Abstract
This paper studies the behavior of SmAlO₃ and NdAlO₃ when they are subject to high pressures. This work is undertaken using angle-dispersive synchrotron x-ray powder diffraction and Raman spectroscopy at pressures up to 24.2 and 39.0 GPa, respectively. It is found that SmAlO₃ undergoes an orthorhombic (Pnma) to rhombohedral (R-3c) structure transition at around 10 GPa; this transition is induced by the rotation of the AlO₆ octahedra toward that of the ideal perovskite structure when the material is subject to high pressures. The tilting of the AlO₆ octahedra also decreases at high pressures in NdAlO₃. It is found that NdAlO₃ maintains its original rhombohedral structure for pressures of up to 39.0 GPa. The structural changes observed in these compounds help establish the electrical and magnetic properties of RAlO₃ (R = Sm or Nd) at high pressures.

1. Introduction
In recent decades, perovskites and their derivatives have become the focus of considerable research because of their useful properties, such as ferromagnetism, photocatalysis, optoelectronic, and superconductivity [1–6]. Intense research has been carried out on ABO₃-type perovskites subject to high pressure as better understanding of their physical properties is important for practical applications and is of fundamental interest to the condensed matter and physics communities. TbMnO₃ has the largest known ferroelectric polarization among spin-driven ferroelectrics; this is induced by the magnetoelectric phase transition that occurs at high pressures [7]. The quenched nonmagnetic state of these ABO₃-type perovskites has been interpreted as a spin crossover, i.e. the transition of the Fe³⁺ ions from the high (S = 5/2) to the low spin state (S = 1/2) in REFeO₃ (RE = Pr, Eu, or Lu), GaFeO₃, and BiFeO₃ [8–10]. To further understand the behavior that originates from the couplings between the electronic, magnetic, and structural properties of these materials, investigations into the structural changes that occur at high pressures are required. Two important structural modifications are observed in ABO₃ perovskites: the tilting of the BO₆ octahedra and cation displacements. Any changes in these two characteristics can cause a structural phase in ABO₃ perovskites. For example, BiFeO₃ shows two structural phase transitions; one occurs at 3 GPa and the second at pressures greater than 10 GPa. The first structural change occurs when the rhombohedrally distorted perovskite transitions to a distorted monoclinic structure, as characterized by the superimposition of tilts and cation displacements. Subsequently, the distorted monoclinic structure transforms into a nonpolar orthorhombic Pnma structure due to cation displacements in BiFeO₃ [8, 11, 12]. LaAlO₃ and PrAlO₃ have been observed to exhibit a decrease of the lattice distortion and a decrease in the tilts of the AlO₆ octahedra, which lead to a rhombohedral-to-cubic phase transition, when subject to high pressures [13, 14]. For rare-earth-based perovskite-type oxides REAI₃O₉ (RE = rare earth), aluminates with perovskite structure are formed from La to Lu, with varying physical and chemical properties [15]. Due to the different...
radii of rare earth atoms, the different rare earth elements form perovskite structure with different levels of distortion within the lattice. Typically, SmAlO$_3$ exhibits an orthorhombic symmetry and NdAlO$_3$ shows a rhombohedral symmetry at ambient pressure and room temperature. SmAlO$_3$ and NdAlO$_3$ have been the subject of considerable research due to their excellent physical properties; these materials are widely used as a substrate for superconducting devices [16–18]. As an important oxygen ion conductor, they also are represent a promising electrolyte for use in solid-oxide fuel cells [19]. Pressure and temperature are key parameters in determining their physical properties. For instance, studies on the temperature dependences of the structural phase transition of these materials have revealed different processes in these compounds. When subject to increases in temperatures, SmAlO$_3$ shows two structural phase transitions; first the materials transitions from having a orthorhombic structure to a rhombohedral geometry, and subsequently it shows a transition to a cubic phase [20–22]. As for NdAlO$_3$, the phase transition from a rhombohedral structure to a cubic geometry occurs at a temperature of approximately 2180 K [23]. A high pressure can also modify the mechanical and electronic properties of the materials; these changes are induced by the pressure changing the interatomic distances within the structure. Here we present an in-situ investigation into the structural changes that occur in REAlO$_3$ (RE = Sm or Nd) when it is subject to high pressures.

