Assessing the role of historical temperature regime and algal symbionts on the heat tolerance of coral juveniles

K. M. Quigley¹*, C. J. Randall¹, M. J. H. van Oppen¹,² and L. K. Bay¹

ABSTRACT
The rate of coral reef degradation from climate change is accelerating and, as a consequence, a number of interventions to increase coral resilience and accelerate recovery are under consideration. Acropora spathulata coral colonies that survived mass bleaching in 2016 and 2017 were sourced from a bleaching-impacted and warmer northern reef on the Great Barrier Reef (GBR). These individuals were reproductively crossed with colonies collected from a recently bleached but historically cooler central GBR reef to produce pure and crossbred offspring groups (warm–warm, warm–cool and cool–cool). We tested whether corals from the warmer reef produced more thermally tolerant hybrid and purebred offspring compared with crosses produced with colonies sourced from the cooler reef and whether different symbiont taxa affect heat tolerance. Juveniles were infected with Symbiodinium tridacnorum, Cladocetiium goreeui and Durusdinium trenchii and survival, bleaching and growth were assessed at 27.5°C and 31°C. The contribution of host genetic background and symbiont identity varied across fitness traits. Offspring with either both or one parent from the northern population exhibited a 13- to 26-fold increase in survival odds relative to all other treatments where survival probability was significantly influenced by familial cross identity at 31°C but not 27.5°C (Kaplan–Meier P=0.001 versus 0.2). If in symbiosis with D. trenchii, a warm sire and cool dam provided the best odds of juvenile survival. Bleaching was predominantly driven by Symbiodiniaceae treatment, where juveniles hosting D. trenchii bleached significantly less than the other treatments at 31°C. The greatest overall fold-benefits in growth and survival at 31°C occurred in having at least one warm dam and in symbiosis with D. trenchii. Juveniles associated with D. trenchii grew the most at 31°C, but at 27.5°C, growth was fastest in juveniles associated with C. goreeui. In conclusion, selective breeding with warmer GBR corals in combination with algal symbiont manipulation can assist in increasing thermal tolerance on cooler but warming reefs. Such interventions have the potential to improve coral fitness in warming oceans.

KEY WORDS: Coral, Bleaching, Heat tolerance, Symbiodiniaceae, Selective breeding

INTRODUCTION
Coral reefs provide a suite of ecosystem services to people worldwide, including livelihoods, sustenance and storm protection (Moberg and Folke, 1999). The monetary contribution of reefs to regional economies is high (Young et al., 2012); the Great Barrier Reef (GBR) alone contributes 6.4 billion AUD to the Australian economy annually from tourism, fishing, recreation and scientific research, notwithstanding the benefits gained from its social, cultural and spiritual values (O’Mahoney et al., 2017). However, a range of local and global threats has had substantial negative impacts on the health and survival of corals. The GBR has seen long-term deterioration from crown-of-thorns starfish predation, cyclones and storms, water quality and climate change (De’ath et al., 2012). Marine heat waves in 2016 and 2017 resulted in extensive bleaching that severely impacted live coral cover across the northern and central sectors (Hughes et al., 2017). Temperatures that induce bleaching in corals, defined as the loss of their obligate dinoflagellate symbionts (family Symbiodiniaceae) and/or the reduction of symbiont pigments, are now three times more likely than they were three decades ago (Heron et al., 2016). Mitigation strategies are urgently needed to slow or halt further loss of corals from bleaching to maintain the ecological and social values of coral reefs until global warming is curbed.

Both host genetic background and Symbiodiniaceae identity influence the overall stress tolerance of the coral host and all of its microbial associates (i.e. the holobiont, Rohwer et al., 2002), and both have been implicated in the variation in survival from mass bleaching (Császár et al., 2009; Dixon et al., 2015; Hoadley et al., 2019; Manzello et al., 2019; Micog et al., 2009). One study estimated that the adaptive potential of thermal tolerance in adult Acropora millepora corals is greater for the symbiont compared with the host, given high heritability in a number of key traits (Császár et al., 2010). The host genetic background also greatly influences stress tolerance, where having one or both parents from a warmer reef provided a 5-fold or 10-fold increase in survival at high temperatures of coral larvae (Dixon et al., 2015), and demonstrates a strong link between host genotype and thermal tolerance. Finally, an increased potential for a dominant role of the host to confer thermal tolerance has been implicated in cases where colonies are collected from areas with more extreme thermal histories (Dixon et al., 2015; Thompson and van Woesik, 2009).

Coral photosymbionts within the family Symbiodiniaceae exhibit a high level of trait variability and local adaptation (Howells et al., 2012; LaJeunesse et al., 2018; reviewed in Quigley et al., 2018). Symbiodiniaceae diversity in hospite also greatly influences coral bleaching tolerance (McIlroy et al., 2016; Mies et al., 2018; Yuyama et al., 2016). For example, a change in relative abundance (shuffling) from Cladocetiium to Durusdinium increased bleaching tolerance of adult colonies by up to 1.5°C (Berkelmans and van Oppen, 2006), in which the presence of Durusdinium explained ~24% of the variability in bleaching (Baird et al., 2009; Mizerek et al., 2018). Symbiodiniaceae shuffling during bleaching events can also occur.
in juveniles (Yorifuji et al., 2017; Yuyama and Higuchi, 2014). *Acropora tenuis* juveniles harbouring *Cladocpium goreai* experienced greater mortality compared to those with *Durasdinium* at elevated temperature and light levels (Yuyama et al., 2016), although the opposite pattern has also been found (Abrego et al., 2008). Juveniles with mixed communities of *Symbiodinium tridacnidorum*, *C. goreai* and *D. trenchii* exhibited increased survival at 30°C compared to 31–32°C, with surviving juveniles harbouring more *D. trenchii* (Yorifuji et al., 2017). This indicates the importance of different symbionts in determining host temperature tolerance.

