I. INTRODUCTION

In most basic textbooks on electricity, the use of a time-dependent source to drive a circuit is reduced to sinusoidal driving. This is of paramount importance to introduce the concept of filtering in Fourier space, a technique that appears in many other fields of physics including wave optics. Such time-dependent circuits also provide an opportunity to train the students in solving linear differential equations and have therefore a certain pedagogical value.

In this article, we propose to revisit the standard RC series circuit subjected to sinusoidal driving in order to present an inverse use of the differential equation that governs the time evolution of the capacitor charge. More precisely, we show explicitly how the proper shaping of the voltage enables one to reach the stationary regime associated with sinusoidal driving in a time much shorter than the characteristic time of the circuit. Similarly, we explain how this technique can be extended to the fast discharge of a capacitor or to the sudden change in the driving frequency. Here, fast refers to a time scale small compared to the RC time constant. We detail the experimental implementation of those ideas that are well adapted to experimental classes involving computer control of an instrument, a voltage source in this case.

The method is generic and is directly inspired by the inverse engineering technique developed in the growing field of Shortcuts To Adiabaticity with applications in classical mechanics, optical devices, quantum and statistical physics. The shortcut method can be used as a simple experimental project dedicated to the computer control of a voltage source. Besides the specific example addressed here, the proposed method provides an original use of simple linear differential equations to control the dynamical quantities of a physical system and has therefore a certain pedagogical value.

II. DESCRIPTION OF THE SETUP

We consider a simple electric circuit made of a resistor placed in series with a capacitor driven by a time dependent voltage source (see Fig. 1(a)). The charge obeys the first order differential equation

\[ \dot{q}(t) + \frac{q(t)}{\tau} = \frac{V(t)}{R}, \]  

with \( \tau = RC \). For sinusoidal driving

\[ V(t) = V_0 \sin(\omega t), \]

the solution of Eq. (1) is given by the superposition of the response with the source set to zero and the forced response:

\[ \dot{q}(t) = q_0(t) + q_f(t). \]

In mathematical language, we call these two responses the homogeneous and the particular solutions. The homogeneous solution reads

\[ q_0(t) = A_0 \exp(-t/\tau), \]

while the particular inhomogeneous solution is of the following form:

\[ q_f(t) = A_1 \sin(\omega t) + A_2 \cos(\omega t). \]

We readily find

\[ A_1 = \left( V_0 \tau / R \right) / \left( 1 + \omega^2 \tau^2 \right) \]

and

\[ A_2 = -\omega t A_1. \]

Using the amplitude phase notation

\[ q_f(t) = A \sin(\omega t - \varphi) \]  

with \( \varphi = \arctan(\omega t) \) and \( A = (V_0 \tau / R) \sqrt{1 + \omega^2 \tau^2} \). With this notation, we clearly see the existence of a time delay, \( \varphi/\omega \), between the driving and the response obtained through the time evolution of the charge. It is worth noting that the forced solution is a particular solution of the second order differential equation without dissipation

\[ \ddot{q}_f + \omega^2 q_f = 0. \]

The constant \( A_0 \) is determined by the initial condition on the full solution. Assuming that the charge is zero initially, \( q(0) = 0 \), we find

\[ q(t) = \frac{V_0 \tau / R}{1 + \omega^2 \tau^2} \left\{ \sin(\omega t) - \omega t \left[ \cos(\omega t) - e^{-t/\tau} \right] \right\}. \]
The transient regime lasts over the time interval for which the term $e^{-t/\tau}$ is not negligible with respect to one. The time $t_{\infty}$ required to reach the stationary regime should be such that $t_{\infty} \approx 2\pi$. In the limit $\omega t \gg 1$, the charge and therefore the current undergo a large number of oscillations before reaching the stationary regime. This transient towards the stationary regime is most conveniently observed in the so-called phase space $(q, \dot{q})$, where the system converges towards an elliptical attractor whose size is dictated by the driving voltage amplitude and the characteristics of the circuit

$$
\left( q^2(t) + \frac{1}{\omega^2} \left( \frac{dq}{dt} \right)^2 \right) \rightarrow \frac{(V_0/\tau/R)^2}{1 + \omega^2 t^2}.
$$

