Parametric model reduction via rational interpolation along parameters

Ion Victor Gosea ∗, Serkan Gugercin ∗∗, and Benjamin Unger ∗∗∗

Abstract—We present a novel projection-based model reduction framework for parametric linear time-invariant systems that allows interpolating the transfer function at a given frequency point along parameter-dependent curves as opposed to the standard approach where transfer function interpolation is achieved for a discrete set of parameter and frequency samples. We accomplish this goal by using parameter-dependent projection spaces. Our main result shows that for holomorphic system matrices, the corresponding interpolatory projection spaces are also holomorphic. The coefficients of the power series representation of the projection spaces can be computed iteratively using standard methods. We illustrate the analysis on three numerical examples.

I. INTRODUCTION

For a parameter vector \( p \in \mathbb{P} \subseteq \mathbb{R}^n \), consider the parametric dynamical system in the state-space form

\[
\Sigma(p): \begin{cases}
E(p) \dot{z}(t;p) = A(p)x(t;p) + B(p)u(t), \\
y(t;p) = C(p)x(t;p), \\
x(0;0) = 0,
\end{cases}
\]

with matrix functions \( E, A : \mathbb{P} \to \mathbb{R}^{N \times N}, B : \mathbb{P} \to \mathbb{R}^{N \times m}, \) and \( C : \mathbb{P} \to \mathbb{R}^{L \times N} \). We assume that \( E(p) \) is nonsingular for every \( p \in \mathbb{P} \). In (1), we refer to \( x, u, \) and \( y \) as the states, inputs, and outputs, respectively. The parametric dynamical systems of the form (1) arise in many applications ranging from inverse problems to optimal control to uncertainty quantification and the parameter vector \( p \) enters the model in various ways, representing, for example, material properties, system geometry, and operating conditions; see, e.g., [7], [13], [20] and the references therein. Our standing assumption is that \( N \) is large and hence simulating (1) for a given input \( u \) and a given parameter \( p \) is expensive. Therefore, as required in many prominent applications, the need to repeat these simulations/computations for many parameter values and input selections leads to a big computational burden. This is what parametric model reduction (PMOR) aims to resolve. The goal of PMOR is to replace the full-order model (FOM) (1) by a reduced-order model (ROM) of the form

\[
\hat{\Sigma}(p): \begin{cases}
\hat{E}(p) \dot{\hat{z}}(t;p) = \hat{A}(p)\hat{z}(t;p) + \hat{B}(p)u(t), \\
\hat{y}(t;p) = \hat{C}(p)\hat{z}(t;p), \\
\hat{z}(0;p) = 0,
\end{cases}
\]

with \( \hat{E}, \hat{A} : \mathbb{P} \to \mathbb{R}^{n \times n}, \hat{B} : \mathbb{P} \to \mathbb{R}^{n \times m}, \hat{C} : \mathbb{P} \to \mathbb{R}^{n \times \ell} \), and \( n \ll N \) such that the output \( \hat{y}(t;p) \) of the ROM approximates the output \( y(t;p) \) of the FOM with high fidelity over a wide range of parameters and input selection. More precisely, we want the approximation error \( \|y - \hat{y}\| \) to be small for any \( u \in \mathcal{L}_2(0, \infty, \mathbb{R}^m) \) and any parameter \( p \in \mathbb{P} \).

A. Projection-based PMOR

There are plethora of methods to construct the ROM \( \hat{\Sigma}(p) \), we refer the reader to [2], [6], [7], [13], [20] for details. Common to most of these approaches is that they can be realized via a Petrov-Galerkin framework: Construct two MOR bases \( V, W \in \mathbb{R}^{N \times n} \) such that \( x(t;p) = V\hat{x}(t;p) \). Then, substitute this approximation into (1) and enforce a Petrov-Galerkin condition on the residual to obtain the reduced-order matrices as

\[
\hat{E}(p) := W^TE(p)V, \quad \hat{A}(p) := W^TA(p)V, \\
\hat{B}(p) := W^TB(p), \quad \hat{C}(p) := C(p)V.
\]

The task of model reduction is thus essentially equivalent to determining \( n \)-dimensional subspaces \( V := \text{span}(V) \) and \( W := \text{span}(W) \) of \( \mathbb{R}^N \) such that the ROM (2) obtained via projection onto these spaces is a good approximation of (1). Even though it is not the focus of this paper, we note that there are data-driven approaches to PMOR in which \( \hat{\Sigma}(p) \) is constructed without access to the FOM dynamics in (1) and with only access to input-output data; see, e.g., [3], [9], [11], [12], [15], and the references therein.