2. Experimental details

The raw materials used in this study are Sm$_2$O$_3$ (99.99% purity), Nd$_2$O$_3$ (99.99% purity), Al(NO$_3$)$_3$·9H$_2$O (99.99% purity), and citric acid (AR). The SmAlO$_3$ was synthesized using the subsequent procedure: first Sm$_2$O$_3$ was dissolved into nitric acid and distilled water was added to yield a dilute Sm nitrate solution. Al(NO$_3$)$_3$·9H$_2$O was then added to the distilled water and mixed with the Sm nitrates following a stoichiometric ratio of Sm:Al = 1:1. The citric acid was then added to obtain a solution with a citrate/acid/nitrate ratio of 1.2. A magnetic agitator was then used to ensure continuous stirring of the mixed solution. The temperature of the solution was increased to 353 K to induce evaporation until a sticky brown gel was generated. The gel was then baked at 423 K and subsequently calcined at a temperature of 1473 K for 10 h in an air atmosphere by intermediate grinding and pelleting. The preparation of NdAlO$_3$ followed a similar procedure to that used in the preparation of SmAlO$_3$.

Powder x-ray diffraction (XRD) was performed to measure the phase purity (Rigaku Rotaflex x-ray diffractometer) using a Cu-K$_\alpha$ radiation source under normal conditions. The high-pressure XRD measurement was conducted using an angle-dispersive synchrotron radiation source at the beamline X17C of the National Synchrotron Light Source, Brookhaven National Laboratory, USA. A symmetric diamond anvil cell (DAC) with an anvil culet of 300 μ of the National Synchrotron Light Source, Brookhaven National Laboratory, USA. A symmetric diamond anvil cell (DAC) with an anvil culet of 300 μ of the National Synchrotron Light Source, Brookhaven National Laboratory, USA. A symmetric diamond anvil cell (DAC) with an anvil culet of 300 μ was utilized to generate the high-pressure conditions using T301 stainless steel as the gasket, which was preindentied to a thickness of 40 μm. The as-prepared sample together with a small piece of ruby which acted as the pressure calibrant [24], and a 4:1 methanol/ethanol mixture for use as a pressure-transmitting medium were then loaded into the DACs. The experimental parameters including the distance between sample and detector were calibrated using CeO$_2$ (a standard material). The software FIT2D was used to convert the information regarding the image plates into intensity versus diffraction angle 2θ patterns. The high-pressure Raman spectra were obtained using a Raman spectrometer and a 532 nm excitation laser at a power of 3 mW. The preparation of the DACs and loading samples followed the same techniques as those used for the high-pressure XRD experiments. To exclude the effects of deviatoric stress caused by nonhydrostatic effects, Ne was used as the pressure-transmitting medium in the high-pressure Raman measurements.

3. Results and discussion

3.1. XRD results at ambient pressure

We found that SmAlO$_3$ has an orthorhombic structure with a $P_{nma}$ space group at room temperature, which is in agreement with the previous reports [25, 26]. As shown in the inset of figure 1(a), it can be regarded as a three-dimensional AlO$_6$ network with the interstitial spaces occupied by Sm atoms. Like LaAlO$_3$, NdAlO$_3$ has a rhombohedral structure with R-3c space group at room temperature; this structure is shown in the inset of figure 1(b) [23, 27, 28]. The distorted rhombohedral structure shows an antiphase $a'−a−a$ (tilt system in Glazer’s notation) tilt of the adjacent octahedra, whereas the distortions of the orthorhombic structure have the combined $a'−a−c'+a−a'−c$ octahedral tilting [29].

The refinement of ambient-pressure diffraction patterns was realized using the Rietveld method and the generalized structure analysis system (GSAS) software [30]. SmAlO$_3$ and NdAlO$_3$ were refined in the $P_{nma}$ phase with the lattice constants of $a = 5.2991(8)$ Å, $b = 7.4767(8)$ Å, and $c = 5.2966(9)$ Å, and the R-3c phase with $a = b = 5.3183(2)$ Å and $c = 12.9244(7)$ Å. Figure 1 presents the refined patterns of

