Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Two in one: Overlapping CT findings of COVID-19 and underlying lung diseases

Lung diseases

ABSTRACT

Coronavirus disease 2019 (COVID-19) is associated with pneumonia and has various pulmonary manifestations on computed tomography (CT). Although COVID-19 pneumonia is usually seen as bilateral predominantly peripheral ground-glass opacities with or without consolidation, it can present with atypical radiological findings and resemble the imaging findings of other lung diseases. Diagnosis of COVID-19 pneumonia is much more challenging for both clinicians and radiologists in the presence of pre-existing lung disease. The imaging features of COVID-19 and underlying lung disease can overlap and obscure the findings of each other. Knowledge of the radiological findings of both diseases and possible complications, correct diagnosis, and multidisciplinary consensus play key roles in the appropriate management of diseases. In this pictorial review, the chest CT findings are presented of patients with underlying lung diseases and overlapping COVID-19 pneumonia and the various reasons for radiological lung abnormalities in these patients are discussed.

1. Introduction

Coronavirus disease 2019 (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is associated with pneumonia and has various pulmonary manifestations on computed tomography (CT). Although the typical findings of COVID-19 pneumonia are predominantly peripheral ground-glass opacities with or without consolidations, throughout the course of the disease, atypical findings may be observed which resemble the imaging findings of other lung diseases. The sensitivity and specificity of chest CT for diagnosis of COVID-19 pneumonia vary according to the presence of typical and atypical findings. In addition to diagnosis of COVID-19, chest CT is used to evaluate the severity of the disease and prognosis, to manage treatment, to determine pulmonary complications in the acute phase, and to assess fibrotic lung diseases in the late phase. Furthermore, chest CT plays a vital role in the differentiation of COVID-19 pneumonia from other lung diseases.

Diagnosis of COVID-19 pneumonia is much more challenging for both clinicians and radiologists when there is a concomitant lung disease. Chest CT findings may belong to both the pre-existing lung disease and COVID-19 pneumonia. Moreover, underlying lung diseases such as chronic obstructive pulmonary disease (COPD) and interstitial lung diseases may worsen COVID-19 pneumonia. Therefore, correct diagnosis with imaging and clinical findings is essential for the appropriate management. Knowledge about the chest CT findings of underlying lung diseases, possible complications, and COVID-19 pneumonia can lead the radiologist to the correct diagnosis.

The aim of this pictorial review was to present the chest CT findings of patients with underlying lung diseases and overlapping COVID-19 pneumonia and to discuss the various reasons for radiological lung lesions in these patients.

2. Interstitial lung diseases

Idiopathic interstitial pneumonias are classified as major idiopathic interstitial pneumonia, rare idiopathic interstitial pneumonia, and unclassifiable idiopathic interstitial pneumonia. Major idiopathic interstitial pneumonia has six subgroups; idiopathic interstitial fibrosis (IPF), nonspecific interstitial pneumonia (NSIP), cryptogenic organizing pneumonia (COP), acute interstitial pneumonia (AIP) respiratory bronchiolitis (RP), associated interstitial lung disease (ILD), and desquamative interstitial pneumonia (DIP), while rare idiopathic interstitial pneumonia includes LIP and pleuroparenchymal fibroelastosis.

IPF shows UIP patterns which are listed as macrocystic

honeycombing, reticulation, traction bronchiectasis, architectural distortion, and focal ground-glass opacity with apicobasal gradient on chest CT. The main CT features of NSIP are ground-glass opacities, which are usually bilateral and symmetric with lower lobe predominance and subpleural sparing. Although COP may show diverse CT findings, the most common features are atoll sign, bilateral patchy and often migratory consolidative or ground-glass opacities with predominantly peripheral or peribronchovascular distribution.

AIP can be divided into two phases as exudative phase and the organizing phase. GGOs with or without air space consolidation are seen due to diffuse alveolar damage in the exudative phase. Traction bronchiectasis and architectural distortion occur due to fibrosis in the organizing phase.