For the linear parametric dynamical systems (1) and (2) we consider here, the concept of transfer function provides a natural framework to analyze the MOR problem. Let \( Y(s,p) \) and \( U(s,p) \) denote Laplace transforms of \( y(t;p) \) and \( u(t;p) \). Then, by taking the Laplace transform of (1), we obtain

\[
Y(s,p) = H(s;p)U(s,p)
\]

where

\[
H(s;p) := C(p) (sA(p) - A(p))^{-1} B(p)
\]

is the transfer function of \( \Sigma(p) \). Similarly, the transfer function of the ROM \( \hat{\Sigma}(p) \) is given by

\[
\hat{H}(s;p) := \hat{C}(p) \left(s\hat{E}(p) - \hat{A}(p)\right)^{-1} \hat{B}(p).
\]

In this paper, we will focus on interpolatory approaches to construct \( \hat{H}(s;p) \). Interpolatory MOR is one of the most commonly employed frameworks to MOR and yield (locally) optimal approximations in the \( H_2 \)-norm. We skip those details here and refer the reader to [2]. The interpolatory framework we develop here deviates from the usual approach in the literature as we explain next.
B. Interpolation problem to construct $\hat{\Sigma}(p)$

The common approach to interpolatory PMOR chooses $V$ and $W$ so that $\hat{H}(s,p)$ interpolates $H(s,p)$ at some selected right frequency samples $\{\lambda_i\}_{i=1}^{N_s}$, left frequency samples $\{\mu_j\}_{j=1}^{N_p}$, parameter samples $\{\pi_i\}_{i=1}^{N_p}$ along the right interpolation (tangent) directions $\{r_i\}_{i=1}^{N_s} \in \mathbb{C}^m$ and left interpolation (tangent) directions $\{\ell_i\}_{i=1}^{N_p} \in \mathbb{C}^\ell$; i.e.,

$$H(\lambda_i, \pi_i) = \hat{H}(\lambda_i, \pi_i) \quad \text{and} \quad \ell_i^\top H(\mu_i, \pi_i) = \ell_i^\top \hat{H}(\mu_i, \pi_j)$$

for $i = 1,2,\ldots,N_s$ and $j = 1,2,\ldots,N_p$. One can also enforce interpolating the derivatives of $H$ with respect to $s$ and $p$, and the discussion here directly extends. However, for brevity, we only focus on simple interpolation in this paper. We show in Theorem II.1 how to construct $V$ and $W$ to satisfy the interpolation conditions listed above. These are discretized interpolation conditions in the sense that they hold over a discrete set of sampling points.

In this paper, we consider a more general problem of interpolating $H(s,p)$ along parameter-dependent curves in the frequency domain. More precisely, we are interested in solving the following problem.

**Problem I.1** Consider the dynamical system (1) with transfer function $H(s,p)$. For given functions $\lambda: \mathbb{P} \to \mathbb{C}$, $\mu: \mathbb{P} \to \mathbb{C}$, $r: \mathbb{P} \to \mathbb{C}^m$, and $\ell: \mathbb{P} \to \mathbb{C}^\ell$, construct a ROM with transfer function $\hat{H}(s,p)$ that tangentially interpolates $H(s,p)$ along the right tangent directions $r_i$ and at $\mu$ along the right tangent directions $\ell_i$ for all parameters, i.e., $\hat{H}(s,p)$ satisfies

$$H(\lambda(p),p)r(p) = \hat{H}(\lambda(p),p)r(p), \quad \text{and} \quad \ell(p)^\top H(\lambda(p),p) = \ell(p)^\top \hat{H}(\lambda(p),p), \quad \text{for all } p \in \mathbb{P}.$$

In general, we cannot expect to find constant matrices $V, W \in \mathbb{R}^{n \times n}$ with small $n$ such that (6) is satisfied for all parameters $p \in \mathbb{P}$. Instead, motivated by the lower-bound for the Kolmogorov $n$-widths [23, Thm. 3], we propose to construct parameter dependent model reduction bases $V(p)$ and $\hat{V}(p)$, exemplified by the matrix functions

$$V, \hat{V}: \mathbb{P} \to \mathbb{R}^{N \times n}.$$

Our analysis is inspired by the ideas presented in [24], which studied the balanced truncation method for parametric system.

