Abstract

In Drosophila photoreceptors Ca^{2+}-permeable channels TRP and TRPL are the targets of phototransduction, occurring in photosensitive microvilli and mediated by a phospholipase C (PLC) pathway. Using a novel Drosophila brain slice preparation, we studied the distribution and physiological properties of TRP and TRPL in the lamina of the visual system. Immunohistochemical images revealed considerable expression in photoreceptors axons at the lamina. Other phototransduction proteins are also present, mainly PLC and protein kinase C, while rhodopsin is absent. The voltage-dependent Ca^{2+} channel cacophony is also present there. Measurements in the lamina with the Ca^{2+} fluorescent protein G-CaMP ectopically expressed in photoreceptors, revealed depolarization-induced Ca^{2+} increments mediated by cacophony. Additional Ca^{2+} influx depends on TRP and TRPL, apparently functioning as store-operated channels. Single synaptic boutons resolved in the lamina by FM4-64 fluorescence revealed that vesicle exocytosis depends on cacophony, TRP and TRPL. In the PLC mutant norpA bouton labeling was also impaired, implicating an additional modulation by this enzyme. Internal Ca^{2+} also contributes to exocytosis, since this process was reduced after Ca^{2+}-store depletion. Therefore, several Ca^{2+} pathways participate in photoreceptor neurotransmitter release: one is activated by depolarization and involves cacophony; this is complemented by internal Ca^{2+} release and the activation of TRP and TRPL coupled to Ca^{2+} depletion of internal reservoirs. PLC may regulate the last two processes. TRP and TRPL would participate in two different functions in distant cellular regions, where they are opened by different mechanisms. This work sheds new light on the mechanism of neurotransmitter release in tonic synapses of non-spiking neurons.

Introduction

Light transduction in Drosophila occurs in retinal microvillar arrangements running along the photoreceptor soma, termed rhabdomere. The axon of this non-spiking neuron releases histamine in a tonic manner [1,2]. It presents a T-bar ribbon synapse, a particular structure of the active zones specialized for fast and sustained multivesicular neurotransmitter release in response to graded membrane depolarizations. R1–R6 photoreceptors make multiple axo-axonic synaptic contacts with large monopolar (LI-L3) and amacrine cells in the lamina (Fig. 1A). Cell somata are located in the outermost part of this neuropile, leading to a particular situation where axonal arrays (named cartridges) are the predominant components of the lamina. The axons of centrifugal medullar neurons (C2–C3), a T-shaped centripetal neuron (T1) and a wide field tangential neuron (Tα) are also found in the lamina [3,4]. In the rhabdomere, photon absorption triggers rhodopsin isomerization into an active state which, upon interaction with a G\textsubscript{q}-protein, activates phospholipase C (PLC\textsubscript{δ1}). This enzyme, encoded by norpA [5], hydrolyses phosphatidylcholine-sitol bisphosphate (PIP\textsubscript{2}) into inositol trisphosphate (IP\textsubscript{3}) and diacylglycerol (DAG). This signaling cascade has been widely implicated in the activation of TRP and TRPL [6], the two channels carrying the phototransduction current [7,8]. Although the mechanism of channel gating remains undetermined, there is evidence that under experimental conditions, DAG, polyunsaturated fatty acids (PUFAs) [9,10], PIP\textsubscript{3} [11,12] and protons [13] are involved in opening TRP and TRPL, whereas IP\textsubscript{3} receptor does not [14,15]. Interestingly, TRP and TRPL expressed in heterologous systems [16] are activated by Ca^{2+} depletion of the endoplasmic reticulum (ER). Here we confirm the presence of TRP in the lamina [17], where we report that TRPL is also expressed. For the first time, we provide evidence that these channels are implicated in neurotransmitter release in the lamina, where they apparently allow Ca^{2+} influx via a store-operated channel (SOC) mechanism [18] and could also be regulated by a PLC-mediated cascade [6]. Furthermore, we show that the voltage-dependent Ca^{2+} channel cacophony, the only fly homo-
logue of vertebrate N-, P/Q- and R-type [17,19,20], is present in the lamina where it plays an important role in photoreceptor synaptic transmission, probably as a first step in a complex cascade involving both intracellular and extracellular Ca\textsuperscript{2+} signalling.