RB-associated ILD and DIP are also known as smoking-related ILD. Centrilobular opacities, patchy GGOs, and bronchial wall thickening which show upper lobe predominance or diffuse distribution are observed on CT images of RB-ILD. Emphysema, GGOs, reticulation, and cysts with apicobasal gradient and peripheral predominance are seen in DIP.

LIP, which is usually associated with autoimmune diseases or AIDS, is characterized by GGOs, perivascular cysts, septal thickening, and centrilobular opacities with basilar predominance. Pleuroparenchymal fibroelastosis shows marked apical pleural thickening, subpleural consolidation with traction bronchiectasis, architectural distortion, and volume loss in the upper lobes. Moreover, the long-term lung changes of COVID-19, including traction bronchiectasis, reticulation, and honeycombing, can aggravate ILD findings (Fig. 1). Evaluation by comparing with previous CT images of patients with ILD will be very useful for differential diagnosis.

Patients with FVC of <80%, fibrotic changes, and obesity have been shown to have increased death rates in patients with both ILD and COVID-19. The data did not suggest any harm related to the treatment of ILD in patients with COVID-19, which could be because similar treatments, including steroids, immunomodulators, and antifibrotics, are used in both COVID-19 and ILD. The differentiation of CT and clinical findings of ILDs from COVID-19, including traction bronchiectasis, reticulation, and honeycombing, can be used in both COVID-19 and ILD.

3. Connective tissue diseases

Connective tissue diseases (CTDs) are a varied group of systemic inflammatory disorders that often affect the lungs. The CTDs that frequently have thoracic involvement are rheumatoid arthritis (RA), systemic sclerosis (SS), systemic lupus erythematosus (SLE), polymyositis (PM), dermatomyositis (DM), Sjogren syndrome, and mixed connective tissue disease. The main thoracic manifestations of CTDs are ILD and pulmonary arterial hypertension. In addition to pulmonary findings, pleural or pericardial effusions, esophageal dilatation, pulmonary artery enlargement, and mediastinal lymphadenopathies can be seen. Although the radiological findings of CTDs are similar to each other, some clues can help in the differential diagnosis.

Pleural thickening and effusion is the most common thoracic manifestation of RA. Although UIP is the most common ILD pattern in RA, other ILD patterns including NSIP and OP can occur. Obliterative bronchiolitis with mosaic attenuation pattern and follicular bronchiolitis with multiple small nodules can also be seen. Rheumatoid pulmonary nodules are frequently peripherally located in the mid and upper lung regions and may cavitate.

The most common ILD pattern in SS is NSIP, but UIP is also frequently seen. Pulmonary artery enlargement and esophageal dilatation are usually observed whereas pleural involvement is uncommon. In contrast, pleural disease is the most common involvement in SLE. Acute lupus pneumonitis and diffuse alveolar hemorrhage are other rare but severe manifestations of SLE. Consolidations and GGOs are seen and may mimic infection on CT.

The most common ILD patterns are NSIP and OP in DM/PM. Bilateral patchy often triangular or polygonal shaped consolidations with or without reverse halo sign are usually observed on CT.

3.1. Overlapping with COVID-19 and differentiation

The frequency of CTDs was found 0.53% in 18,786 COVID-19 patients hospitalized in 23 centers. The lung involvement in CTDs may both mimic and worsen COVID-19 pneumonia. Bilateral GGOs predominantly located in the lower lobes can be confused in COVID-19 and NSIP. The late phase of COVID-19 with the interstitial disease can also mimic CTD-associated ILD with persistent GGOs or fibrous stripe.
The concentration of fibrosis in the anterior aspects of the upper lobes also known as the anterior upper lobe sign and isolation of fibrosis to the lung bases with sharp demarcation in the craniocaudal image also known as the straight-edge sign can be helpful for the diagnosis of CTD-related ILD. But, fibrotic lung changes within anterior upper lobes in some COVID-19 related ARDS survivors should be kept in mind.

Mediastinal lymphadenopathy and pleural involvement, which are rarely seen in COVID-19 pneumonia, are other frequent imaging findings in CTDs, especially SLE.

Acute lupus pneumonitis and diffuse alveolar hemorrhage, which are rare but severe complications of SLE, may resemble infectious pneumonia including COVID-19 pneumonia both radiologically and clinically.