Trade-offs in coral holobiont traits exist for various coral-Symbiodiniacea associations, especially between *Cladocpium* and *Durasdinium* in both juveniles (Cantin et al., 2009; Little et al., 2004) and adults (Jones and Berkelmans, 2010). Corals hosting *Durasdinium* often survive better at high temperatures compared to those with *Cladocpium*, but grow slower at lower temperatures (Cantin et al., 2009; Cunning et al., 2015; Jones and Berkelmans, 2010; Little et al., 2004). Moreover, juveniles harbouring *S. microadriaticum* grew faster than those with *Brevisiolium minutum* (McIlroy and Coffroth, 2017), and skeletal growth was faster in juveniles with *C. goreai* compared with *Durasdinium* despite lower *C. goreai* population growth rates (Yuyama and Higuchi, 2014). Host-driven variation in thermal tolerance (Baird et al., 2009; Cunning et al., 2015) has rarely been examined in concert with Symbiodiniacea identity or been manipulated to experimentally quantify changes in thermal tolerance due to the host-symbiont interaction (Abrego et al., 2008; Kenkel et al., 2015b; Manzello et al., 2019; Mieog et al., 2009).

To address this research gap, we crossed coral colonies sourced from a comparatively warm northern reef of the GBR that had survived both the 2016 and 2017 mass coral bleaching events with colonies from a central reef that experienced lower mean and maximum annual temperatures and also survived the 2016 and 2017 bleaching events. Juveniles from these crosses were infected with one of three Symbiodiniacea taxa (*S. tridacnidorum*, *C. goreai* and *D. trenchii*) and survival, growth, and bleaching were assessed at two temperatures (27.5°C and 31°C). The interactive effects of host genotype and symbiont identity on juvenile coral performance was then estimated for three key fitness traits; survival, bleaching tolerance, and growth.

**RESULTS**

Host genetic background at the familial cross (WW1, WW2, WW3, WC, CW) and parental source (WW, WC, CW; W indicates warm northern parent and C indicates cool central parent) levels influenced juvenile survival, growth and bleaching across the three symbiont treatments at 27.5°C and 31°C (Fig. 1, Table 1). Juveniles with two warm parents generally demonstrated overall higher performance across fitness traits (detailed below), whilst juveniles with a warm dam and a cool dam also performed better across some fitness traits. Secondly, symbiont treatment influenced juvenile survival and growth under thermal stress, with juveniles hosting *D. trenchii* generally performing better than the other symbionts across all familial crosses. This pattern was particularly strong for bleaching fitness in juveniles of parents sourced from the warm reef.

Hosted *D. trenchii*, regardless of host genetic background, conferred significantly higher odds of survival in juveniles, including up to a 26-fold increase in survival odds relative to all other treatments [i.e., in comparison to the global mean; generalized linear mixed model (GLMM) WC $P=0.002$] (Fig. 2) and 20-fold increase in juveniles with a warm sire and *D. trenchii* (GLMM $P=0.02$). Juveniles with two warm parents and either *C. goreai* or *D. trenchii* displayed a 16-fold increase in the odds of survival (GLMM both $P=0.01$). Juveniles with one warm dam and *C. goreai* exhibited a 13-fold increase in survival (GLMM $P=0.03$). Odds of survival were not significantly greater for juveniles with a cool dam hosting *C. goreai* (GLMM $P=0.2$) or any of the genetic crosses with *S. tridacnidorum* (GLMM $P=0.2$--0.7).

Familial cross and the source of the dam were also important in determining other fitness traits at elevated temperatures. Juveniles with two warm parents were the only genetic combinations with increased log odds of bleaching resistance in surviving juveniles (Fig. 2). These juveniles, hosting *D. trenchii* or *S. tridacnidorum*, experienced an 18–33-fold decrease in probability of bleaching, respectively [Markov chain Monte Carlo (MCMC) *D. trenchii* $P=0.008$; *S. tridacnidorum* $P=0.004$], whereas juveniles with one cool dam and *C. goreai* exhibited 66-fold increased odds of bleaching (MCMC $P=5e-4$). Only juveniles produced from a warm dam significantly conferred increased odds of growth, but only when juveniles were associated with *D. trenchii* (MCMC $P=0.001$) (Fig. 2).

**Temperature and symbiont effects on survival, growth and bleaching**

**Survival**

After 70 days, overall juvenile survival at 27.5°C was higher than at 31°C (47±0.03% versus 21±0.03%). Symbiont identity explained 4.4% of model variation in survival, whereas familial cross identity explained 0.7% and temperature explained 11.7% (Table 2).