In Fig. 1(b), we have constructed such a phase space representation by plotting the voltage $V_2(t)$ (proportional to $dq/dt$) as a function of $V_1(t)$ (proportional to $q(t)$) for the following experimental parameters: $V_0 = 10 \text{ V}$, $R = 9.9863 \times 10^3 \pm 1.1 \ \Omega$, $C = 32.8 \pm 0.49 \ \text{nF}$ (measured with a multimeter Agilent 34405A), $\tau = RC = 327.5 \ \mu\text{s}$, $\omega = 2\pi \times 10 \ 000 \ \text{Hz}$, and an acquisition time of $35 \times 2 \pi/\omega$.

The dimensionless parameter $\omega t \approx 20.5$ has been chosen sufficiently large to ensure that the system undergoes a significant number of oscillations before reaching the stationary regime. The voltage $V_1(t)$ has been recorded using a LeCroy Wavesurfer44Xs oscilloscope (10000 data points are acquired) and averaged over 20 repetitions of the protocol. The voltage $V_2(t)$ cannot be obtained directly since both the voltage source and the oscilloscope that reads the $V_1(t)$ voltage are connected to ground. We therefore inferred the voltage $V_2(t)$ by numerically performing the subtraction: $V_2(t) = V(t) - V_1(t)$. We observe on the phase plot the well-known clockwise rotation of the trajectory together with the limit cycle (visible as the thick ellipse), which sets in after a long time.

### III. OUR APPROACH

In the following, we propose to engineer the voltage source to reach the stationary regime on a much shorter time scale $t_f \ll \tau$. For $t > t_f$, the voltage will be the sinusoidal driving voltage given by (2). Within our approach, $t_f$ can be chosen at will, in principle, arbitrarily small. We adopt an inverse engineering approach. To this end, we first fix the boundary conditions that we would like on the charge $q(t)$: $q(0) = q_0$ and $\dot{q}(t_f) = q_f(t_f)$ for the followings: $q(0), q_f(t_f) = q_q(t_f) = \dot{q}(t_f)$ and $\ddot{q}(t_f) = \ddot{q}(t_f) = -\omega^2 q(t_f)$. The last condition is important since the stationary trajectory we aim to reach is a solution of the second-order linear differential equation (4).

We add the following constraints $q(0) = 0$ and $\dot{q}(0) = 0$ to ensure a smooth initial variation of the charge. As the motion of the charge is sinusoidal, the boundary conditions on the first and second derivatives must be chosen consistently. The second step consists in choosing an interpolation function for the charge. Having set 6 boundary conditions, we will therefore use an interpolation function featuring 6 free parameters. In practice and for the sake of simplicity, we make a fifth order polynomial

$$
q(t) = \left[ 10q(t_f) - 4t_f \dot{q}(t_f) + \frac{t_f^2}{2} \ddot{q}(t_f) / 2 \right] \left( \frac{t}{t_f} \right)^4 + \\
+ \left[ -15q(t_f) + 7t_f \dot{q}(t_f) - \frac{t_f^2}{2} \ddot{q}(t_f) / 2 \right] \left( \frac{t}{t_f} \right)^4 + \\
+ \left[ 6q(t_f) - 3t_f \dot{q}(t_f) + \frac{t_f^2}{2} \ddot{q}(t_f) / 2 \right] \left( \frac{t}{t_f} \right)^5.
$$

By plugging this time-dependent form for the charge into Eq. (1), we find the voltage $V(t)$ that we should impose on the circuit to obtain the desired evolution of the charge. This is the essence of the inverse engineering technique.