Patients with CTDs may have more severe COVID-19 disease due to immune dysregulation. However, COVID-19 may cause the aggravation of underlying ILD. The NSIP pattern of CTDs may convert to fibrotic NSIP or UIP pattern with the late effects of COVID-19 pneumonia.

In addition to the lung involvement of CTDs, opportunistic infections due to immunosuppressive treatment or secondary infectious diseases can occur and interfere with the imaging findings. For example, in a patient with COVID-19 pneumonia, cavitating rheumatoid lung nodules can be confused with secondary infections and vice versa. Clinical findings and knowledge about imaging findings of underlying lung diseases play a key role in correct diagnosis (Fig. 2).

4. Sarcoidosis

Sarcoidosis is a multisystemic chronic inflammatory disorder characterized by non-caseating granulomas. Thoracic involvement is the most common finding and is responsible for most of the morbidity and mortality in patients with sarcoidosis. Typical radiological findings of pulmonary sarcoidosis are hilar and mediastinal lymphadenopathy, and parenchymal abnormalities predominantly located in the upper and middle zone. Micro/macronodules, GGOs, and airspace consolidation are suggestive of active and reversible disease whereas parenchymal distortion, honeycomb-like opacities, traction bronchiectasis, volume loss, and retraction of hila are indicators of the sequela and irreversible sarcoidosis.

4.1. Overlapping with COVID-19 and differentiation

The estimated frequency of COVID-19 was reported as 5.1% in one of the largest multicenter clinical cohorts of sarcoidosis with a 9% overall mortality rate. In addition to typical findings, sarcoidosis can mimic various lung diseases, including COVID-19 pneumonia. The imaging findings of active sarcoidosis and acute COVID-19 pneumonia may mimic each other, whereas irreversible sarcoidosis resembles the late findings of COVID-19. Pulmonary involvement of sarcoidosis may reduce normal lung parenchyma volume and cause severe disease in patients with COVID-19 pneumonia.

GGOs, alveolar consolidation, and crazy paving patterns may be seen in both sarcoidosis and COVID-19 pneumonia. However, upper and middle zone predominance, perihilar predilection, and the presence of small nodules with perilymphatic distribution and peribronchovascular thickening are indicators of sarcoidosis. Also, mediastinal and hilar lymphadenopathies are typical features of sarcoidosis, but are not common in COVID-19 pneumonia. However, the presence of lymphadenopathies in COVID-19 were related to disease severity.

Furthermore, laboratory examinations do not help in differentiation.
as elevated C-reactive protein (CRP) and lymphopenia occur in both diseases. Although corticosteroid treatment is used for both acute flare-ups of sarcoidosis and COVID-19 pneumonia, the management of the two diseases changes according to different scenarios. Therefore, multidisciplinary management is required, with the consultation of rheumatology and pulmonology, as well as specialists of infectious diseases and radiology.

5. Other autoimmune diseases

Antineutrophil cytoplasmic autoantibody (ANCA)-associated vasculitides are multisystem disorders that have three main clinicopathological variants including granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis (EGPA), and microscopic polyangiitis (MPA). ANCA-associated vasculitides may affect both airways and parenchyma and have secondary findings such as lymphadenopathy, and pleural and pericardial effusion. Although thoracic involvement of ANCA-associated vasculitides is varied and poorly specific, some imaging features can help in the differential diagnosis. The most common CT finding of GPA is bilateral multiple pulmonary nodules or consolidations that may cavitate. The other imaging findings are GGOs frequently with peribronchovascular and perihilar distribution, airway thickening, bronchiectasis, and centrilobular nodules.

The main imaging findings of EGPA are bilateral transient, patchy, non-segmental GGOs and consolidations without predilection of any lung lobe. Interlobular septal thickening because of edema and eosinophilic infiltration, bronchial dilatation, and wall thickening due to airway involvement can also occur.