Survival varied significantly across juveniles with distinct familial cross identities and symbionts (Fig. 3). Juveniles exposed to different Symbiodiniacea all exhibited significantly higher probability of survival at 27.5°C compared to 31°C [mean survival at 31°C at the final timepoint±s.e.: *D. trenchii*: 45.7±5% versus 30.5±5%; Kaplan–Meier (KM) comparison between 27.5°C and 31°C $P=0.029$; *C. goreai*: 56.7±5% versus 12.9±4%; KM $P<0.0001$; *S. tridacnidorum*: 26.5±6% versus 13±5%; KM $P=0.0015$]. The three top surviving familial crosses at 31°C were those with *D. trenchii* symbionts with at least one warm dam (WC, WW1, WW2: 50±18% to 38±9%, Fig. 3).

Juvenile survival varied significantly among comparisons across all familial cross identities and symbionts at 27.5°C (KM $P=0.008$) and 31°C (KM $P<0.0001$). However, when averaged over Symbiodiniacea treatments, there was a significant difference in survival probability due to familial cross at 31°C (KM $P=0.0019$), but not at 27.5°C (KM $P=0.2$). This was predominantly driven by the poor performance at 31°C of CW when associated with *C. goreai* (KM $P<0.0001$), and across familial crosses exposed to *S. tridacnidorum* generally (KM $P=0.056$).

The three crosses of juveniles with two warm parents exhibited differential survival between the two temperature treatments infected with the three symbiont taxa (Fig. 3). For example, juveniles from the WW1 and WW2 familial crosses infected with *D. trenchii* did not differ in survival probabilities between 27.5°C and 31°C, although WW3 juveniles did (KM $P=0.79$, 0.4 and 0.0046, Fig. 3). All juveniles infected with *C. goreai* survived significantly less at 31°C (KM $P=3e-4$–0.0015, Fig. 3). Juveniles with one warm dam survived equally well at 31°C compared to 27.5°C when exposed to *C. goreai* and *D. trenchii* (KM $P=0.17$–0.61, Fig. 3). Juveniles at 31°C with one cool dam exhibited the lowest survival over the shortest period of time, particularly when hosting *C. goreai* (KM $P<0.0001$, Fig. 3). Survival was not significantly worse for the other two symbiont taxa across the two temperatures (KM $P=0.18$ and 0.085, Fig. 3).
Growth and mortality
Familial cross and symbiont identity explained little of the model variation in growth and mortality between the two temperature treatments (0.27% and 0.33%, respectively) (Table 2). By the final timepoint, juveniles at 27.5°C were on average two times larger compared to juveniles at 31°C (0.7±0.06 – 0.3±0.05 mm², Fig. 4A insets). Juveniles at 27.5°C with C. goreaui and D. trenchii were the largest, and all juveniles decreased in size at 31°C, in which juveniles infected with C. goreaui were the smallest overall. At 27.5°C, juveniles with one warm dam and a cool sire were generally smaller (Fig. 4A). At 31°C, juveniles with at least one warm dam were on average larger, especially when infected with D. trenchii (0.6±0.11 – 0.5±0.29 mm²).

Growth of surviving juveniles
If only juveniles that survived were assessed, symbiont identity explained 69.8% of the variability in the change in growth, and genetic background only explained 3.8% (Table 2). Overall, from the first to last timepoint, all juveniles at 27.5°C and 31°C decreased in size, with the exception of juveniles with a warm dam and D. trenchii symbionts with one warm dam and a cool sire. At 31°C, juveniles with at least one warm dam were on average larger, especially when infected with D. trenchii (0.6±0.11 – 0.5±0.29 mm²).
Table 1. Genetic background of the five reproductive families (i.e. crosses) used in this study

| Familial Cross | Dam   | Sire    | Genetic cross |
|----------------|-------|---------|---------------|
| WW1            | Tijou | Tijou 2A| WW            |
| WW2            | Tijou | Tijou 2A| WW            |
| WW3            | Tijou | Tijou 3 | WW            |
| WC             | Tijou | Backnumbers 50 | WC |
| CW             | Backnumbers 2 | Tijou 2A | CW |

C, cold (central); W, warm (far northern).

(+88.9±158%; Fig. 4B). Examining only those juveniles that survived to 70 days shows they grew in both temperature treatments (>20–40% change, Fig. 4B inset). Surviving juveniles with D. trenchii grew more compared to juveniles hosting S. tridacnidorum and C. goreaui at 31°C compared to 27°C, although these differences were not significant, likely due to the high variability across surviving juveniles with D. trenchii (Tukey post-hoc Gaussian MCMCGLMM P=0.5–0.8) (Fig. 4B inset). When infected with S. tridacnidorum, the few surviving juveniles in all five crosses exhibited negative to moderate growth regardless of host genetic background at both temperatures (27.5°C: −9.5–13.6%; 31°C: −5–23%) (Fig. 4C). Surviving juveniles infected with C. goreaui grew more compared to juveniles with D. trenchii and S. tridacnidorum at 27.5°C across the five crosses, in which the greatest average growth occurred at 27.5°C (10.6–47.9%), compared with 31°C (−2.4–21%). There were no significant differences in growth between 27.5°C and 31°C when averaged across familial crosses with S. tridacnidorum (Tukey post-hoc Gaussian MCMCGLMM, P=0.86–0.98) or C. goreaui (P=0.12–0.92) or D. trenchii (P=0.13–0.99).