As a concrete example, we propose to reach the stationary regime in a quarter of the driving period $t_q = \pi/(2\omega)$ (see Fig. 2a). As a result, we find the final values for the charge $q(t_f) = A_q^q$, $\dot{q}(t_f) = -\omega A_q^a$, $\ddot{q}(t_f) = -\omega^2 A_q^b$. With such boundary conditions, we have found the following voltage for the time interval $0 \leq t \leq t_f$.

$$
V(t) = -\frac{V_0}{2} \left( \frac{t}{t_f} \right)^2 \left( 1 + \frac{1}{1 + \omega^2 t_f^2} \right) a_2 + a_3 \left( \frac{t}{t_f} \right)^3 + a_4 \left( \frac{t}{t_f} \right)^2 + a_5 \left( \frac{t}{t_f} \right)^3,
$$

with

$$
\begin{align*}
a_2 &= 3 \left( \frac{t}{t_f} \right)^2 \left[ -20 + 8\omega^2 t_f \right], \\
a_3 &= 120 \left( \frac{t}{t_f} \right)^3 + 4 \left( 5 + 14 \omega t_f \right), \\
a_4 &= -60 \left( \frac{t}{t_f} \right)^2 - 2 \omega t_f^2 - 9\omega^2 t_f + 30 \left( 1 + \omega t_f \right)^2, \\
a_5 &= -12 + 6\omega^2 t_f + \omega t_f^2.
\end{align*}
$$

Fig. 1. (a) The RC circuit under study. (b) Phase portrait of our system, displaying the measured evolution of the voltage $V_2(t)$ as a function of $V_1(t)$ for a voltage source $V(t) = V_0 \sin(\omega t)$. Here, $V_0 = 10 \text{ V}$, $\omega = 2\pi = 10 \times 10^3 \text{ Hz}$, $\tau = 327.5 \ \mu\text{s}$, and 10 000 experimental data points have been gathered to produce the curve, with a subsequent average over 20 realizations. The insets provide the explicit variation with time of the voltage source, $V(t)$, and the voltage drop across the capacitor, $V_1(t)$.
measured through $t_f$, one clearly observes that the charge time evolution towards the stationary regime. Comparing the inset of Fig. 2(a). As expected, we observe the rapid convergence of the imposed source voltage is discretized with a time step of 2.5 ns. Interestingly, our fast protocol for the generation of a period $t_f$ is chosen to be $t_f = \pi/(2\omega) = 25 \mu s$. From $t$ equal to zero to $\pi/(2\omega)$, the signal $V(t)$ has been calculated to force the evolution of the charge towards the stationary regime and to be continuously connected to the sinusoidal driving voltage for $t \geq t_f$.

(b) Experimental evolution of the voltage $V_2(t)$ as a function of $V_1(t)$ for the driving voltage that ensures the discharge of the capacitor in $t_f = 10 \mu s$ for an initial charge in the stationary regime associated with the driving frequency 10 kHz. The amplitude and frequency are the same as for Fig. 1. Insets represent the voltages $V_1(t)$ and $V_1(t)$ as a function of time.

These coefficients satisfy all our boundary conditions. For $t \geq t_f$, the voltage is simply the sinusoidal driving voltage (see Eq. 2)). To drive the voltage source, $V(t)$, with such a time dependency, we use the LabVIEW control of the arbitrary waveform generator Keysight 33611A (see upper insets of Fig. 2(a)). The imposed source voltage is discretized with a time step of 2.5 ns. Interestingly, our fast protocol for the chosen boundary values does not exhibit a voltage overshoot: the designed voltage has an amplitude always smaller than or equal to $V_0 = 10 \text{ V}$ in our experiment. The resulting measured voltages are summarized in the phase space plot of Fig. 2(a). As expected, we observe the rapid convergence towards the stationary regime. Comparing the inset of Fig. 2(a), one clearly observes that the charge time evolution measured through $V_1(t)$ responds to the change in the voltage source $V(t)$ with a delay. It is worth noticing that the convergence towards the stationary regime has been dramatically accelerated thanks to our protocol as it can be seen by comparing Figs. 1(b) and 2(a). The stationary regime is approximately reached in a time $6t \approx 2 \text{ ms}$ when the voltage source is applied suddenly while our fast protocol requires a quarter of a period $\pi/2\omega = 25 \mu s$. The gain in time is therefore about 2 orders of magnitude. We have taken boundary conditions at a final time for a quarter of period just for convenience and simplicity, but the method still holds for shorter amounts of time.