Once the parameter dependent bases are chosen, the ROM is constructed via projection onto the spaces $V(p) := \text{span}(V(p))$ and $\hat{V}(p) := \text{span}(\hat{V}(p))$, i.e.,

$$\hat{E}(p) := W(p)^\top E(p)V(p), \quad \hat{A}(p) := W(p)^\top A(p)V(p),$$

$$\hat{B}(p) := W(p)^\top B(p), \quad \hat{C}(p) := C(p)V(p).$$

(7)

**Remark I.2** Time- and state-dependent projection matrices are currently heavily investigated in the efficient approximation of transport-dominated phenomena, where a nonlinear projection framework is used to overcome slowly decaying Kolmogorov $n$-widths; see, e.g., [8], [18], [21] and the references therein.

After this introduction, we recall some preliminary results in section II. Our main contribution is presented in section III with additional computational details presented in section IV.

Notation: Besides standard notation, we use multi-indices, i.e., for $j = (j_1, \ldots, j_\nu) \in \mathbb{N}_0^\nu$ and $p = (p_1, \ldots, p_\nu)$ we write

$$p^j := \prod_{i=1}^{\nu} p_i^{j_i}.$$  

II. PRELIMINARIES

A. Interpolation conditions

Interpolatory model reduction [2] constructs reduced-order models whose transfer function interpolates the transfer function of the original model at selected interpolation points. For a fixed parameter $\sigma \in \mathbb{P}$, interpolation via projection can be guaranteed as follows [2], [4].

**Theorem II.1 (Tangential interpolation)** For a fixed parameter $\sigma \in \mathbb{P}$ consider the FOM (1) with transfer function $H(s,\sigma)$ and the ROM (2) with transfer function $\hat{H}(s,\sigma)$ constructed as in (3) using $W, V \in \mathbb{R}^{\nu \times r}$ for interpolation points $\lambda_0, \mu_0 \in \mathbb{C}$, assume that $\lambda_0 E(\sigma) - A(\sigma)$ and $\mu_0 E(\sigma) - A(\sigma)$ are nonsingular. Let $r_0 \in \mathbb{R}^\nu$ and $\ell_0 \in \mathbb{R}^\ell$.

1. If $(\lambda_0 E(\sigma) - A(\sigma))^{-1}B(\sigma)r_0 \in \text{span}(V)$, then $H(\lambda_0, \sigma)r_0 = \hat{H}(\lambda_0, \sigma)r_0$.
2. If $(\ell_0^\top C(\sigma)(\mu_0 E(\sigma) - A(\sigma))^{-1}) \in \text{span}(W)$, then $\ell_0^\top H(\mu_0, \sigma) = \ell_0^\top \hat{H}(\mu_0, \sigma)$.

It is easy to see (cf. [10]) that matrices satisfying the conditions in Theorem II.1 for driving frequencies $\lambda_i$, $\mu_i$ and tangent directions $r_i$, $\ell_i$ $(i = 1, \ldots, n)$ can be constructed by solving the two Sylvester equations

$$A(\sigma)V - E(\sigma)VA + B(\sigma)R = 0, \quad \text{(8a)}$$

$$W^\top A(\sigma) - M^\top W^\top E(\sigma) + L^\top C(\sigma) = 0, \quad \text{(8b)}$$

for the unknowns $V$ and $W$ where

$$A := \text{diag}(\lambda_1, \ldots, \lambda_n), \quad M := \text{diag}(\mu_1, \ldots, \mu_n), \quad R := [r_1 \ldots r_n], \quad L := [\ell_1 \ldots \ell_n].$$

(9a)  

(9b)

If the driving frequencies and tangent directions are closed under complex conjugation, then one can use real versions of the matrices in (9). For fixed $\sigma \in \mathbb{P}$, the condition guaranteeing the existence and uniqueness of solutions to (8) is well-known, see, e.g., [1, Cha. 6].

**Lemma II.2** For $\sigma \in \mathbb{P}$, the Sylvester equations (8) have a unique solution if and only if $\lambda_i$, $\mu_i \not\in \sigma(E(\sigma), A(\sigma))$, where

$$\sigma(E(\sigma), A(\sigma)) := \{s \in \mathbb{C} \mid \text{rank}(sE(\sigma) - A(\sigma)) < N\}.$$  

is the spectrum of the matrix pencil $sE(\sigma) - A(\sigma)$.

B. Holomorphic functions

Our analysis requires that the matrix functions in (1) can be expanded in a power series. If the parameter domain is one-dimensional, this is then equivalent to the matrix functions being holomorphic (resp. analytic). Since we do not intend to restrict our analysis to a single parameter, we recall the appropriate definitions and results for functions of several parameters. For our presentation we follow [16] and [24].
A function $f : \mathbb{C}^\nu \supseteq \mathbb{P} \to \mathbb{C}$ is called holomorphic in $p = [p_j] \in \mathbb{P}$ if the complex derivative
\[
f'(p) = \lim_{h \to 0} \frac{f(p + hq) - f(p)}{h}
\]
events for any $q \in \mathbb{C}^\nu$. It is said to be holomorphic in $\mathbb{P}$, if it is holomorphic in every $p \in \mathbb{P}$. Many of the results for the one-dimensional case extend to a higher dimensional matrix, such as the Cauchy integral formula. In particular, if $f$ is holomorphic, it can locally be represented via a power series. For the analysis of its domain of convergence, we need the following definition, taken from [16].