All but two D. trenchii crosses at 27.5°C and 31°C increased in size (13.5–277.8% change) over the 70-day experiment (exceptions: WC at 27°C, −0.3%; CW at 31°C, no survivors) (Fig. 4C). This is in comparison to mean percent change in growth that varied the most between juveniles at 31°C when infected with C. goreaui (Fig. 4B). Across temperatures, there were no significant differences in growth in any pairwise comparisons across the five crosses with surviving juveniles (Tukey post-hoc Gaussian MCMCGLMM, P=0.34–1) or within each cross (P=0.07–0.1) after averaging across symbiont identity.

Bleaching and mortality

After 70 days, juveniles at 27.5°C scored greater than 1.3 (less bleached) on the CoralWatch Health Score scale, whereas juveniles at 31°C scored less than 0.7 (more bleached) (Fig. 5A inset). Symbiont identity explained most of the model variation between the two temperature treatments (55.1%) in the change in Health Scores and mortality compared with the genetic background of the coral juveniles (6.4%) (Table 2).

Juveniles with C. goreaui and D. trenchii exhibited the darkest colouration at 27.5°C and 31°C, respectively, at the final timepoint (Fig. 5A inset). At 27.5°C, Health Scores of juveniles with different genetic backgrounds were generally distributed by symbiont type, with the darkest colouration measured for juveniles with C. goreaui, then D. trenchii and finally S. tridacnidorum (Fig. 5A). At 31°C, juveniles with two warm parents exhibited on average the highest Health Scores and those with a cool parent exhibited the lowest (Fig. 5A). However, juveniles with one warm and one cool parent were the darkest at 31°C, (WC 1.3±0.6), WW2 and WW1 intermediate (0.82±0.2 and 0.5±0.15 respectively) and CW and WW3 bleached heavily (0.05±0.05) (data not shown).

At 27.5°C, juveniles with one warm dam and one cool sire associated with S. tridacnidorum increased their Health Score the most from the first to last timepoint (~50%), whereas Scores decreased the most in juveniles with either one warm dam or both warm parents with S. tridacnidorum (Fig. 5B). Alternatively, at 31°C, on average all juveniles from all genetic crosses decreased in their Health Scores, where juveniles with one warm or cool dam varied in their temperature response (Fig. 2B).

Bleaching in surviving juveniles

Overall, after 70 days, surviving juveniles at 27.5°C darkened in their Health Scores (+5% change), whereas juveniles at 31°C paled (~28% change) (Fig. 5B inset). In surviving juveniles compared across models, symbiont identity explained 92.9% of the variability in bleaching and genetic background explained 64.8%.

Surviving juveniles infected with C. goreaui darkened at 27.5°C (+22%), but bleached the most at 31°C (-46%) (Fig. 5B inset). Juveniles infected with D. trenchii paled at 27.5°C (~11%), but bleached less at 31°C (~21%) than juveniles associated with other Symbiodiniaceae. Surviving juveniles infected with S. tridacnidorum paled at both temperatures in four of the five crosses (~26.9 to −33.3 and −66 to +50%) (Fig. 5B inset, C). Health Scores in the surviving juveniles in the 31°C treatment ranged from −11% change in colouration (WW2 with D. trenchii) to −67% (WW3 with S. tridacnidorum and D. trenchii), indicating substantial phenotypic variability for bleaching tolerance within the warm parent crosses (Fig. 5C). WW2 juveniles bleached the least at 31°C compared to other familial crosses when averaged over all symbiont combinations (~16±7%) (Fig. 5C). The other two warm parent crosses bleached at 31°C across all symbiont treatments (WW1: −29±26%, WW3: −58±6%). At 31°C, WC juveniles with D. trenchii remained relatively unchanged in their Health Scores compared with the 27.5°C treatment (Fig. 5C). WW2 juveniles bleached the least compared to other treatments when infected with D. trenchii at 31°C compared with 27.5°C (Fig. 5C).

Irrespective of symbiont identity, bleaching in WW2 juveniles was only significantly less compared to juveniles from WW3 (Tukey post-hoc Gaussian GLMM, P=0.037). There were no significant differences in bleaching alone amongst the other WW crosses (Tukey post-hoc Gaussian GLMM, P=0.995–1) or WC (P=0.76–1).

DISCUSSION

Variable contribution of symbiont and host genetics across multiple coral traits

Symbiont identity and host genetic background varied in their influence on juvenile fitness. Bleaching was significantly reduced in

surviving offspring with two warm parents, with the lowest bleaching tolerance predicted by a cool dam. Compared to bleaching, growth was less influenced by both host genetic background and symbiont identity, although juveniles hosting D. trenchii with a warm dam grew the most at 31°C. Having a dam or both parents sourced from a warmer reef significantly improved juvenile survival at 31°C by up to 26-fold, irrespective of whether juveniles hosted D. trenchii or C. goreaui. Our findings show that the heat tolerance boost to larvae provided by parents sourced from a warm reef, which was previously demonstrated in larvae (Dixon et al., 2015), is maintained at the juvenile life-history stage. Interestingly, under field conditions, the contribution of host genetics was found to be minimal in the Caribbean species Porites astreoides (but see Kenkel et al., 2015b), whereas symbiont identity and environmental factors explained variation in growth, survival and thermal stress in Acropora millepora on the GBR (Mieog et al., 2009). Hence, these results demonstrate the role of parental genotype in increasing juvenile survival in a broadcast spawning species under elevated temperature.