3.2. The lattice evolution of SmAlO$_3$ at high pressures

A high-pressure synchrotron powder XRD experiment was performed to reveal the structural behaviors of SmAlO$_3$. The XRD patterns were recorded at with the samples subject to a set of pressures up to 24.2 GPa. Figures 2(a) and (b) present some of the measured and enlarged typical powder diffraction patterns of SmAlO$_3$, respectively. The original phase can be seen to exhibit new peaks at 10.4 GPa; at this pressure the ethanol–methanol pressure-transmitting medium is known to become solid giving rise to nonhydrostatic conditions [31]. However, it is known that these stresses can induce peak broadening effects; significant changes are observed in the multiplicity and the relative intensity of the Bragg reflection peaks, as shown in the enlarged patterns depicted in figure 2(b). The intensity of reflection peaks of (113), (133), and (214) of the original phase start to decrease at a pressure of 10.4 GPa and disappear at around 15.1 GPa. These findings indicate that a structural phase transition is initiated at a pressure above 10.4 GPa and is completed at around 15.1 GPa. Upon releasing the pressure, the original phase was obtained. The orthorhombic SmAlO$_3$ was refined for all pressures below 10.4 GPa by the previous method. The results shown in figure 2(c) present the Rietveld refinement result at 4.8 GPa with $R_p = 6.52\%$ and $R_{wp} = 4.48\%$.

In the case of ABO$_3$ with $M_A/M_B > 1$, Zhao et al [32, 33] found that the temperature of zone-boundary phase transition, $T_c$, decreases with increasing pressure, (i.e. $dT_c/dP < 0$). In this work, the site parameter,
$M_i$, was defined as:

$$M_i = (R_i N_i / B) \exp \left( \frac{R_0 - R_i}{B} \right),$$

where $N_i$, $R_i$, $R_0$, and $B$ represent the coordination number, the average bond length at ambient pressure, the bond-valence parameters, and the universal constant (0.37 Å), respectively [33]. It was found that LaAlO$_3$ with $M_A / M_B > 1$ underwent a rhombohedral-to-cubic phase transition at a pressure of approximately 14 GPa [13]. The same transition was also observed in NdNiO$_3$ at 6 GPa [34]. Similarly, LaGaO$_3$ underwent an orthorhombic-to-rhombohedral phase transition around 2.5 GPa [35]. In these perovskites, the same phase transitions could be observed as a result of increasing temperature [23, 36–38]. In the case of SmAlO$_3$ with $M_A / M_B > 1$, the first phase transition from an orthorhombic to a rhombohedral structure occurred within the temperature range of 1023–1058 K [21, 22]. As discussed from above, SmAlO$_3$ is also expected to undergo a phase transition from an orthorhombic ($Pnma$) to a rhombohedral ($R-3c$) structure when the material is subject to high pressure. The structural phase transition observed in SmAlO$_3$ occurs at 10.4 GPa. The Rietveld refinement results indicate that SmAlO$_3$ is completely transformed into a rhombohedral phase at a pressure of 15.1 GPa, as shown in figure 2(d) with $R_p = 5.01\%$ and $R_{wp} = 3.17\%$. The result obtained in the case of SmAlO$_3$ show in good agreement with the predictions. Angel et al [39] and Ross et al [40] developed a novel bond-valence matching relation-based method for predicting the changes in GdFeO$_3$-type orthorhombic perovskites structures at high pressures. It was shown that the BO$_6$ octahedra became less tilted and the symmetry of the structure increased when
the BO₆ octahedra were more susceptible to compression than the AO₁₂ polyhedra under high pressures. The structure was predicted to evolve toward lower symmetry configurations when the AO₁₂ polyhedra were more susceptible to compression than the BO₆ octahedra under a pressure loading [33, 41]. This prediction was in good agreement with other studied orthorhombic perovskites, such as TbMnO₃, GdMnO₃, LaMnO₃, GdAlO₃, and YAlO₃ [40, 42–45]. The normalized volume change of the AlO₆ octahedra in SmAlO₃ is more susceptible to compression than the unit cell for pressures below 15.1 GPa, as shown in figure 3(a). This suggests that the symmetry of the structure of SmAlO₃ increases at high pressures. It also provides the evidence for the transition from the low symmetry (Pnma) phase to the high symmetry (R-3c) phase. Since the octahedral distortions in the ABO₃-type oxides are crucial in the process of structural phase transitions, we can conclude that the observed structural phase transition in SmAlO₃ is induced by the AlO₆ octahedra rotation toward the that of the ideal perovskite structure under high pressures. Figure 3(b) shows the changes in the AlO₆ octahedra in the low-pressure and high-pressure phases.