**Definition II.3 (Reinhardt domain)** An open set $\Omega \subseteq \mathbb{C}^\nu$ is called Reinhardt domain, if $p = (p_1, \ldots, p_\nu) \in \Omega$ implies $(\exp(it_1)p_1, \ldots, \exp(it_\nu)p_\nu) \in \Omega$ for all $(t_1, \ldots, t_\nu) \in \mathbb{R}^\nu$ where $i$ denotes the imaginary unit.

**Theorem II.4** Let $\mathcal{P} \subseteq \mathbb{C}^\nu$ be a connected Reinhardt domain containing $0$ and suppose that $f : \mathbb{P} \to \mathbb{C}$ is holomorphic in $\mathbb{P}$. Then there exist unique $f_i \in \mathbb{C}$ for $i \in \mathbb{N}_0^\nu$ such that
\[
f(p) = \sum_{i \in \mathbb{N}_0^\nu} f_ip_i \quad \text{for each } p \in \mathbb{P}. \tag{10}
\]

Note that for simplicity, we have presented Theorem II.4 solely for the expansion point $\bar{p} = 0$. For practical applications, we may want to use a different expansion point or rescale the parameter domain and the system matrices such that $0$ is included in $\mathbb{P}$.

A question that arises immediately is whether there is a holomorphic version of the implicit mapping theorem available. This is indeed the case. For our analysis, we use the following extension of the implicit mapping theorem [24].

**Proposition II.5** Consider a function $\mathcal{F} : \mathbb{C}^\nu \times \mathbb{C}^{n_1 \times n_2} \to \mathbb{C}^{n_1 \times n_2}$ and suppose there exists $p_0 \in \mathbb{C}^\nu$ and $X_0 \in \mathbb{C}^{n_1 \times n_2}$ such that $\mathcal{F}(p_0, X_0) = 0$ and $\mathcal{F}$ is holomorphic around this point. If
\[
0 = \frac{\partial}{\partial h} \mathcal{F}(p_0, X_0 + hD) \bigg|_{h=0}
\]
implies $D = 0$, then there exists an neighborhood $\mathcal{P} \subseteq \mathbb{C}^\nu$ around $p_0$ and a holomorphic function $X : \mathcal{P} \to \mathbb{C}^{n_1 \times n_2}$ such that
\[
\mathcal{F}(p, X(p)) = 0
\]
for all $p \in \mathcal{P}$.

### III. Rational Interpolation Along Parameter-Dependent Curves

In this section, we establish the main result that guarantees existence of holomorphic functions $V(p)$ and $W(p)$ such that the reduced model in (7) solves the new interpolation problem defined in Problem I.1.

**Theorem III.1** Consider the dynamical system (1) and assume that $E, A, B, C$ are holomorphic in the compact set $\mathcal{P} \subseteq \mathbb{C}^\nu$. Assume that for $i = 1, \ldots, n$ the holomorphic functions $\lambda_i, \mu_i : \mathcal{P} \to \mathbb{C}$ are such that
\[
\lambda_i(p), \mu_i(p) \not\in \sigma(E(p), A(p))
\]
for all $p \in \mathcal{P}$. If the tangent directions $r_i : \mathcal{P} \to \mathbb{C}^m$ and $\ell_i : \mathcal{P} \to \mathbb{C}^\ell$ are holomorphic, then there exists holomorphic functions $V, W : \mathcal{P} \to \mathbb{C}^{N \times n}$ satisfying
\[
A(p)V(p) - E(p)V(p)\Lambda(p) + B(p)R(p) = 0, \quad (11)
\]
\[
W^T(p)A(p) - M^T(p)W^T(p)E(p) + L^T(p)C(p) = 0 \quad (12)
\]
for all $p \in \mathcal{P}$, where $\Lambda(p), M(p), R(p), L(p)$ are defined as in (9), but now with parametric dependence.