Survivors from reefs that bleached with historically warmer temperatures provide increased survival benefits to offspring

When averaged over Symbiodiniaceae treatments, juvenile survival was significantly influenced by familial cross at 31°C but not at 27.5°C, where juveniles with at least one warm dam exhibited higher survival probability at warmer temperatures. Warmer days and variable environmental conditions may select for genotypes that are more able to cope with increasing sea surface temperatures (Palumbi et al., 2014). Therefore, the warmer conditions in the far northern GBR suggest that the surviving corals on these reefs may

Fig. 3. Kaplan–Meier survival probabilities of juveniles and associated P-values across Symbiodiniaceae treatments and distinct familial cross identities 27.5°C (blue) and 31°C (red). The top row corresponds to survival averaged across all families for each symbiont taxa.
harbour the greatest frequency of adaptive genetic variants associated with thermal tolerance (Dixon et al., 2015; Jin et al., 2016). Our results demonstrate that having at least one parent, but especially both, from a warmer reef and as bleaching survivors provides a 16–26-fold increase in odds of overall juvenile survival. Furthermore, if paired with *D. trenchii*, a warm sire and cool dam provides the best odds of juvenile survival. Compared to previous estimates of a 5–10-fold increase in survival of aposymbiotic *A. millepora* larvae (Dixon et al., 2015), having a bleaching-surviving parent who is also sourced from a warmer reef represents a 16-fold greater thermal tolerance boost, although differences in gamete developmental temperatures between these two populations should also be considered. Physiological performance at ambient temperatures should also be considered given the variable breadth of mean monthly temperatures across reefs, for example, the wider temperature range of Backnumbers reef compared to Tijou in winter. The benefit of using survivors from reefs with historically warmer environments to enhance juvenile survival therefore appears to be promising but requires further testing.

**Host-symbiont interactions influence juvenile fitness in response to thermal stress**

The greatest overall fold-benefits in survival and growth under elevated temperature occurred in having at least one warm dam and in symbiosis with *D. trenchii*. There was also a trend towards higher probability of survival in juveniles with *D. trenchii* compared with *C. goreau*, when exposed to warmer but not ambient temperatures, consistent with previous reports in adult corals (Baker et al., 2004; Berkelmans and van Oppen, 2006) and *A. millepora* juveniles (Mieog et al., 2009). Interestingly, *D. trenchii* provided little increased survival odds at 31°C compared with *C. goreau* in juveniles with two warm parents.

Survival at 31°C also varied significantly across the different juvenile crosses infected with *C. goreau*, where juveniles produced from a single cool dam crossed with a warm sire fared the worst, although direct effects of seawater temperature during gamete development may also influence these patterns in survival. These results add further complexity to understanding how host–symbiont interactions relate to thermal tolerance, including at the coral species-level (Abrego et al., 2008; Mieog et al., 2009), across developmental stages and now by different host genotypes and symbiont taxa, which can account for 91% of bleaching variance (Hoadley et al., 2019). These results may indicate maternal effects that extend into the juvenile life stage or that coral genotype-symbiont interactions are heritable traits (Parkinson and Baums, 2014; Quigley et al., 2016), and appear to be predominantly driven by host genotypic differences between crosses.

We also detected high variability in survival, bleaching and growth across the different crosses with two warm parents. Given this variability, the high heritability of many of these traits, and the strong influence of host genotype (Cunning et al., 2015; Drury et al., 2017; Kenkel et al., 2013, 2015b), caution should be taken when choosing source material for brood stock production during selective breeding. The selection of parental genotypes from bleaching survivors from naturally warm far northern reefs may require substantial effort given the high variability in warm parental genotypes seen here, but when identified, should greatly increase the chances of producing heat tolerant individuals for reef restoration.