These results contribute to understand tonic neurotransmitter release in ribbon-type synapses and presynaptic enhancement by intracellular Ca\textsuperscript{2+} in non-spiking neurons.

**Results**

**TRP, TRPL, Other Phototransduction Proteins and Cacophony are Present in Photoreceptors Axons**

To carry out our study, we developed a novel preparation of *Drosophila* brain slices suitable for functional and immunohistochemical studies in the visual system (Fig. 1A,B). Remarkably, this preparation retained the ability to respond to light, manifested as vesicle exocytosis in the lamina. We observed a light-induced decay in FM4-64 fluorescence in preloaded axonal varicosities (Fig. 1C–E; see below and SI for details on bouton quantification). Consistent with a previous report [17], we detected TRP immunoreactivity in the retina and lamina of *wt* flies (Figs. 2A,C, left; n = 12). This was observed by two different monoclonal antibodies directed against the C-terminal region of this channel, with indistinguishable results (Fig. 2E). We also found high immunolabelling for TRPL channels (monoclonal antibody directed against the C-terminal). Thus, both light-dependent channels are present in the same regions of the visual system (Fig. 2B,D, left; n = 10). The specificity of α-TRP and β-TRPL antibodies was verified in *npl\textsuperscript{102}; trp\textsuperscript{144}* null double mutants, where no significant staining was detected (Fig. 2F; n = 6). We examined whether TRP and TRPL immunoreactivity in the lamina corresponded to photoreceptor axons projecting to this neuropile. These axons were identified by ectopic membrane tagged GFP expression (UAS-CD8::GFP) under the GMR-Gal4 driver. In the lamina of adult flies, GMR drives the expression of reporter proteins in the axons of all photoreceptors (R1–R8) [21]. We evaluated whether this marker displayed the same distribution as TRP and TRPL (Fig. 2A–D, center). For dense fluorescence patterns, the degree of random overlap has to be considered for each single colocalization experiment. We applied the confined displacement algorithm (CDA) to assess the colocalization of proteins in small structures, [22,23]. The CDA allows the evaluation of random colocalization which is subtracted from the Manders colocalization coefficient. This “effective colocalization” therefore corrects for random colocalization and provides an estimate of protein colocalization beyond the random level (see Methods and Text S1). Figure S1 shows a representative example for colocalization analysis of α-TRP and GFP signals, including the ROIs for CDA determined after image deconvolution and segmentation (see Methods). Our results indicate that TRP and TRPL colocalize significantly with GFP (~30% above the random colocalization; Fig. 3G), indicating that these channels are preferentially distributed within the photoreceptors axons, and perhaps in other cell types as well.

We explored the presence of other key phototransduction proteins in this neuropile, in order to examine a possible functional role in TRP/TRPL activation in the photoreceptor axons. We found a high level of PLC and PKC immunoreactivity (Figs. 3A,B), which colocalized significantly with CD8::GFP (~25–30% each, above the random values; Fig. 3G). These results show that PLC, PKC, TRP and TRPL are present in photoreceptor axons. In addition, positive immunostaining was found in other axons that we did not further identify. In contrast, we observed a weak immunostaining for G\textsubscript{q}-protein and InaD in photoreceptor axons (~4–7% above the random values, respectively; n = 6; Figs. 3C,D,G). Rhodopsin (Rh1) immunostaining was confined to the retina, with no detectable presence in the lamina (Figs. 3F; n = 3). Altogether, these results raise the possibility that TRP and TRPL activation in the lamina is mediated by a mechanism involving PLC and PKC.