The pressure dependence of the lattice parameters (a pseudocubic cell is adopted) of SmAlO₃ at pressures up to 24.2 GPa are shown in figure 4. The cell parameter, \( c_{PC} \), exhibits anomalous behavior above 12.9 GPa due to the nonhydrostatic conditions that are induced [46]. The volume of the unit cell of SmAlO₃ decreases smoothly with increasing pressure. The state equation was fitted with the following 3rd-order Birch–Murnaghan state equation,

\[
P = \frac{3}{2} B_0 \left[ \left( \frac{V_0}{V} \right)^{7/3} - \left( \frac{V_0}{V} \right)^{5/3} \right] \times \left[ 1 + \frac{3}{4} \left( B'_0 - 4 \right) \times \left[ \left( \frac{V_0}{V} \right)^{2/3} - 1 \right] \right],
\]

where \( B_0 \) is the bulk modulus and \( B'_0 \) is its pressure derivative at the equilibrium volume, \( V_0 \). By fitting the equation, we obtained \( B_0 = 223(10) \) GPa and \( B'_0 = 4 \) (fixed) for \( V_0 = 51.42(11) \) Å³ for the orthorhombic (Pnma) phase and \( B_0 = 262(9) \) GPa and \( B'_0 = 4 \) (fixed) for \( V_0 = 51.18(10) \) Å³ for the rhombohedral (R-3c) phase.

The high-pressure structural evolution was further investigated by evaluating the Al–O bond length and the Al–O–Al bond angle as a function of pressure (figure 4). The AlO₆ octahedra generate three Al–O bond

![Figure 3](image-url)

**Figure 3.** (a) Pressure dependence of the normalized volumes of the AlO₆ octahedra in and the unit cell of SmAlO₃. (b) The AlO₆ octahedra changes during the low-pressure phase and the high-pressure phase.
Figure 4. (a) The lattice parameters and (b) the unit cell volume of SmAlO$_3$ as a function of pressure. The Birch–Murnaghan equation of state is indicated as a solid line. The pseudocubic cell parameters for the $Pnma$ phase are $a_{pc} = a/\sqrt{2}$, $b_{pc} = b/2$, and $c_{pc} = c/\sqrt{2}$, whereas in the case of the $R-3c$ phase the pseudocubic cell parameters are $a_{pc} = a/sqrt{2}$, $b_{pc} = b/2$ and $c_{pc} = c/2\sqrt{3}$.

(c) The bond length of Al–O and (d) the bond angle of Al–O–Al as a function of pressure for SmAlO$_3$.

To exclude the effects of deviatoric stress caused by nonhydrostatic pressures, we also undertook high-pressure Raman spectroscopy using Ne as the pressure-transmitting medium; the results are shown in figure 5. In the $Pnma$ structure, there are 24 Raman active modes: $7A_{1g} + 7B_{1g} + 5B_{2g} + 5B_{3g}$. In the range 100–400 cm$^{-1}$, we observed seven Raman modes, as shown in figure 5(a). We obtained the vibration modes, as shown in figure 5(b).
The Raman peak of the $A_{1g}$ mode around 200 and 345 cm$^{-1}$ corresponds to a rotation about the $y$-axis of the Sm atoms and a stretching mode in the direction parallel to the $x$-axis of the O1 atom in SmAlO$_3$. The $B_{3g}$ mode that is observed at around 139 cm$^{-1}$ corresponds to a rotation about the $z$-axis of the Sm atoms. The $B_{1g}$ mode situated at around 110 and 170 cm$^{-1}$, and the $A_{1g}$ mode at around 287 cm$^{-1}$ correspond to a rotation of the AlO$_6$ octahedra. The $B_{2g}$ mode around 144 cm$^{-1}$ corresponds to a rotation of Sm atoms about the $x$-axis [47–50].

With increasing pressure, the intensity of the $B_{1g}$ mode situated at around 110 cm$^{-1}$ and the $A_{1g}$ mode at around 200 and 345 cm$^{-1}$ decreased at a pressure of 9.3 GPa and disappeared completely around 18.0 GPa, as shown in figure 5(a). This indicates that a structural phase transition occurs at approximately 9.3 GPa, which is consistent with the XRD results obtained for SmAlO$_3$. However, the Raman spectroscopy results suggest that the structural phase transition of SmAlO$_3$ is completed at a pressure of around 18.0 GPa; this pressure is higher than that obtained from the high-pressure XRD results (15.1 GPa). A primary reason for this discrepancy is the different pressure-transmitting medium used in these studies. This difference is due to the fact that hydrostatic loading induced by the methanol–ethanol mixture can be maintained up to 10 GPa, whereas the Ne can maintain hydrostatic loading up to 20 GPa [51, 52]. We also note that Raman spectroscopy is more sensitive than powder XRD when it comes to distinguishing the small difference between the $Pnma$ and $R-3c$ space groups in the RAIO$_3$ systems.