**Trade-offs between survival and growth across different symbiont associations**

Hosting *Durusdinium* at elevated temperatures generally provides a significant increase in heat tolerance, but decreased host growth compared with hosting *Cladocopium* (Jones and Berkelmans, 2010; Stat and Gates, 2011; but see Howells et al., 2013). We found evidence of...
trade-offs between survival and growth in which juveniles with D. trenchii grew more and had greater probability of survival at elevated temperatures whereas juveniles infected with C. goreaui grew more at 27.5°C. This aligns with previous reports for a growth advantage of corals hosting C. goreaui at cooler temperatures (Cantin et al., 2009; Little et al., 2004). Increased growth rates in juveniles with Durusdinium have been observed and may be associated with these symbionts colonizing coral juveniles at faster rates compared to C. goreaui (Yuyama and Higuchi, 2014) given initial levels of symbiosis establishment and/or pigmentation varies by symbiont type (Cumbo et al., 2018; Yamashita et al., 2014). However, we only saw slight differences in symbiosis establishment across symbiont treatments at the start of the experiment, where coral colouration is a proxy for cell density (Mean CoralWatch Health Scores at day 1: C. goreaui, 2.1; S. tridacnidorum, 2.4; D. trenchii, 2.5). We found no evidence for a trade-off in growth and survival for Durusdinium at 31°C, where juveniles hosting Durusdinium would have been expected to have greater probability of survival at warmer temperatures but grow less (Petty et al., 2015; but see Manzello et al., 2019). Modelling results suggest that these trade-offs may detrimentally impact reef recovery as the increased abundance of heat tolerant D. trenchii leads to reductions in host growth rates (Ortiz et al., 2013). However, juveniles hosting D. trenchii both exhibited higher probability of survival and grew more compared to juveniles hosting other Symbiodiniaceae taxa at warmer temperatures. This aligns with previous evidence showing no trade-off costs between growth and survival for Durusdinium once temperatures increase past 26°C (Cunning et al., 2015).

The strong symbiont effect found here was surprising given the initially low Symbiodiniaceae CoralWatch Health Score (i.e. Score<3≈10^6 cells/cm^2, Siebeck et al., 2006). Symbiodiniaceae cell density strongly influences host physiology, and if the total cost to the host in maintaining symbionts is low and the benefit high, the optimal symbiont density may be low (Cunning and Baker 2014). Hence, even low densities of symbionts may significantly influence host functioning, as our data suggest. Indeed, after only 4 h post-exposure to Symbiodiniaceae, small but significant host transcriptional responses co-occurred with symbiont uptake in coral juveniles (Mohamed et al., 2016) and with as few as four Symbiodiniaceae cells in Aiptasia larvae (Buchar et al., 2016). These data suggest that even at low densities, symbionts may significantly influence host growth and survival.

Drivers of bleaching tolerance in coral juveniles

Bleaching responses were variable across symbiont treatments at elevated temperatures, consistent with previous reports (reviewed in Quigley et al., 2018). Although initial infection across temperatures and symbiont treatments were similar (see Materials and Methods), variability in bleaching responses at later time points may have been due to differences in symbiosis establishment rates and/or chlorophyll content (Cumbo et al., 2018; Yamashita et al., 2014; Yuyama and Higuchi, 2014). At elevated temperatures, juveniles harbouring D. trenchii bleached less compared to juveniles hosting S. tridacnidorum and C. goreaui. Taken in conjunction with our results for survival and growth, this suggests that the thermal optimum for the coral–D. trenchii association is higher compared to other combinations.

Although juveniles did not exhibit bleaching (i.e. a negative change in Health Score) at 27.5°C when averaged among all genetic backgrounds and symbiont treatments, juveniles infected with
S. tridacnidorum and D. tenuichii paled or bleached at 27.5°C. Juveniles with S. tridacnidorum also bleached at 31°C. This may indicate that the optimal temperature for D. tenuichii is higher than 27.5°C. It may also suggest that the symbiosis between A. spathulata juveniles and S. tridacnidorum was not stable (sensu van Oppen et al., 2001) or compatible, an observation that has been made for multiple types within Cladocopium and S. microadriaticum (Micog et al., 2009). S. tridacnidorum is a key early symbiont partner for some Acropora juveniles (Quigley et al., 2016; Suzuki et al., 2013) but is lost at later life stages (Quigley et al., 2017b). Thus far, only ITS1-type C2 (sensu van Oppen et al., 2001, equivalent to ITS2-type C3 sensu LaJeunesse, 2002) has been identified from adult A. spathulata collected from Pelorus and Heron Islands in the central and southern GBR, respectively (Genbank accession AF380538, van Oppen et al., 2001), suggesting that over time, strains within Symbiodinium do not provide equivalent fitness benefits across ontogeny.

**Signatures of local adaption**

Evidence of local adaptation fuelling fitness trade-offs is well known (Hereford, 2009), and the trade-off costs for immigrants are high in some reef environments (Howells et al., 2013). For example, adult fragments translocated between inshore and offshore sites in the Florida Keys exhibited high survival but reduced growth (Kenkel et al., 2015a) and colonies with Cladocopium versus Durusdinium had higher egg densities in the absence of temperature anomalies (Jones and Berkelmans, 2011). Intraspecific hybrid juveniles produced from parents sourced from the central and southern GBR exhibited decreased survival compared to southern GBR purebreds when transplanted to the southern GBR (van Oppen et al., 2014). In contrast, intraspecific hybrid offspring from far northern and central GBR populations transplanted to central reef conditions did not exhibit trade-offs in larval weight and survival, settlement competency or juvenile field survival (Quigley et al., 2016). This may be due to the relatively short period of time in the field (~1 month) or the temperatures at the central transplant site falling within the thermal reaction norm of both populations. Both studies only transplanted in one direction and thus it is unclear if these patterns would be maintained if transplanted back to the warmer, far northern reef environments. Finally, some species of corals were not typified by high levels of local adaptation or trade-offs in growth, survival and in their response to stress (Drury et al., 2017, but see Polato et al., 2010). Understanding fitness trade-offs at each end of their thermal physiological ranges (i.e. thermal reaction norms, Roth et al., 2012) is key to fully assessing how the selective crossing of different populations with varying levels of local adaptation will influence overall reef trajectories.

