagram calculation, where the propagators include the self consistent scalar and vector fields in the nucleus.

It is demonstrated in Ref. [11] that the in-medium changes to a free nucleon quark distribution can be included as follows. The effect of the scalar field is incorporated by simply replacing the free masses with the effective masses in nuclear medium, giving the distribution $\Delta f_{q/N0}(x)$ [22] and the Fermi motion of the nucleon is included by convoluting this distribution $(\Delta f_{q/N0}(x))$ with the Fermi smearing function, $f_{N/A_0}(\tilde{y}_A)$, producing the distribution

$$\Delta f_{q/A_0}(\tilde{x}_A) = \int d\tilde{y}_A \int dz \delta \left( \tilde{x}_A - \tilde{y}_A z \right) \Delta f_{q/N0}(z) f_{N/A_0}(\tilde{y}_A).$$

The effect of the vector field is then incorporated via the scale transformation

$$\Delta f_{q/A}(x_A) = \frac{\varepsilon_F}{E_F} \Delta f_{q/A_0} \left( \tilde{x}_A = \frac{\varepsilon_F}{E_F} x_A - \frac{V_0}{E_F} \right),$$

where $\varepsilon_F = \sqrt{p_F^2 + M_N^2} + 3V_0 = E_F + 3V_0$ is the Fermi energy of the nucleon, $p_F$ the Fermi momentum and $V_0$ is the zeroth component of the vector field felt by a quark.

To calculate the spin-dependent quark distribution in the nucleon, $\Delta f_{q/N0}(x)$, we use the NJL model to describe the nucleon as a quark-diquark bound state, taking into account both scalar $(J^\pi = 0^+, T = 0$, colour $\mathbf{3})$ and axial-vector $(J^\pi = 1^+, T = 1$, colour $\mathbf{3})$ diquark channels. Details of these free space calculations, along with a description of the proper-time regularization scheme used throughout this paper, may be found in Ref. [15].

In short, the quark distribution functions are determined from the Feynman diagrams of Fig. 1, with the resulting distribution $\Delta f_{q/N0}(x)$, having no support for negative $x$. Hence, this is essentially a valence quark picture.

By calculating these Feynman diagrams using the effective (density dependent) masses obtained from the nuclear matter equation of state (discussed below) and performing the transformation, Eq. (4), to include the mean vector field, we obtain the spin-dependent $u$ and $d$ distributions in a bound proton. Separating the isospin factors, gives

$$\Delta u_A^s(x) = \Delta f_{q/D}^s(x) + \frac{1}{2} \Delta f_{q/(D)/N}^s(x) + \frac{1}{3} \Delta f_{q/N}^s(x),$$

$$\Delta d_A^s(x) = \frac{5}{6} \Delta f_{q/(D)/N}^s(x) + \frac{1}{2} \Delta f_{q/D}^s(x),$$

$$\Delta d_A^a(x) = \frac{1}{2} \Delta f_{q/D}^a(x) + \frac{2}{3} \Delta f_{q/N}^a(x),$$

The superscripts $s$, $a$ and $m$ refer to the scalar, axial-vector and mixing terms, respectively, the subscript $q/N$ implies a quark diagram and $q/(D)/N$ a diquark diagram. Because the scalar diquark has spin zero, we have $\Delta f_{q/(D)/N}^s(x) = 0$ and hence the polarization of the $d$ quark arises exclusively from the axial-vector and the mixing terms.

The NJL model is a chiral effective quark theory that is characterized by a 4-Fermi contact interaction. Using Fierz transformations any 4-Fermi interaction can be decomposed into various interacting $qq$ and $q\bar{q}$ channels [19]. The terms relevant to this discussion are

$$\mathcal{L} = \bar{\psi} \left( i \gamma \cdot m \right) \psi + G_\alpha \left( \bar{\psi} \gamma^\mu \gamma^\nu \psi \right) + G_\alpha \left( \bar{\psi} (i \gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu) \psi \right) + G_\alpha \left( \bar{\psi} (i \gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu) \psi \right) + G_\alpha \left( \bar{\psi} (i \gamma^\mu \gamma^\nu + \gamma^\nu \gamma^\mu) \psi \right).$$

FIG. 1: Feynman diagrams representing the spin-dependent quark distributions in the nucleon, needed to determine $\Delta f_{q/N}(x)$, given in Eq. (2). The single line represents the quark propagator and the double line the diquark $t$-matrix. The shaded oval denotes the quark-diquark vertex function and the operator insertion has the form $\gamma^+ \gamma_5 \delta \left( x - \frac{k}{p^} \right) \frac{1}{2} (1 \pm \tau_2)$. The second diagram, which we refer to as the “diquark diagram”, symbolically represents two diagrams, each with the operator insertion on a different quark line within the diquark.
where $m$ is the current quark mass, $\beta^A = \sqrt{\frac{3}{2}} \Lambda^A$ ($A = 2,5,7$) are the colour $\mathbf{3}$ matrices and $C = i\gamma_2\gamma_0$. In the $q\overline{q}$ channel we include scalar, pseudoscalar and vector components and in the $qq$ channel we have the scalar and axial-vector diquarks. The scalar $q\overline{q}$ interaction term generates the scalar field, that is, the constituent quark mass $M$ (vacuum value $M_0$) via the gap equation. The vector $q\overline{q}$ interaction will be used to generate the vector field in-medium. The $qq$ interaction terms give the diquark $t$-matrices whose poles correspond to the masses of the scalar and axial-vector diquarks. The nucleon vertex function and mass, $M_N$, are obtained by solving the homogeneous Faddeev equation for a quark and a diquark [15]. Because we need to solve this equation many times to obtain self-consistency, we approximate the quark exchange kernel by a momentum independent form (static approximation). This necessitates the introduction of an additional parameter, $c$, as explained in Ref. [10].