If present in the synaptic terminals, TRP and TRPL may participate in exocytosis because they permeate Ca\textsuperscript{2+}. It is
antibodies, tested on a trpl302;trpCM wt magnification view of TRP immunostaining in the lamina of vertebrate N-, P/Q- and R-type voltage-gated Ca$^{2+}$ channels and shares ~68% of its amino acidic sequence with the N-type Ca$^{2+}$ [17], the primary subtype involved in neurotransmission. We explored if cacophony is present in the lamina by testing antibodies against T-, L-, R-, P/Q- and N- subtypes (no specific antibody for cacophony is available). We found positive immunoreactivity exclusively for the α-N-type antibody in the lamina (Fig. 3E, n = 4), where it displayed a significant colocalization of ~30% above the random value with GFP (Fig. 3G). These results suggest that cacophony is present in photoreceptor axons at the lamina. This possibility is supported by the functional assays described below.

**Cacophony-dependent Ca$^{2+}$ Signaling in Photoreceptor Axons**

The slices were also amenable for physiological experiments. We first examined whether cacophony channels are implicated in depolarization-induced Ca$^{2+}$ entry in the photoreceptor axons in the lamina. To measure Ca$^{2+}$ signals, we ectopically expressed the fluorescent Ca$^{2+}$-indicator protein G-CaMP [24] under the GMR driver. GMR-Gal4/UAS-G-CaMP flies expressed G-CaMP in photoreceptor somata and axons (Fig. 4A,B); single varicosities were resolved in detail at high magnification in the lamina (Fig. 4C).

In slices from GMR-Gal4/UAS-G-CaMP flies, depolarization induced a mean absolute increase of 0.68 ± 0.11 in G-CaMP fluorescence (Fig. 4D,E; n = 4). These responses were significantly reduced by 100 nM of the spider toxin PLTX-II (0.38 ± 0.90; n = 5; Fig. 4D,E), a cacophony channel blocker [25]. These results suggest that cacophony is involved in Ca$^{2+}$ influx in photoreceptor axons.

**Synaptic Vesicle Exocytosis in the Lamina**

The immunohistochemical and Ca$^{2+}$ imaging studies described above suggest that cacophony is involved in exocytosis. To examine this possibility, we monitored FM4-64 loading into axonal varicosities as an indicator of previous vesicle release. Bouton quantification (see Methods) was done in an x,y,z volume of 36x36x3 mm$^3$. Gradient and size filters were applied to z-projections of 10 images (Δz = 0.3 mm) to create binary images (Figure S2A,B), where the ROIs were automatically quantified (see Methods). The size filter for bouton quantification was set to consider the most representative bouton population (in terms of area) in the lamina, as shown by the distribution of the FM4-64 loaded-boutons in slices from wt flies (0.5 to 1.1 μm$^2$; Fig. S2C). This procedure was systematically used to quantify boutons in an unbiased manner.