MPA is characterized by bilateral, diffuse, or patchy GGOs with consolidations due to diffuse alveolar hemorrhage or hemorrhagic diffuse alveolitis in the acute phase whereas reticular pattern and interstitial fibrosis may occur secondary to repetitive hemorrhage in the chronic phase. IgG4-related disease is another systemic disorder that is associated with elevated IgG4 levels and has recently attracted increasing attention. The CT findings are variable and consist of rounded consolidations and GGOs, thickening of bronchovascular bundles, interlobular septae, bronchiectasis, and honeycombing. In addition to parenchymal and airway involvement, pleural thickening, mediastinal lymphadenopathy, and fibrosing mediastinitis can occur. Pleural effusion is a rare finding in patients with IgG4-related disease.

5.1. Overlapping with COVID-19 and differentiation

In a cohort of 102 ANCA-associated vasculitides, 29 patients had COVID-19 with a 27.6% severe disease rate and a 10.3% mortality rate. COVID-19 and vasculitides may have similar pathways and clinical characteristics such as neutrophil extracellular traps, high venous thromboembolism, hypo/anosmia, cough, and myalgia. In addition to the clinical features, both diseases may show similar radiological characteristics including ground-glass opacities and consolidations.

GGOs are seen in both EGPA and COVID-19 pneumonia. But, rounded GGOs are usually seen in COVID-19 pneumonia while patchy migratory GGOs and usually coexisting small centrilobular nodules are suggestive of EGPA. MPA in the acute phase mimics the acute phase of COVID-19 pneumonia, and MPA in the chronic phase resembles the late phase of COVID-19 pneumonia. Moreover, all ANCA-associated vasculitides can worsen late fibrotic changes of COVID-19 pneumonia.

Tracheal wall thickening, especially in the subglottic region, and nodules with cavitation are suggestive of GPA while these imaging findings are not expected in COVID-19 pneumonia. However, cavitation especially within consolidation areas can occur in COVID-19 pneumonia. Nodules with cavitation can also mimic secondary infections.
including fungal and bacterial pneumonia or septic emboli in patients with COVID-19. Increased clinical symptoms such as fever, dyspnea, and cough would help the differentiation. Furthermore, tracheal stenosis can also occur in patients with COVID-19 after long-term intubation and tracheostomy. The location of tracheal stenosis on CT images guides the radiologist in the differential diagnosis. Subglottic stenosis suggests GPA whereas stenosis matching the location of the endotracheal tube on prior images is suggestive of prolonged intubation (Fig. 3).

The presence of ANCA is the key in differentiating COVID-19 pneumonia from ANCA-associated vasculitis. When both diseases occur at the same time, the disease management is more challenging. COVID-19 has higher mortality rates in patients with ANCA-associated vasculitides than in the general population. Furthermore, the use of rituximab which is the most commonly used therapeutic agent in ANCA-associated vasculitides can cause a more severe hospital course of COVID-19 and re-infection. The hospitalization and management of the overlapping diseases should be arranged according to the clinical findings by multidisciplinary specialists.

IgG4-related disease can show poorer COVID-19 outcomes. Although consolidations and GGOs can be seen in both IgG4-related disease and COVID-19 pneumonia, fibrosing mediastinitis should suggest IgG4-related disease.

6. Pneumoconioses

Pneumoconioses are a broad group of lung diseases caused by the inhalation of particles. Silicosis, coal worker pneumoconiosis, and asbestosis are the most common types of pneumoconiosis. Multiple, well-defined, uniform nodules predominantly located in upper lobes and hilar/mediastinal lymphadenopathies commonly with calcification are the main imaging features in silicosis and coal-worker pneumoconiosis. Fibrotic, focal soft-tissue masses with irregular margins, calcification, and associated surrounding pericartical emphysema in upper zones are seen as complicated forms of silicosis and coal-worker pneumoconiosis. While pleural plaques, pleural effusion, subpleural lines, and reticulation are the most common CT findings of asbestosis, traction bronchiectasis, honeycombing, and parenchymal bands can occur in the later phase of the disease.

6.1. Overlapping with COVID-19 and differentiation

COVID-19 rates among mineworkers exceed the population rates in South Africa. Mineworkers are at risk for both pneumoconiosis and COVID-19 pneumonia because of working in crowded and poorly ventilated places. COVID-19 may also cause severe outcomes, especially in patients with interstitial lung disease due to pneumoconiosis.