To calculate the mean scalar and vector fields, we need the equation of state for nuclear matter. This can be rigorously derived for any NJL Lagrangian using hadronization techniques, but in a simple mean-field approximation the result for the energy density has the following form [10]:

$$E = E_V - \frac{V_0^2}{4G_s} + 4\int \frac{d^3p}{(2\pi)^3} \Theta(p_F - |\vec{p}|) \varepsilon_p,$$

where $\varepsilon_p = \sqrt{\vec{p}^2 + M_N^2} + 3V_0$ and the vacuum term $E_V$ has the familiar “Mexican hat” shape.

The parameters of the model are $\Lambda_{IR}$, $\Lambda_{UV}$, $M_0$, $c$, $G_\pi$, $G_s$, $G_\alpha$, $G_\omega$, where $\Lambda_{IR}$ and $\Lambda_{UV}$ are the infrared and ultraviolet cutoffs used in the proper-time regularization. The infrared scale is expected to be of the order $\Lambda_{QCD}$ and we set it to $\Lambda_{IR} = 0.28$ GeV. We also choose the free constituent quark mass to be $M_0 = 400$ MeV [23] and use this constraint to fix the static parameter, $c$. The remaining six parameters are fixed by requiring $f_\pi = 93$ MeV, $m_\pi = 140$ MeV, $M_N = 940$ MeV, the saturation point of nuclear matter ($\rho_B, E_B = (0.17 \text{ fm}^{-3}, 15.7 \text{ MeV}$) and lastly the Bjorken sum rule at zero density to be satisfied, with $g_A = 1.267$. We obtain $\Lambda_{UV} = 0.66$ GeV, $c = 0.95$ GeV, $G_\pi = 17.81$ GeV$^{-2}$, $G_s = 8.41$ GeV$^{-2}$, $G_\alpha = 1.36$ GeV$^{-2}$ and $G_\omega = 5.58$ GeV$^{-2}$.

With these model parameters the diquark masses at zero density are $M_s = 0.65$ GeV and $M_\alpha = 1.2$ GeV and vector field strength is $V_0 = 0.044$ GeV. At saturation density the effective masses become $M^* = 0.32$ GeV, $M_s^* = 0.52$ GeV, $M_\alpha^* = 1.1$ GeV and $M_N^* = 0.75$ GeV.

The results for the $u$ and $d$ spin-dependent quark distributions, at the model scale, are presented in Fig. 2. There are four curves for each quark flavour, representing the different stages leading to the full nuclear matter result.

Using these quark distributions we are able to construct the structure functions, $g_{1p}$ and $g_{1p}^A$, where the superscript $A$ represents a structure function in the nuclear medium. Analogous results for the spin-independent quark distributions [15] allow us to determine the isoscalar structure functions $F_{2N}$ and $F_{2N}^A$, and hence determine the EMC effect. Evolving [20] these distributions to a scale of $10 \text{ GeV}^2$, we give in Fig. 3 our results for the ratios $F_{2N}^A/F_{2N}$ and $g_{1p}^A/g_{1p}$, that is.
the EMC and the polarized EMC effect. In the valence quark region, the model is able to reproduce the spin-independent EMC data extremely well. For the polarized ratio we find a significant effect, of the order twice the size of the unpolarized EMC effect.

The nuclear quenching effects on the individual quark flavours is presented in Fig. 4. We find that the effect on both the u and d distributions is large and approximately equal over the valence quark region. The resemblance between $g_1^D/g_1^P$ and the ratio $\Delta u^A(x)/\Delta u(x)$ is simply because the up distribution is enhanced by a factor 4 relative to the down and strange distributions in proton structure functions. Absent from our model is the U(1) axial anomaly and sea quarks (at the model scale), which prevents a reliable description of structure functions at low x. For this reason in Figs. 3 and 4 we do not plot our results in this region.

A thorough understanding of how nuclear medium effects arise from the fundamental degrees of freedom – the quarks and gluons – represents an important challenge for the nuclear physics community. An experimental measurement of the polarized EMC effect would be another important step toward this goal, providing important insights into the quark polarization degrees of freedom within a nucleus. Our prediction of a remarkably large signature suggests that this measurement is feasible, and if these results are confirmed experimentally would yield vital, new information on quark dynamics in the nuclear medium.