A limitation of this study is the lack of cool purebred juveniles due to the extirpation of larvae from these crosses. However, because implementation of this intervention would be based on the deployment of interpopulation hybrids, and given the information provided by the cross with the cool dam, it is not completely necessary to have information on performance of purebred offspring from the cooler reef. Furthermore, different source parental colonies were used to produce the WC and CW crosses, which likely introduced additional variability into the results. As with the detected variability in survival, bleaching and growth in the warm parent crosses, this potential, but unknown variability further highlights that the selection of source material for brood stock production will be key in assuring the success of any intervention method aimed at increasing thermal tolerance in corals.

**Conclusion**

The production and reseeding of cool reefs with corals that have a comparatively high thermal tolerance can facilitate adaptation to climate change. This technique has thus been proposed as a way of increasing the likelihood of successful reef-restoration initiatives (Anthony et al., 2017; Quigley et al., 2019; van Oppen et al., 2014, 2015). Despite the small sample size of reproductive colonies, this study demonstrates that crosses consisting of two parents from the warmest reef provided increased growth and survival coupled with decreased bleaching under experimentally elevated temperature in coral juveniles. The greatest overall fold-benefits in survival and growth occurred in having at least one warm dam and in symbiosis with D. tenuichii. Encouragingly, even the use of a warm dam in combination with a cool sire provided considerable host benefits. This *ex situ* breeding of corals from warm with cool reefs may thus be used to prepare cooler reefs for further warming and summer heat waves. The next phase in the development of this intervention strategy should focus on field-based experiments to confirm these observations in the wild.

**MATERIALS AND METHODS**

Coral spawning, juvenile settlement and symbiosis establishment

Gravid Acropora spathulata colonies were collected from Tijou Reef (far northern GBR; 13°10′44.0″S, 143°36′54.6″E, permit G16/38488.1) and Backnumbers Reef (central GBR; 18°30′49.8″S, 147°09′10.7″E, permit G12/35236.1) between 20–24 November and 1–5 December 2017, respectively. Corals were dislodged with a hammer and chisel and maintained on board research vessels in flow-through seawater until they were returned to the Australian Institute of Marine Science National Sea Simulator Facility (via charter plane from Tijou Reef and via ship from Backnumbers Reef).

Tijou Reef was typified by an average higher temperatures compared with central Backnumbers Reef [15-year monthly average sea-surface temperature (SST)=26.4°C and 25.8°C, respectively; Fig. 1A,B], and a lower annual range in monthly SST (15-year average annual range in monthly SST=4.2°C and 5.2°C, respectively) (NASA’s MODIS Aqua Global level 3 monthly daytime SSTs at a 4.6-km spatial resolution from 2002–2017; Minnett et al., 2004). Experimental conditions of 31°C were therefore hypothesized to exert less stress (Degree Heating Weeks) upon corals sourced from Tijou reef compared with Backnumbers reef (Fig. 1C). In 2016 and 2017, both reefs were impacted by bleaching [bleaching categories; 2016: 3 (Tijou), 3 (Backnumbers); 2017: 2 (Tijou), 4 (Backnumbers); Hughes et al., 2018].

Methods for spawning and the production of coral larvae and juveniles followed those outlined in (Quigley et al., 2017a). Briefly, three far northern colonies were individually crossed with three central colonies, resulting in 30 distinct familial crosses. We will hereafter refer to crosses as hybrids as defined by the nature of the intraspecific crosses (Chan et al., 2019). All 30 familial crosses were reared at 27.5°C. By the time of larval settlement, only five familial crosses remained, with all larvae from the purebred Backnumbers Reef familial crosses and other cross combinations (CW and WC) were exhausted through a combination of use in larval experiments and through culture attrition. Hence, those data are not presented here. The five familial crosses focused on here include three crosses produced from parents from a warm far northern reef (WW1, WW2, WW3), one cross with a warm dam and cool sire (WC) and one cross with a cool dam and warm sire (CW) (Table 1; Table S1). Larvae were reared at a density of 1.5 larvae/ml in 15 l cone-shaped rearing tanks at 27.5°C, with 0.2 l/min flow-through seawater, resulting in one turnover per h per tank, with gentle aeration to keep larvae in the water column. These familial crosses were then settled at 27.5°C onto new (unconditioned) carbonate plugs en masse by adding the larvae from each cross into separate, sterilized 45-l tanks and turning off flow-through seawater for 24 h to allow larvae to settle. Once flow resumed, settled juveniles were grown on plugs for 11 days.