In wt slices, high-K$^+$ pre-treatment in the presence of FM4-64 in chilled Ringer induced massive exocytosis, as revealed by the large number of fluorescently labeled boutons observed in the lamina (199 ± 22; n = 17, Fig. 5Ab,C). Spontaneous vesicle release was estimated in unstimulated slices exposed to FM4-64 in normal extracellular solution in the dark for 10 minutes (control). Compared to high-K$^+$ exposure, the number of fluorescently labeled boutons observed in these conditions (20 ± 3, n = 5; Fig. 5Aa,C) was small, confirming that indicator uptake by the boutons was mainly activity-dependent. Once loaded with FM4-64 (Fig. S3Aa), re-exposure to high K$^+$ for 5 minutes induced a dramatic decrease in fluorescence, an indication of a massive unloading of boutons preloaded with FM4-64 (Fig. S3), directly
demonstrating a strong exocytosis in response to depolarization. Altogether, these results show that the preparation is suitable for recording activity-dependent vesicle exocytosis in the lamina. To evaluate a role of cacophony in exocytosis, we induced depolarization with high-K\(^+\) in a solution containing PLTX-II and FM4-64. Under these conditions, the number of labeled boutons in wt slices was significantly reduced (47±8; n = 7; p < 0.01; Fig. 5Ac,C), supporting the idea that this channel is implicated in exocytosis. To further investigate this possibility and considering that PLTX-II could also affect other Ca\(^{2+}\) channels [26], we took advantage of the cacophony thermosensitive mutant cacTS [27]. At permissive temperature (chilled Ringer) the number of labeled boutons observed after depolarization by high-K\(^+\) was 136±11 (n = 6; Fig. 5Da,E). In contrast, in slices incubated at the non-permissive temperature (37 \(\pm\) C) for 10 minutes, exocytosis was dramatically reduced (21±9, n = 8; p < 0.01; Fig. 5Db and 5E; representing a reduction of 85%). To assess a possible effect of high temperature exposure during exocytosis, wt flies were loaded with FM4-64 by high-K\(^+\) at 37 \(\pm\) C for 10 min. The number of boutons loaded in wt in these conditions (112±14, Fig. 5D, right and 5E) was in fact reduced by 45% compared to chilled Ringer (199±22; n = 17, Fig. 5Ab,C), indicating a temperature effect. However, this temperature-dependent reduction cannot account for the 85% decrease observed in cacTS for the same temperature change, thus confirming that impaired cacophony channel function causes a significant decrease in exocytosis. Consistent with the requirement of Ca\(^{2+}\) influx from the extracellular space, experiments conducted in the absence of external Ca\(^{2+}\) revealed a dramatic decrease in vesicle loading (36±5 labeled boutons, n = 11; Fig. 5Ad,C). Taken together, these results show that cacophony is necessary for vesicle exocytosis in the lamina.

Our observations that TRP and TRPL channels are also present in the photoreceptor synaptic terminals raised the question of whether these Ca\(^{2+}\)-permeable channels may also contribute to vesicle release. To address this issue, we evaluated FM4-64 loading after high-K\(^+\)-induced depolarization in synaptic terminals of the lamina in TRP/TRPL mutants. In TRP (\(\text{trp}\)) and TRPL (\(\text{trpl}\)) single mutants the level of exocytosis induced by depolarization was comparable to wt flies (150±19 labeled boutons, n = 7, Fig. 5Ac,C and 122±16, n = 9, Fig. 5Af,C, respectively; p > 0.05). In contrast, a severe impairment in vesicle release was observed in \(\text{trpl}\); \(\text{trp}\) double mutants (49±9 labeled boutons, n = 22, p < 0.01; Fig. 5Ag,C). The basal bouton loading observed in non-depolarized double mutant slices was significantly lower than

(C) G\(_{\text{q}}\)-protein subunit (right); CD8::GFP (center); Merge (right). (D) InaD (left); CD8::GFP (center); Merge (right). (E) Cacophony (left); CD8::GFP (center); Merge (right). (F) Rhodopsin (Rh1; left); CD8::GFP (center); Merge (right). (G) Effective colocalization of TRP, TRPL, other transduction proteins and cacophony with photoreceptor axons (CD8::GFP) in the lamina. The segmented signals for the different proteins were randomized within the confined regions of photoreceptor axons as described in Methods and illustrated in Supporting Figure S2B. A maximum displacement radius of 20 pixels was considered for randomization. n = 20 images for all the immunostainings studied.

doi:10.1371/journal.pone.0044182.g003
under depolarization (17±5, n = 5; p<0.01; Fig. 5C). These results are consistent with the presence of a voltage-dependent Ca^{2+} influx in the terminals, independent of TRP and TRPL.

It was conceivable that the inability of trpl;trp synaptic terminals to undergo exocytosis could be caused by degeneration of the vesicle release mechanism. To test for this possibility, the Ca^{2+} ionophore A-23187 (250 nM) was added to the external solution in the presence of FM4-64. This treatment induced vigorous vesicle release, being the number of labeled boutons in trpl;trp flies similar to wt in the same conditions (90±6; n = 5 and 130±15; n = 5; Figs. 5Bb and a, respectively). This result indicates that the failure of the double mutant to undergo exocytosis relied on the absence of the Ca^{2+}-permeable channels, TRP and TRPL, rather than on a morphological defect of the terminals. Interestingly, the presence of either TRP or TRPL is sufficient to sustain synaptic exocytosis.