**Proof:** We show the assertion only for $V$. The proof for $W$ follows similarly. Define the holomorphic function
\[
\mathcal{F} : \mathbb{C}^{N \times n} \times \mathbb{C}^{N \times n} \to \mathbb{C}^{N \times n},
\]
\[
(p, V) \to A(p)V - E(p)V\Lambda(p) + B(p)R(p).
\]
Let $p_0 \in \mathcal{P}$. Then, using Lemma II.2, there exists $V_0 \in \mathbb{C}^{N \times n}$ satisfying $\mathcal{F}(p_0, V_0) = 0$. In addition, for any $V \in \mathbb{C}^{N \times n}$ we obtain
\[
\frac{\partial}{\partial \epsilon} \mathcal{F}(p_0 + \epsilon V_0 + \epsilon \bar{V}, V_0 + \epsilon V) = A(p_0)\bar{V} - E(p_0)V\Lambda(p).
\]
From Lemma II.2 we conclude that $\frac{\partial}{\partial \epsilon} \mathcal{F}(p_0, V_0 + \epsilon \bar{V}) = 0$ if and only if $\bar{V} = 0$. Thus, Proposition II.5 implies that there exists a neighborhood $\mathcal{P} \subseteq \mathbb{C}^\nu$ around $p_0$ and a holomorphic function $V : \mathcal{P} \cap \mathbb{P} \to \mathbb{C}^{N \times n}$ satisfying $\mathcal{F}(p, V(p)) = 0$. Let $\mathcal{P}$ denote the maximal neighborhood such that the previous construction holds. It remains to show that $\mathcal{P}\cap\mathbb{P} = \mathcal{P}$. Assume $\mathcal{P}\cap\mathbb{P} \neq \mathcal{P}$ and let $\pi \in \mathcal{P}\setminus\mathcal{P}$. Repeating the construction, we obtain a neighborhood $\mathcal{P} \subseteq \mathbb{C}^\nu$ and holomorphic function $V : \mathcal{P} \cap \mathbb{P} \to \mathbb{C}^{N \times n}$ satisfying $\mathcal{F}(p, V(p)) = 0$. Assume first $\mathcal{P}\cap\mathbb{P} \neq \mathcal{P}$. Then there exists $\tilde{\pi} \in \mathcal{P}\cap\mathcal{P}$. Due to Lemma II.2 and the assumptions we conclude $V(\tilde{\pi}) = V(\tilde{\pi})$. From the holomorphic identity theorem [17, Thm. 1.2.14] we infer $V = \bar{V}$, a contradiction. If, on the other hand, $\mathcal{P}\cap\mathbb{P} = \mathcal{P}$, we can select further points in $\mathcal{P}$ until we obtain an open covering of $\mathcal{P}$. Since $\mathcal{P}$ is compact, we can choose a finite covering and proceed as before. We conclude $\mathcal{P}\cap\mathbb{P} = \mathcal{P}$. \[\blacksquare\]

**Corollary III.2** Suppose that the assumptions from Theorem III.1 are satisfied and construct a ROM as in (7). Then the ROM satisfies the interpolation conditions (6) for all $p \in \mathbb{P}$, thus solving Problem I.1.

**Remark III.3** Using [22, Prop. 3.24], Theorem III.1 can be extended to structured systems with a transfer function of the form $H(s;p) = C(p)(\sum_{k=1}^K h_k(s;p)A_k(p))^{-1}B(p)$, which includes, for instance, delay equations, fractional systems, and viscoelastic dynamics.

### IV. Computational Details

Even though we have established the theoretical framework for constructing $V(p)$ and $W(p)$ to solve the new parametric interpolation problem, for a numerically efficient PMOR framework we need to consider the computational aspects in solving (11) and (12), and performing the projection (7).

For the brevity of presentation we restrict ourselves in this section to standard state-space systems with $E(p) \equiv I_N$. For a parameter-dependent $E$ matrix, the construction is similar, but the formulas are more involved.
A. Numerical construction of $V(p)$ and $W(p)$

Assuming that holomorphic matrix functions, Theorem II.4 ensures that we can decompose these matrices as

$$A(p) = \sum_{i \in \mathbb{N}_0^N} p^i A_i, \quad V(p) = \sum_{i \in \mathbb{N}_0^N} p^i V_i$$

$$B(p) = \sum_{i \in \mathbb{N}_0^N} p^i B_i, \quad R(p) = \sum_{i \in \mathbb{N}_0^N} p^i R_i.$$  

In many practical applications, the system matrices are directly available in such a form with a finite number of terms. Then the Sylvester equation (11) becomes

$$0 = \sum_{j \in \mathbb{N}_0^N} (A_j V_j - V_j A_j + B_j R_j)p^{i+j}$$

$$= \sum_{\rho \in \mathbb{N}_0^N} \sum_{i+j=\rho, i,j \in \mathbb{N}_0^N} (A_j V_j - V_j A_j + B_j R_j)p^{i+j}.$$  