Although imaging features of silicosis and coal worker pneumoconiosis are not usually confused with COVID-19, subpleural lines and

Fig. 4. COVID-19 pneumonia and asbestosis.
Axial CT images (a, b) demonstrate bilateral calcified pleural plaques secondary to asbestosis and bilateral GGOs due to COVID-19 pneumonia. In the previous CT image (c) (8 months earlier) there are reticular densities and mild GGOs adjacent to the pleural plaques compatible with asbestosis, which may be confused with COVID-19 pneumonia.

Fig. 5. COVID-19 pneumonia and cystic fibrosis.
Axial (a) and coronal (b) CT images show widespread bronchiectases and bronchial wall thickenings in both lungs due to cystic fibrosis. In the left lung, multiple cystic bronchiectases have destroyed the lung parenchyma causing significant volume loss. GGOs can be seen in the right lung due to COVID-19 pneumonia.
interlobular linear opacities in asbestosis can mimic the recovery phase of COVID-19 pneumonia. Associated linear opacities with pleural plaques in asbestosis can help the differential diagnosis. Furthermore, interstitial fibrosis in pneumoconiosis may not only mimic long-term persistent lung disease after COVID-19 but may also cause severe COVID-19 disease and progression to chronicity of lung abnormality. Therefore, vaccination and self-isolation become more important in these patients.(Fig. 4).

Cystic fibrosis (CF) is an autosomal recessive inherited disease resulting from defective mucociliary clearance. The most common pulmonary CT features of CF are upper lobe predominant bronchiectasis, bronchial wall thickening, mosaic attenuation pattern, tree-in-bud pattern, consolidation, and atelectasis. The tree-in-bud pattern may occur due to the involvement of small airways or endobronchial spread of infection. Consolidation is usually seen secondary to infection in exacerbations of CF. In addition to infection, consolidation and GGO can also be seen due to hemoptysis caused by enlarged bronchial arteries.

Although infectious agents commonly cause acute exacerbations in individuals with CF, the incidence of COVID-19 pneumonia (0.07%) and severe disease appear not to be higher than in the general population. Lower incidence may be the result of higher awareness of infection and control practices in patients with CF. However, post-transplant individuals experience more severe disease. Consolidation and GGO on CT images can be seen in patients with CF due to pulmonary hemorrhage and pneumonia. While clinical findings may help in differential diagnosis, an enlarged bronchial artery on CT can help the diagnosis and guide the interventional treatment of hemoptysis. Bacterial infections can mimic COVID-19 pneumonia both clinically and radiologically in individuals with CF. Laboratory findings such as high neutrophil count and some imaging features including tree-in-bud pattern or lobar pulmonary opacities with bulging fissures suggest bacterial pneumonia. Co-infections can occur especially in hospitalized patients with CF and COVID-19 pneumonia. The co-existence of COVID-19, co-infection and CF in the same patient can cause decreased pulmonary function and increased morbidity and mortality (Fig. 5).

Chronic obstructive pulmonary disease (COPD) is a spectrum of obstructive airway diseases including two major subtypes of chronic bronchitis-small airway disease and emphysema. The main CT findings can be classified as emphysema, airway disease, and associated features. Emphysema can occur as centrilobular and paraseptal. Airway disease can be seen as bronchial wall thickening, centrilobular opacities, and air trapping. Saber sheath trachea, tracheobronchomalacia, tracheobronchial diverticula, bronchiectasis, patchy ground-glass abnormality, mild subpleural reticulation, and pulmonary arterial enlargement can be observed as associated findings.

Although emphysema is not expected to occur in patients with COVID 19, reticulation, bronchial wall thickening, and ground-glass opacities may be seen in both COPD and COVID-19 pneumonia. Furthermore, traction bronchiectasis may occur in the late phase of COVID-19 pneumonia and mimic the findings of COPD. Underlying COPD in patients with COVID-19 might also result in a more severe, long-term, persistent lung disease and interstitial fibrosis. GGOs of COVID-19 within emphysema may resemble a crazy-paving pattern which can be an indicator of severe COVID-19. However, air cysts predominantly located in the anterior part of the lungs can be seen...
secondary to COVID-19 pneumonia itself or prolonged ventilation and mimic emphysema\textsuperscript{52,65} (Fig. 6). COPD patients with emphysema and COVID-19 may be at high risk of pneumothorax. Early diagnosis of pneumothorax and definition of CT findings of both diseases would be helpful for clinicians and provide appropriate management of the diseases.