Altogether, these results are consistent with the hypothesis that TRP, TRPL and cacophony are involved in vesicle release in the lamina. However, the fact that exocytosis is almost completely abolished by removal of either cacophony or of both, TRP and TRPL, is intriguing. In the experiments described in the following sections, we aimed to unravel the mechanism of neurotransmitter release in photoreceptor terminals and to clarify the relative contribution of these different types of Ca^{2+}-permeable channels to this process.

**Contribution of Intracellularly Liberated Ca^{2+} to Exocytosis**

We investigated whether Ca^{2+} provided by the ER was relevant for vesicle release by depleting this organelle using pharmacolog-
Drosophila Synapse: TRP, TRPL and cacophony

The immunohistochemical stainings presented above suggested that PLC is involved in depolarization-induced synaptic activity in the lamina.

\[ \text{Ca}^{2+} \text{ influx Mediated by TRP and TRPL as Store-operated Channels} \]

Considering that intracellular Ca\(^{2+}\) release and that TRP/TRPL contribute to vesicle release in the lamina, we examined the possibility that these channels function as store-operated channels (SOCs) in the photoreceptors axons. We utilized a well-established experimental protocol to test the participation of SOCs, known as the “Ca\(^{2+}\)-depletion protocol” [29]. In this protocol, the Ringer solution is exchanged by a Ca\(^{2+}\)-free (0-Ca\(^{2+}\)) Ringer supplemented with Thg (10 \(\mu\)M) to deplete the ER of Ca\(^{2+}\), a condition that should open SOCs, if present. If a subsequent restitution of regular Ringer induces a transient Ca\(^{2+}\) influx, it is taken as an indication of SOC activity. In GMR-Ga4/UAS-G-CaMP flies, this protocol induced a significant increase in Ca\(^{2+}\)-dependent GCaMP fluorescence in the lamina (mean absolute change = 0.38±0.06, \(n = 5\); not shown). This result is consistent with the existence of a SOC mechanism in photoreceptors terminals in the lamina. Considering the difficulty to express G-CaMP in trpl;trp flies due to genetic constraints (see Methods), we carried out the same experiment in the wt and in the double mutant using the Ca\(^{2+}\) indicator Rhod-2 AM. In wt slices loaded with this fluorophore, the Ca\(^{2+}\)-depletion protocol induced a mean absolute increase in fluorescence of 0.67±0.09, \(n = 4\); Fig. 7A,E). In contrast, no change in Rhod-2 fluorescence was observed in trpl;trp slices (0.06±0.03, \(n = 4\); Fig. 7B,E).

It might be thought that Ca\(^{2+}\) release caused by SERCA inhibition activates PLC [28], thereby leading to the opening of TRP/TRPL, without involving a SOC mechanism. Thg (0-Ca\(^{2+}\)) exposure should actually increase cytosolic Ca\(^{2+}\), however after 10 min in this solution, internal Ca\(^{2+}\) should be back to original level [29]. Accordingly, there was no significant difference in fluorescence between this condition (Fig. 7A, center) and the initial condition (Fig. 7A, left; mean absolute change = −0.04±0.03; \(n = 5\)).
Altogether, these results suggest that TRP and TRPL activation in the photoreceptor axons in the lamina is mediated by a store-operated mechanism.