In a similar manner, the reverse transformation from the stationary regime to the complete discharge of the capacitor can also be driven in a short amount of time. The calculation of the desired voltage is obtained in the very same manner using the proper boundary conditions for the charge. Figure 2(b) (lower panel) illustrates such an experimental realization with the same electrical circuit using $V_0 = 10 \text{ V}$, $\omega/2\pi = 10 \text{ kHz}$, and $t_f = 10 \mu s$.

Combining the previous methods, one can readily extend the control of the circuit driving to connect two stationary states associated with two different driving frequencies, going through the state of “rest” (vanishing $V_1$ and $V_2$) as an intermediate. We have realized this experiment by driving the system at 20 kHz and then at 10 kHz as explicitly shown in Fig. 3. We present in the upper panel such a transformation performed with a sudden change in the frequency and in the lower panel the reaching of the new stationary regime in $t_f = 35 \mu s$ thanks to a proper shaping of the voltage source (see the inset of Fig. 3(b)).

These coefficients satisfy all our boundary conditions. For $t \geq t_f$, the voltage is simply the sinusoidal driving voltage (see Eq. 2)). To drive the voltage source, $V(t)$, with such a time dependency, we use the LabVIEW control of the arbitrary waveform generator Keysight 33611A (see upper insets of Fig. 2(a)). The imposed source voltage is discretized with a time step of 2.5 ns. Interestingly, our fast protocol for the chosen boundary values does not exhibit a voltage overshoot: the designed voltage has an amplitude always smaller than or equal to $V_0 = 10 \text{ V}$ in our experiment. The resulting measured voltages are summarized in the phase space plot of Fig. 2(a). As expected, we observe the rapid convergence towards the stationary regime. Comparing the inset of Fig. 2(a), one clearly observes that the charge time evolution measured through $V_1(t)$ responds to the change in the voltage source $V(t)$ with a delay. It is worth noticing that the convergence towards the stationary regime has been dramatically accelerated thanks to our protocol as it can be seen by comparing Figs. 1(b) and 2(a). The stationary regime is approximately reached in a time $6t \approx 2 \text{ ms}$ when the voltage source is applied suddenly while our fast protocol requires a quarter of a period $\pi/2\omega = 25 \mu s$. The gain in time is therefore about 2 orders of magnitude. We have taken boundary conditions at a final time for a quarter of period just for convenience and simplicity, but the method still holds for shorter amounts of time.

In a similar manner, the reverse transformation from the stationary regime to the complete discharge of the capacitor can also be driven in a short amount of time. The calculation of the desired voltage is obtained in the very same manner using the proper boundary conditions for the charge. Figure 2(b) (lower panel) illustrates such an experimental realization with the same electrical circuit using $V_0 = 10 \text{ V}$, $\omega/2\pi = 10 \text{ kHz}$, and $t_f = 10 \mu s$.