9. Malignant diseases

Thoracic malignancies consist of metastases and primary malignancies such as lung, airway, pleural, and chest wall tumors. Lung metastases are usually seen as well-circumscribed, rounded solid lesions of variable sizes, while primary lung tumors are often characterized by sub-solid density, air bronchogram, and lobulated or spiculated margin.\textsuperscript{17} In addition to solitary nodules and mass, primary lung tumors particularly adenocarcinomas can also appear as consolidation and GGOs and resemble infectious diseases. Pleural effusion, pleural thickening, and mediastinal lymphadenopathy can accompany both primary and secondary cancers.\textsuperscript{60}

9.1. Overlapping with COVID-19 and differentiation

An underlying malignant disease can worsen the outcome of COVID-19. The pooled incidence of cancer in COVID-19 patients was 6%.

The incidence of COVID-19 in cancer patients is highest in hematological and lung cancers. Patients with lung cancer have been associated with a near doubling of severe COVID-19.\textsuperscript{7,69} Potential causes of higher rates of severe disease and death are impaired immunity due to chemotherapy, especially in hematological malignancies and lung involvement, particularly in lung cancer. Receiving chemotherapy 4 weeks before the symptoms of COVID-19 leads to a high risk of death.\textsuperscript{59} Vaccination before chemotherapy and self-isolation during chemotherapy is very important to prevent COVID-19 in cancer patients.

COVID-19 may mimic lung cancer by showing atypical chest CT findings including isolated upper lobe involvement, the presence of a solitary lesion, and pleural effusion.\textsuperscript{14} On the other hand, the presence of cystic change, vessel convergence sign and pleural retraction are mostly seen in lung cancer.\textsuperscript{70} In addition to solitary lesions, multiple GGOs and consolidations may resemble mucinous lung adenocarcinomas and hemorrhagic metastases such as angiosarcoma.\textsuperscript{1}

New GGOs can be confused with new foci of lung adenocarcinoma in patients with both diseases. In addition, interlobular septal thickening and crazy paving pattern in COVID-19 pneumonia may imitate lymphangitic carcinomatosis in cancer patients. Follow-up chest CT may be useful in differentiation, as previously reported dynamic changes of COVID-19 pneumonia occur in a shorter period of time. GGOs and consolidations of COVID-19 pneumonia can also obscure metastases in cancer patients, so the investigation of lung metastases and disease progression can be performed after the resolution of COVID-19 pneumonia.

Besides COVID-19, cancer patients are prone to other opportunistic infectious diseases which can be confused with COVID-19 pneumonia. Anamnestic, increased tumor markers, and clinical findings suggesting viral infection can help to establish the correct diagnosis (Fig. 7).
Pulmonary edema is caused by the increased accumulation of fluid in the pulmonary interstitium and alveoli due to the increased hydrostatic pressure, permeability, or both. Although the most common reasons for pulmonary edema are heart failure and acute respiratory distress syndrome (ARDS), several other reasons such as acute mitral valve insufficiency, pulmonary embolus, re-expansion, reperfusion, and neurogenic injuries can cause pulmonary edema. GGOs, consolidations, bronchovascular thickening, and septal thickening are the most common imaging features of pulmonary edema.

The distribution of the imaging abnormalities provides clues to the etiology of pulmonary edema. Unilateral right lung, especially upper lobe, involvement suggests acute mitral valve insufficiency, while pulmonary edema secondary to neurogenic injury usually affects lung apices. Gravitational gradient usually appears in ARDS. Bilateral peripheral opacities, also known as the batwing sign, are often seen in heart failure. Pleural effusion and cardiomegaly usually accompany the parenchymal findings of pulmonary edema due to decompensated heart failure.