The numbers of plugs with settled juveniles were quantified for each familial cross and subsequently divided among three replicate tanks for...
symbiosis establishment at 27.5°C. Juveniles were exposed to one of three treatments of the following Symbiodiniaceae taxa cultured at the Australian Institute of Marine Science Algal Culture Facility: S. triadacnidorum (monoclonal SCF022.01), G. goreaui (monoclonal SCF055-01.10) and D. trenchii (heterogeneous SCF082) following Quigley et al., 2014. For symbiosis establishment, the water volume in each 45-l tank was reduced and cells from each Symbiodiniaceae type were added to each tank such that the final volume was equal to 5 l with the added volume of symbiont cells, for a final algal cell density of \(1 \times 10^6\) ml\(^{-1}\). Flow was suspended for 12 h. This procedure was repeated 2 days later, this time suspending flow for 36 h. All inoculated juveniles were subsequently kept at 27.5°C for 8 days and symbiosis establishment was visually confirmed over this period under a microscope. Juveniles were fed daily with a mix of Artemia (0.5 nauplii/ml) and a mixed species microalgae recipe (10\(^6\) cells/ml), and were exposed to a 12:12 day:night light cycle of \(\sim\)171 PAR. Fluo-4 was then randomly divided across treatment tanks, and half from each symbiosis-establishment treatment were placed into 31°C treatment tanks without ramping, totalling six tanks (three replicate tanks at 27.5°C and three replicate tanks at 31°C).

**Trait measurements in juveniles**

Juvenile survival, bleaching and growth were assessed through image analysis. Images were taken with a Nikon D810 with a Nikon AF-S 105 mm f/2.8 G Micro ED Lens with four Ikelite DS160 Strobes. Images were taken starting on the first day of exposure to 31°C, with five time points measured and analysed at 1, 9, 35, 49 and 70 days of heat exposure. All images include a scale bar and mini coral bleaching colour-reference card (CoralWatch Health Score). Juveniles were scored as highly pigmented (3–D6), pale (2–D4), bleached (1–D1, translucent tissue), or dead (0, missing or bare skeleton with or without algal or cyanobacterial overgrowth) (Fig. S1). On the first day of heating, all juveniles per family were scored (mean colour score±s.e.; S. triadacnidorum: 2.2±0.1 to 2.4±0.1, G. goreaui: 2.0±0.1 to 2.1±0.1, D. trenchii: 2.2±0.1 to 2.5±0.1). Juveniles were also scored for colour at subsequent timepoints. Growth was determined using the ‘Area’ tool in ImageJ (Rueden et al., 2017) after calibrating each image to the scale bar.

**Statistical analyses**

**Survival**

All statistical analyses were done in R (version 3.5.1, 2018-07-02) (R Core Team, 2013). Statistical tests for all traits were assessed at two levels of host genetic background: by familial cross (WW, WW, WC, CW) and by the geographical source of the parental corals (WW, WC, CW). Survival was assessed using a generalized linear model, fit with a binomial distribution (alive or dead) and included the interactive fixed effects of symbiont identity, host genetic background (e.g. familial cross or parental source location), and temperature treatment, with time (five factorial levels for each timepoint) and replicate tanks (six factorial levels in which three are within each temperature treatment) set as random effects blocking factors using the ‘MASS’ and ‘nlme’ packages (Pinheiro et al., 2014; Venables and Ripley, 2002). Kaplan–Meier Survival curves and associated P-values were calculated using the survfit function from the ‘Survival’ package (Terry, 2015). Tukey post-hoc tests were performed using the package ‘lsmeans’ (Lenth and Hervé, 2015). Assumptions of normality and homogeneity of variances were assessed with the sjPlot package (Lüdecke, 2017). No auto-correlation patterns were detected in the residuals. The relative contributions of symbiont identity and host genetic background were quantified from MCMCglmm models from manually calculated Marginal and Conditional R\(^2\) values.

**Bleaching and growth**

Percent change in the bleaching score and juvenile area were calculated for each individual juvenile across host genetic background and symbiont type. Percent change was calculated between the first and last timepoint \([\frac{(T_{\text{final}}-T_{\text{initial}})}{T_{\text{initial}}} \times 100]\). Percent change was used given that the initial level of symbiosis establishment and/or pigmentation varied slightly by symbiont type (see ‘Trait measurements in juveniles’ above for details).

**Relative importance of genetic identity and symbiont for survival, growth and bleaching**

The odds of survival, bleaching and growth were estimated by calculating the proportion of variance attributed to symbiont identity, host genetic background and their interaction (Dixon et al., 2015). A model incorporating the interactive effects of genetic and symbiotic identity was fit, as described above, with the random effects of time and replicate tanks averaged across both temperature treatments. Models were fit using global intercept contrast coding such that each treatment (familial cross×symbiont combination) was compared to the global mean of all treatments (i.e. the mean of all other treatments together). The relative importance (proportion of variance) of genetic identity and symbiont interactions were estimated as described above.

To assess the effect of genetic and symbiotic identity on the percentage change in bleaching level of surviving juveniles, a Bayesian Gaussian mixed effects model in a Bayesian framework utilising the package ‘MCMCglmm’ was used (nitt=50,000; burnin=10,000; thin=20) (Hadfield, 2010). The interaction of symbiont by host genetic identity was set as the fixed factor, with replicate tanks treated as a random effect. Percentage change in area was assessed using the same model construction as described above. The ‘lmmeans’ package was used to extract relevant comparisons. Assumptions of chain mixing, posterior distribution normality and lack of autocorrelation were met. The relative contributions of symbiont identity and host genetic background were quantified from MCMCglmm models from manually calculated Marginal and Conditional R\(^2\) values.