We next investigated if the Ca\textsuperscript{2+} increase associated with TRP/TRPL SOC activity was able to evoke exocytosis in the varicosities. Slices from wt flies were exposed to Thg in 0-Ca\textsuperscript{2+} external solution for 10 min and then returned to normal Ringer supplemented with FM4-64. If the depletion protocol triggers exocytosis, the dye will be subsequently incorporated into axonal varicosities. As shown in Fig. 7C,F a significant number of boutons was labeled by this procedure (58 \pm 6, n = 7). To check if exposure to 0-Ca\textsuperscript{2+} Ringer could be by itself responsible for the exocytosis observed upon return to regular external solution, we repeated the experiment in the absence of Thg. In this case, the number of loaded boutons (24 \pm 7, n = 5, p<0.05; Fig. 7F) was significantly smaller than when loaded by the Ca\textsuperscript{2+}-depletion protocol and comparable to control loading in Ringer (20 \pm 3, n = 5; see Fig. 5C). This result supports the presence of Ca\textsuperscript{2+}-permeable SOC channels and that they represent an additional source of Ca\textsuperscript{2+} for the synaptic events occurring in the varicosities.

Importantly, in the trpl\textsuperscript{dp} mutant the Ca\textsuperscript{2+}-depletion protocol failed to induce vesicle exocytosis, as revealed by the low number of labeled boutons observed (29 \pm 4, n = 6; Fig. 7D,F), that was comparable to basal bouton loading in these mutants (17 \pm 5, n = 5; Fig. 5C). As previous experiments with the Ca\textsuperscript{2+} ionophore (A-23187) demonstrated that the double mutant has the potential for vesicle release (Fig. 5B), the impaired exocytosis induced by the depletion protocol in these slices points to a SOC function of TRP and TRPL.

Altogether, these results indicate that there is a Ca\textsuperscript{2+} influx through TRP and TRPL channels localized to the axons. These channels appear to be activated by a store-depletion mechanism and may contribute to Ca\textsuperscript{2+}-dependent vesicle exocytosis.

It is remarkable that TRP and TRPL function differently in the rhabdomere and in the axonal terminals of the photoreceptors, where they appear to be opened by different mechanisms.

**Discussion**

TRP and TRPL are the targets of *Drosophila* phototransduction in the rhabdomere, gated by an as yet undetermined PLC-
Ca\textsuperscript{2+} signals induced in the lamina by the ‘Ca\textsuperscript{2+} depletion protocol’ are abolished in the trpl;trp mutant. Slices were bathed with 0-Ca\textsuperscript{2+} solution supplemented with 10 μM Thg (Thg(0Ca\textsuperscript{2+})) during 8 min to produce internal Ca\textsuperscript{2+} stores (ER) depletion. Afterwards the slices were returned to regular Ringer. (A, B) Z-projections of 4 confocal images were obtained from the lamina in slices preloaded with Rhod-2 and treated with the depletion protocol. Rhod-2 fluorescence in wt (A) or trpl;trp (B) slices in regular Ringer (left), during application of Thg(0Ca\textsuperscript{2+}) solution (center) and after regular Ringer was restored (right). (C-D) Z-projections of 10 confocal optical sections (Δz = 0.3 mm) showing representative bouton loading of FM4-64 in wt (C) and trpl;trp (D) slices, upon returning to regular Ringer after Thg depletion. (E) Quantification of Rhod-2 fluorescence change after restoring Ringer in wt and trpl;trp (B). (F) Quantification of FM4-64 bouton labeling induced by the depletion protocol (C and D, denoted by ‘0Ca\textsuperscript{2+}+Thg’) or upon returning to Ringer after treatment with 0-Ca\textsuperscript{2+} solution without Thg (‘0Ca\textsuperscript{2+}’). Bars: mean ± SEM calculated in z-projections of 10 images. Size: x/y/z = 36/36/0.3 μm. * p<0.05 with respect to wt. Pseudocolor scale in arbitrary units.

doi:10.1371/journal.pone.0044182.g007

**Presence of TRP, TRPL, Other Phototransduction Proteins and Cacophony in the Lamina and Medulla**

We confirmed that, in addition to the rhodolome, TRP localizes to the lamina and the medulla [17]. Additionally, we found TRPL in these two neuropiles, where photoreceptors synapse with secondary neurons. We studied the lamina, where most photoreceptors make synaptic connections into well-defined structures [3].