Using the holomorphic identity theorem [17, Thm. 1.2.14], we conclude that for $\rho \in \mathbb{N}_0^N$ we have

$$0 = \sum_{i,j = \rho, i,j \in \mathbb{N}_0^N} (A_j V_j - V_j A_j + B_j R_j)$$

$$= A_0 V_0 - V_0 A_0 + \sum_{i+j=\rho, j \neq \rho} A_i V_j - V_j A_i + \sum_{i+j=\rho} B_i R_j,$$  

which provides an iterative method to solve for the coefficients $V_i$. A similar strategy can be obtained for the coefficients for $W$, which we omit here to avoid redundancy.

**Corollary IV.1** Under the assumptions of Theorem III.1 the Sylvester equation (13) is uniquely solvable for each $\rho \in \mathbb{N}_0^N$.

**Proof:** This follows immediately from $A_0 = A(0)$, $A_0 = \Lambda(0)$, and Lemma II.2.

Note that when the interpolation frequencies and tangent directions are closed under conjugation, the $V_j$ can be chosen to be real thus yielding a real-valued matrix $V(p)$ for each real parameter $p \in \mathbb{P}$.

In numerical computations, we cannot compute all the coefficients $V_i$ and thus have to truncate the power-series expansion at an index based on a tolerance. In other words, for a given tolerance $\tau$, we truncate the power series expansion when $\max_{p \in \mathbb{P}} |p^i||V_i| \leq \tau$, and similarly for $W(p)$. As a consequence, we cannot ensure exact interpolation any longer. A similar issue arises in the usual interpolatory model reduction framework when the required subspaces vectors in Theorem II.1, namely $(\lambda_0 E(\pi) - A(\pi))^{-1}B(\pi)\pi_0$ and $(\mu_0 E(\pi) - A(\pi))^{-1}C(\pi)$, are computed via iterative solves; see, e.g., [5]. We revisit this issue in Section VI.

B. Constructing the reduced matrices

For simplicity, we only focus on $\tilde{A}(p)$ in (7); but the discussion extends directly to other reduced order quantities. We will work with the truncated quantities, i.e.,

$$A(p) = \sum_{\|k\| \leq \rho_v} p^k A_k,$$

$$W(p) = \sum_{\|k\| \leq \rho_w} p^k W_j, \quad V(p) = \sum_{\|k\| \leq \rho_v} p^k V_i.$$  

For every new parameter vector $\pi \in \mathbb{P}$, forming $V(\pi)$ and $W(\pi)$ can be efficiently done using the truncated form as in (14). However constructing $\tilde{A}(\pi)$ requires computing $\tilde{A}(\pi) = W(\pi)^T A(\pi) V(\pi)$, which involves two matrix multiplications in the original dimension $N$. We resolve this issue using the truncated forms (14):

$$\tilde{A}(\pi) = \sum_{\|j\| \leq \rho_w} \sum_{\|k\| \leq \rho_v} \sum_{\|\ell\| \leq \rho_v} (W_j^T A_k V_i) \pi^{i+j+k}.$$  

Note that the reduced coefficients $W_j^T A_k V_i \in \mathbb{R}^n$ in (15) can be precomputed (in the offline stage). Assuming $\rho_v, \rho_w$ and $\rho_v$ are modest integers, storing all the coefficients $W_j^T A_k V_i$ and then forming the overall sum can be efficiently computed in the online stage.

V. NUMERICAL EXAMPLES

A. A toy example

Consider a simple example for which the dimension of the parameter set is $n = 1$ (and the parameter enters only in the vector $B$). The matrices are as follows

$$A(p) = -\text{diag}(1, 1, 2), \quad C(p) = [2 \ 1 \ 1],$$

$$B(p) = \begin{bmatrix} p & -1 & 1 \end{bmatrix}^T, \quad E(p) = I_3.$$  

Hence, it follows that

$$A_0 = -\text{diag}(1, 1, 2), \quad C_1 = \begin{bmatrix} 1 & 1 & 2 \end{bmatrix}, \quad A_i, C_i = 0 \forall i \geq 1$$

$$B_0 = \begin{bmatrix} 0 & 1 & 1 \end{bmatrix}^T, \quad B_1 = \begin{bmatrix} 1 & -1 & 1 \end{bmatrix}^T, \quad B_i = 0 \forall i \geq 2.$$  