Figure 5(c) summarizes the Raman shift changes that occur as a result of changes in pressure. The $A_{1g}$ mode at around 287 cm$^{-1}$ and $B_{1g}$ mode around 170 cm$^{-1}$ soften continuously with increasing pressure up to a pressure of 9.3 GPa; this indicates a decrease in the octahedral tilt angle with increasing pressure. This finding is consistent with the XRD results, as shown in figure 4(d). Compared with the Raman curves of LaAlO$_3$ and NdAlO$_3$ with its rhombohedral structure at ambient pressure and room temperature [13],
Figure 6. (a) XRD patterns of NdAlO₃ as a function of pressure. (b) The evolution of the intensity of the (113) superlattice reflection normalized by the (012) refraction at high pressure. (c) The XRD of NdAlO₃ at 39.0 GPa. The inset shows the enlarged view of superlattice reflection intensity I₁₁₃.

SmAlO₃ shows a structural phase transition from orthorhombic-to-rhombohedral symmetry at a pressure of around 9.3 GPa, which is consistent with the XRD results obtained here.

3.3. The lattice evolution of NdAlO₃ at high pressures

Theoretical calculation suggested the existence of a rhombohedral-to-cubic phase transition at a pressure of above 80 GPa [53]. In our study, we obtained the XRD patterns of NdAlO₃ for pressures up to 39.0 GPa, as shown in figure 6(a).

To investigate the possible structural phase transition, we induced the intensity change of one superlattice reflection, I₁₁₃, which is associated with the a*-a*-a*-type rotation of the oxygen octahedra [13], as shown in figure 6(b). The normalized intensity of I₁₁₃/I₀₁₂ decreased with increasing pressure, indicating the possibility of a phase transition from a rhombohedral-to-cubic structure. Unlike LaAlO₃ [13], the Bragg peak (113) is maintained up to pressures of 39.0 GPa, as shown in figure 6(c), which suggests that the rhombohedral structure remains in the case of NdAlO₃ up to the maximum pressure considered in our study.

To obtain the lattice parameters and the state equation, the refinements of the rhombohedral phase of NdAlO₃ were investigated using the GSAS software under the pressures considered in this work. The fitted pattern at a pressure of 19.3 GPa with \( R_p = 2.48\% \) and \( R_wp = 1.43\% \) is shown in figure S1. Figures 7(a) and (b) present the lattice parameters of NdAlO₃ as a function of pressure considering a pseudocubic cell. Interestingly, the P–V curve shows a discontinuity; this discontinuity is obtained by fitting two sets of P–V data separately for pressures below and above 19 GPa. This finding may be affected by the changes in lattice vibration which is related to the high-pressure Raman study presented below. We observed \( B_0 = 230(10) \).
Figure 7. (a) The lattice parameters and (b) the unit cell volume of NdAlO$_3$ as a function of pressure. (c) The bond length of Al–O and (d) the bond angle of Al–O–Al in NdAlO$_3$ as a function of pressure. The solid lines represent linear fittings. The solid line in (b) indicates the Birch–Murnaghan equation of state. The cell parameters are described by a pseudocubic cell $a_{pc} = a/\sqrt{2}$ and $c_{pc} = c/2\sqrt{3}$ describing the R-3c phase.

GPa and $B'_0 = 6.7$ for $V_0 = 310.456(5)$ Å$^3$ for a pressure of 19 GPa. For pressures above 19 GPa, we measured $B_0 = 301(16)$ GPa and $B'_0 = 3.4$ for $V_0 = 309.523(10)$ Å$^3$. The obtained bulk modulus is slightly higher than those observed in other perovskite oxides, such as YAlO$_3$, PrAlO$_3$, and LaAlO$_3$ whose bulk moduli are equal to 192(2), 193.0 (1.2), and 190 (5) GPa, respectively [13, 14, 46].