Combining the previous methods, one can readily extend the control of the circuit driving to connect two stationary states associated with two different driving frequencies, going through the state of “rest” (vanishing $V_1$ and $V_2$) as an intermediate. We have realized this experiment by driving the system at 20 kHz and then at 10 kHz as explicitly shown in Fig. 3. We present in the upper panel such a transformation performed with a sudden change in the frequency and in the lower panel the reaching of the new stationary regime in $t_f = 35 \mu s$ thanks to a proper shaping of the voltage source (see the inset of Fig. 3(b)).
IV. CONCLUSION

In conclusion, we have shown both theoretically and experimentally the usefulness of inverse engineering to drive at will the current in a RC circuit. Our treatment offers specific projects and activities for students that feature both conceptual/mathematical and experimental aspects. While the most rewarding option is to treat both questions in class, it is also possible to restrict to a one-sided treatment. For a successful implementation, we have provided after Eq. (6) a relevant set of parameter values. The idea can be easily implemented as a computer-interfacing project. From a pedagogical point of view, such studies also contribute to the renewal of the teaching of differential equations with application in the growing field of control in physics. This method can be readily generalized to other linear circuits such as the RL circuit. Using the analogy between electricity and classical mechanics, the technique provides interesting and nontrivial solutions in this latter domain. For instance, the transport of a particle in a moving harmonic trap obeys the second-order linear differential equation as follows:

\[ \ddot{x} + \omega_0^2 x = \omega_0^2 x_0^2, \]

where \( x \) denotes the position of the particle and \( x_0 \) that of the bottom (i.e., the center) of the potential. An optimal transport over a distance \( d \) of a particle initially at rest and that reaches its final position at rest imposes the following boundary conditions:

\[ x(0) = 0, \dot{x}(0) = 0, \dot{x}(t_f) = d, \dot{x}(t_f) = 0, \]

and \( x(t) \) is then inferred from Eq. (10). The method can be further improved to take into account non-harmonic traps\(^8\) or to guarantee robust transport.\(^9\) Similarly, this idea has been used to drive, at will, a spin or two spins to generate entangled states.\(^10\)

As presented here, inverse engineering is quite simple and does not require a sophisticated mathematical formalism. It is worth emphasizing that it differs from optimal control theory, which aims at extremalizing a given objective (or cost) function, under some constraints.\(^11\) Here, the protocols we advocate are not meant to be optimal but to perform a given task in a specific, and short, time span.

Other general methods to speed up quantum transformations have been put forward in the context of quantum mechanics such as the counterdiabatic method,\(^12\)\(^13\) the Lewis-Riesenfeld invariant methods,\(^14\)\(^15\) the fast-forward method,\(^16\) or techniques relying on the Lie algebra.\(^17\) Some of those techniques have been recently transposed in the classical world\(^18\) not only in mechanics but also in statistical physics.\(^19\)\(^20\)\(^21\)\(^22\)

26. The attractor in phase space is defined as the parametric representation in the \((q, \dot{q})\) space of the forced solution, i.e., solution (5) without the decaying exponential term. It is thus the locus of points \((q(t), \dot{q}(t))\), parametrized by time \( t \), which yields an ellipse.
27. In practice, the voltage step provides a limitation for \( t_f \) so the simple capacitor-resistor model that we are using here is valid for times larger than the circuit size over the speed of light (say 1 ns). Below this time scale, wave-like effects will play a role and a more elaborate circuit model is required.

Keuffel and Esser Mechanical Drawing Instruments

In the summer of 1964 I sat down to draw the figures for my doctoral thesis. I used a set of mechanical drawing instruments very much like the rather complete set in the picture. The instruments were made by Keuffel and Esser, a firm founded by a pair of German immigrants in 1867. The offices were in lower Manhattan, and the instruments were made in their factory in Hoboken across the Hudson River. The company also manufactured slide rules, including the Thacher calculating device in an earlier segment of this series. The drawing pens were a devil to use, as they had two parallel blades with pointed ends that were adjusted to almost touch each other, and a droplet of ink was held between the blades. The slightest shake of the hand dropped a blot of ink on the paper, ruining the diagram. This set came to the Greenslade Collection from the Kenyon College mathematics department. (Picture and text by Thomas B. Greenslade, Jr., Kenyon College)