Note that $N = 3$ and that we choose $n = 2$ as the reduction order. Choose interpolation points and tangent directions that are independent of the parameter, e.g.,

$$\lambda_1 = 1, \quad \lambda_2 = 3, \quad \mu_1 = 2, \quad \mu_2 = 4,$$

and also $r = \ell = [1; 1]$. Choose the following:

$$A_0 = \begin{bmatrix} 1 & 0 & 3 \end{bmatrix}, \quad M_0 = \begin{bmatrix} 2 & 4 \end{bmatrix}, \quad A_i = 0, \quad M_i = 0 \forall i \geq 1$$

$$R_0 = L_0^T = \begin{bmatrix} 1 \ 1 \end{bmatrix}, \quad R_i = L_i^T = 0, \forall i \geq 1.$$  

For $\rho = 0$, it follows that the equation (13) simplifies to $A_0 V_0 - V_0 A_0 + B_0 R_0 = 0$. Similarly, based also on (13), $V_1$ satisfies the following Sylvester equation

$$A_0 V_1 - V_1 A_0 + A_1 V_0 - V_0 A_1 + B_1 R_0 + B_0 R_1 = 0,$$

which simplifies to $A_0 V_1 - V_1 A_0 = B_1 R_0 = 0$. Hence, explicitly compute the first two Taylor coefficients

$$V_0 = \begin{bmatrix} 0 & 0 \\ \frac{1}{2} & \frac{1}{2} \\ \frac{1}{4} & \frac{1}{4} \end{bmatrix}, \quad V_1 = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ -\frac{1}{2} & -\frac{1}{2} \\ 0 & 0 \end{bmatrix}.$$  

6891
and $V_i = 0, \forall i \geq 2$. Next, compute matrix $W^T = W_0^T \in C^{2 \times 3}$ by solving $W_0^T A_0 - M_0 W_0^T + L_0 C_0 = 0$, as

$$W^T = \begin{bmatrix} \frac{2}{3} & \frac{1}{3} & \frac{1}{3} \\ \frac{2}{3} & \frac{1}{3} & \frac{1}{3} \end{bmatrix},$$

and put together the following reduced realization that does indeed depend on the parameter $p$ as follows

$$\hat{E}^{(1)}(p) = W^T E V(p) = \begin{bmatrix} \frac{5 + p}{p} & \frac{5 + p}{p} & \frac{5 + p}{p} \\ \frac{5 + p}{p} & \frac{5 + p}{p} & \frac{5 + p}{p} \end{bmatrix},$$

$$\hat{A}^{(1)}(p) = W^T A(p) V(p) = \begin{bmatrix} -\frac{p}{2} - \frac{1}{2} & -\frac{p}{2} - \frac{1}{2} & -\frac{p}{2} - \frac{1}{2} \\ -\frac{p}{2} - \frac{1}{2} & -\frac{p}{2} - \frac{1}{2} & -\frac{p}{2} - \frac{1}{2} \end{bmatrix},$$

$$\hat{B}^{(1)}(p) = W^T B(p) = \begin{bmatrix} \frac{5 + p}{p} & \frac{5 + p}{p} & \frac{5 + p}{p} \end{bmatrix},$$

$$\hat{C}^{(1)}(p) = C(p) V(p) = \begin{bmatrix} \frac{5 + p}{p} & \frac{5 + p}{p} & \frac{5 + p}{p} \end{bmatrix}.$$  \hspace{1cm} (17)

We note that the system in (17) interpolates the original one in (16), at the selected frequency points for every value of the parameter $p$. We also note that the system in (17) is equivalent to a minimal realization of (16) for $p \in \{0,1\}$.

**B. Another toy example**

Consider the example defined by the matrices

$$A(p) = \begin{bmatrix} -2 - \frac{1}{3} & 0 & 0 \\ -p & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \quad B(p) = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, \quad C(p) = B^T(p)$$

with $E \equiv I_3$. Hence, it follows

$$A_0 = \begin{bmatrix} -2 & 0 & 0 \\ -p & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \quad A_1 = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

and $A_i = 0$ for all $i \geq 2$. Then, we have also that

$$B_0^T = C_0 = \begin{bmatrix} 1 & 0 & 1 \end{bmatrix}, \quad \text{and} \quad B_i^T = C_i = 0, \forall i \geq 1.$$

For this case, consider two right interpolation points as:

$$A(p) = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix} = A_0, \quad \text{and} \quad A_i = 0, \forall i \geq 1.$$  \hspace{1cm} (18)

Note that in this case we use $W^T(p) = V^T(p)$. The right directions are all ones and the Sylvester equations in (13) simplify to the following collection:

$$A_0 V_0 - V_0 A_0 + B_0 R_0 = 0,$$

$$A_0 V_i - V_i A_0 + A_i V_{i-1} = 0, \forall i \geq 1.$$  \hspace{1cm} (19)

Hence, one can iteratively compute $V_i$ for any positive value of $i$. We do that for all values of $i$ until $\|V_i\| < \tau := 10^{-5}$, yielding 26 Taylor coefficients that need to be computed. Finally, as described in Section IV-B, we put together the reduced-order matrices and evaluate the approximation errors for a 2D grid with $p \in [0,1]$ and $s \in [10^{-2},10^1]$.