As shown in figure 7(a), the lattice parameters of NdAlO$_3$ decrease smoothly with increasing pressure. Interestingly, the values of $a$ and $c$ gradually converge for pressures above 20 GPa. This is likely to be caused by two factors: the peak broadening in the XRD patterns at high pressure and the existence of a higher structural symmetry that is reached by the decreasing of the AlO$_6$ octahedra tilting at high pressure. To further investigate the crystal structure of NdAlO$_3$, we investigated the Al–O bond length and Al–O–Al bond angles of NdAlO$_3$ as a function of pressure; the findings are shown in figures 7(c) and (d). The Al–O bond length decreases as the Al–O–Al bond angles increase with increasing pressure. This suggests that the tilting of the AlO$_6$ octahedra decreases at high pressures, as is the case in SmAlO$_3$.

To obtain insight into the crystal structural changes in NdAlO$_3$ at high pressure, we also undertook high-pressure Raman spectroscopy using Ne as the pressure-transmitting medium; the results are shown in figure 8. In the R-3c structure, there are 5 Raman active modes: $A_{1g} + 4E_g$. Major peaks can be assigned as follows: the band at 240 cm$^{-1}$ of the $A_{1g}$ mode is related to the rotation of the O octahedra; the two bands at 163 and 513 cm$^{-1}$ of the $E_g$ mode are associated with the vibration of the Nd atoms and the bending vibration of O atoms, respectively; the band at 590 cm$^{-1}$ of the $E_g$ mode is related to the out of phase stretching vibration of O atoms [54–56]. The forbidden Raman modes observed at around 380 and 700 cm$^{-1}$ may be related to the vibrations of the Nd$^{3+}$ ions [56].
Figure 8(b) summarizes the Raman shifts that occur with changes in pressure. The Raman peak at 240 cm\(^{-1}\) of the A\(_{1g}\) mode softens continuously with increasing pressure, which is similar to the behavior observed in the A\(_{1g}\) mode of LaAlO\(_3\) and PrAlO\(_3\) subject to high pressure [13, 14]. This is induced by a decrease in the octahedral tilt angle with increasing pressure; these findings are consistent with the XRD results as shown in figure 7(d). Unlike LaAlO\(_3\) and PrAlO\(_3\), the A\(_{1g}\) mode does not disappear or harden with further increasing pressure for pressures up to 34.1 GPa; this illustrates the existence of the original rhombohedral structure. The frequency of the A\(_{1g}\) mode also shows discontinuity between 17.4 and 27 GPa, as shown in figure 8(c). The hydrostatic pressure conditions imposed by Ne can be maintained up to around 20 GPa [57]. To verify whether these effects are a result of changes to the A\(_{1g}\) mode or the influence of nonhydrostatic pressure conditions, we undertook high-pressure Raman spectroscopy using silicon oil as pressure medium, as shown in figures S2 and S3. The frequency of the A\(_{1g}\) mode also shows discontinuity at approximately 10 GPa where nonhydrostatic pressure conditions are induced by the silicon oil pressure-transmitting medium. We can thus conclude that the discontinuity in the A\(_{1g}\) mode is a result of the nonhydrostatic pressure conditions. The intensity of the Raman peak that is located around 380 cm\(^{-1}\) showed a sharp increase at a pressure of around 22 GPa, as shown in figure S4. This may be a result of the lattice vibrations that could cause the discontinuity in the P–V curve obtained from XRD results at high pressure.

Combined with the high-pressure XRD study, we can conclude that NdAlO\(_3\) maintains its original rhombohedral structure for pressures up to 39.0 GPa.
4. Conclusion

In this work, we have investigated the high-pressure structural characteristics of RAlO$_3$ (R = Sm or Nd) at room temperature using angle-dispersive synchrotron x-ray powder diffraction. It was found that SmAlO$_3$ undergoes an orthorhombic (Pnma) to rhombohedral (R-3c) phase transition at a pressure of around 10 GPa; this is caused by the reduction in the tilt and distortion of the AlO$_6$ octahedra that occurs when they are subject to high pressures. The tilting of the AlO$_6$ octahedra in NdAlO$_3$ also decreases with increasing pressures. However, NdAlO$_3$ maintains its original rhombohedral structure for pressures up to 39.0 GPa. The details of the structural changes that occur in these compounds are useful for determining the electrical and magnetic properties of RAlO$_3$ (R = Sm or Nd) at high pressures.