10. Overlapping with COVID-19 and differentiation

COVID-19 can cause pulmonary edema because of increased pulmonary venous pressure and alveolar capillary membrane permeability. In COVID-19, cytokine storm and inflammation induce increased alveolar capillary membrane permeability while dysregulation of the renin angiotensin aldosterone system (RAAS) causes increased hydrostatic pressure and volume overload. Subsequently, ARDS may develop due to secondary inflammation and fibrosis. Therefore, COVID-19 can worsen underlying pulmonary edema and cause decompensated heart failure.

However, imaging findings of pulmonary edema and COVID-19 pneumonia show high similarity with GGOs, consolidations, septal

Fig. 8. COVID-19 pneumonia and pulmonary edema.
Axial CT image (a) of a patient with subacute COVID-19 pneumonia shows cardiomegaly and bilateral pleural effusions (arrow). CT image in lung window (b) demonstrates bilateral peripheral opacities due to COVID-19 pneumonia. Coronal CT image (c) shows that there are also perihilar opacities due to accompanying pulmonary edema.

Fig. 9. COVID-19 and pulmonary thromboembolism.
Coronal CT image of a patient with previously diagnosed CTEPH shows chronic PTE in the right interlobar artery (arrow). Right ventricular dilatation and interventricular septal flattening due to increased right ventricular pressure is seen on axial CT image (b). Axial CT image (c) of the same patient shows bilateral peripheral GGOs compatible with COVID-19 pneumonia.
Axial CT image (d) of another patient with COVID-19 pneumonia demonstrates thrombi in the right lower pulmonary artery branches (arrow). The CT image in the lung window (e) shows bilateral peripheral opacities of subacute COVID-19 pneumonia, and pleura-based opacity is seen in right lower lobe representing pulmonary infarction.
thickening. Although differentiating CT findings can be very challenging, the distribution of GGOs, and the presence of pleural effusion can help the radiological differential diagnosis. The presence of fever also suggests accompanying COVID-19 in patients with pulmonary edema. In addition to treatment for COVID-19 pneumonia, the drugs that decrease the fluid in the lung can contribute to reducing lung damage (Fig. 8).

11. Pulmonary thromboembolism

Pulmonary thromboembolism (PTE) can occur due to coagulation abnormalities which are provoked by various factors including surgery, trauma, chemotherapy, cancer, immobilization, and COVID-19. Although pulmonary CT angiography is very sensitive in the demonstration of PTE, knowledge of accompanying parenchymal findings is the cornerstone, especially in patients with COVID-19 who usually undergo non-contrast chest CT. Acute pulmonary embolism is characterized by wedge-shaped pleural-based opacification or consolidation with air bubbles. The halo sign may be seen secondary to adjacent hemorrhage. Mosaic attenuation and peripheral irregular linear densities due to residual scars from infarcts can be observed in patients with chronic PTE. Enlargement of the pulmonary artery and the right ventricle can also help the diagnosis of PTE.

11.1. Overlapping with COVID-19 and differentiation

The incidence of PTE in hospitalized patients with COVID-19 has been found to be approximately 1.9–8.9%. Critically ill COVID-19 patients requiring ICU show a higher incidence for PTE. Also, underlying chronic PTE may worsen with COVID-19 and vice versa. Predominantly peripheral GGOs and consolidations may obscure accompanying or underlying infarct. Furthermore, imaging findings of pulmonary infarct may overlap with COVID-19 pneumonia. Wedge-shaped and bubbly consolidation can be clues for PTE. Pulmonary CT angiography can be performed upon suspicious radiological and clinical findings. The use of therapeutic anticoagulants and balancing the risk of increased bleeding play a vital role in the management of patients with COVID-19 and accompanying PTE (Fig. 9).

12. Conclusion

The evaluation of lung involvement in patients with COVID-19 and underlying lung disease is challenging both clinically and radiologically. The imaging features of COVID-19 and underlying lung disease can overlap and cause difficulties in the differential diagnosis. Although a multidisciplinary approach is essential for appropriate disease management, radiologists play an important role in facilitating the diagnosis by knowing the imaging findings of COVID-19 and existing lung disease.