**C. A more involved numerical example**

We analyze the dynamical system originally proposed in [19] and later modified in [15], [9] to add a parameter dependence. The dynamics are characterized by the matrices

$$A(p) = \text{diag} (T_1(p), T_2, T_3, T_4) \in \mathbb{R}^{1000 \times 1000}, \quad \text{with}$$

$$T_1(p) = \begin{bmatrix} -1 & p+1000 \\ -100-p & -1 \end{bmatrix}, \quad T_2 = \begin{bmatrix} -1 & 2000 \\ -200 & -1 \end{bmatrix},$$

$$T_3 = \begin{bmatrix} -1 & 4000 \\ -400 & -1 \end{bmatrix}, \quad T_4 = -\text{diag} (1,2,\ldots,1000).$$

with $p \in \mathbb{P} := [0,1]$. Additionally, the constant vectors $B$ and $C$ are given by

$$B = C^T = [10e_6; e_{1000}],$$

where $e_k$ denotes the $k$-dimensional vector of ones.

We choose 40 logarithmically-spaced interpolation points in the interval $[10^{-1},10^3]$ denoted with $\lambda_1, \ldots, \lambda_{10}$ (we are using a one-sided interpolation scheme). Additionally, let the tolerance value be $\tau = 10^{-7}$. It follows that we need to compute the first 11 Taylor coefficients of $V(p)$, i.e., $V_1, V_2, \ldots, V_{10}$, since $V_{11} < \tau$. As in the previous example, use $W(p) = V^T(p)$ as the left projection matrix, and follow the formulas presented in Section IV-B, to compute the corresponding reduced-order matrices.

First we fix the frequency parameter as $s = \lambda_{10} = 8.8862i$, and vary $p$ in between 0 and 1 (50 linearly-spaced points). We depict the approximation errors for different values of $p$ in Fig. 2. We note that the interpolation errors due to the truncation of the power series are small, in the interval $(10^{-9},10^{-6})$, in accordance with the tolerance $\tau = 10^{-7}$.

**Fig. 1.** Approximation errors on a 2D grid $(s,p)$.

**Fig. 2.** Approximation errors for $s = \lambda_{10}$ and varying $p$ in $[0,1]$.

For the next experiment, we fix $p = 0.5$ and vary the frequency parameter $s$ in the interval $[10^{-1},10^3]$ (200 logarithmically-spaced points).

**Fig. 3.** The two transfer functions for $p = 0.5$ and $s \in [10^{-1},10^3]$.  

6892
We depict the magnitudes of the two transfer functions (original and reduced) evaluated for different values of $s$ in Fig. 3, illustrating that FOM response is indeed well matched.

Finally, we construct a 2D grid of parameter pairs $(s, p)$ evaluated on the Cartesian product of the two previously-mentioned discrete sets. Then, for all the $200 \times 50 = 10^4$ pairs, we compute the approximation error. The results are presented in Fig. 4.

VI. CONCLUSIONS AND FUTURE WORK

We have presented a theoretical framework that allows construction of a ROM whose transfer function interpolates the transfer function of the original high-dimensional system at parameter-dependent interpolation frequencies along parameter-dependent tangent directions. The associated parametric projection spaces are proven to have a holomorphic dependency on the parameter and the coefficients of its power series can be computed iteratively using standard methods.

There are many natural avenues to investigate further. For example, interpolation of the higher-order derivatives is a natural next step. In this paper, we did not consider an optimality measure for choosing the projection spaces. One might consider combining our framework with the recent work on optimal parametric model reduction in a joint $H_2 \otimes L_2$ measure [14]. Even though we have considered here the projection-based approaches, data-driven methods have been also considered for parametric systems [15]. Interpreting our reduced model in that framework could provide further hints for data-driven modeling.

As we stated in section IV-A, when the power series expansions are truncated, we can no longer guarantee exact interpolation. We will investigate in a future work how the perturbation results from interpolatory model reduction with inexact solves [5] can be used to quantify the interpolation error due to the truncation.