We developed a Drosophila slice preparation suitable for immunohistochemistry and functional experiments in the lamina. In addition to TRP and TRPL, PLC and PKC exhibited high expression levels, while Gq and INAD were scarce and rhodopsin was absent. The four former proteins colocalized with ectopically expressed GFP, used as photoreceptor marker, whereas Go and INAD colocalization with GFP was low. While TRP, TRPL and PLC were not restricted to photoreceptors, the relevant conclusion is that their presence in photoreceptor axons in the lamina suggests a participation in presynaptic events.

The prominent cacophony immunostaining in the lamina is relevant. This Ca\textsuperscript{2+} channel is involved in synaptic transmission in Drosophila neuromuscular junction, brain and retina [19,30]. Cacophony mutants ERGs show abnormal ‘on-off’ transients [31,32], suggesting a role in synaptic transmission in the lamina.

**Evidence for a Synaptic Role of Cacophony, TRP and TRPL**

A role of cacophony in photoreceptor synaptic transmission is supported by our observation that inhibition of this channel by PLTX-II affected bouton labeling. Although the possibility that PLTX-II could also affect other Ca\textsuperscript{2+} channels cannot be ruled out [26], the role of cacophony in vesicle release was further strengthened by the substantial reduction in FM4-64 fluorescence in the thermosensitive cacophony mutant cac\textsuperscript{TS} at non-permissive temperature. In agreement with this, a mutation in the dskd\textsubscript{3} gene encoding a cacophony subunit abolishes the ERG ‘on’ transient [31]. On the other hand, depolarization–induced G-CaMP Ca\textsuperscript{2+} fluorescence changes in the photoreceptors were significantly decremented by PLTX-II, providing additional evidence involving cacophony in the synaptic events.

The observations that TRP and TRPL are also in the photoreceptors axons and are considerably Ca\textsuperscript{2+}-permeable (P\textsubscript{Ca}:P\textsubscript{Na} ≈ 100:1 and ≈ 4:1, respectively) [8] suggested a synaptic role. Accordingly, vesicle release was drastically impaired in the double mutant. Opening a Ca\textsuperscript{2+} pathway with the ionophore PLTX-II in this mutant, an observation that opposes to a generalized degeneration of synaptic machinery. This evidence involving cacophony in the synaptic events.

FM4-64 is presumably incorporated by all lamina neurons and therefore not only photoreceptor boutons should be labeled.
However, we expect that the dramatic changes in release observed include photoreceptor terminals, which represent the most numerous synaptic contacts in the lamina [33].

Altogether, our results support the participation of TRP, TRPL and cacophony in synaptic transmission in photoreceptor terminals.

Role of Phospholipase C and Internal Ca2+ Reservoirs in Synaptic Transmission

What is PLC doing in photoreceptors synaptic terminals? Depolarization-induced exocytosis was markedly reduced in ntcpA mutant, suggesting a role of PLC in neurotransmitter release. An obvious possibility is that it mediates TRP/TRPL activation. In principle, PLC may act by either DAG or IP3. PUFAs can activate the light-dependent channels when added to intact ommatidia [9], as well as to excised rhabdomeric membrane patches, in which DAG can do the same [10]. Thus, it is conceivable that these lipids may also activate TRP/TRPL channels in the lamina. Nevertheless, there is no evidence that PUFAs are generated in these photoreceptors.

How is PLC activated? In Drosophila photoreceptors, a level of PLC activity has been observed both in vitro and in vivo [28,34]. This basal activity is probably a property of the PLC molecule itself, as it is not affected by mutation of Gq-protein [34]. In addition, a positive modulation of PLC activity by micromolar Ca2+ has been reported in Drosophila head membranes [28]. Therefore, basal PLC activity could be boosted by Ca2+ influx through cacophony (and additional Ca2+ pathways described here) during depolarization-induced vesicle exocytosis, representing a feed-forward mechanism in this graded synapse. Alternatively, PLC activation may be a consequence of a direct activation of Gq by depolarization, as reported in other insects [35]. On the other hand, the substantial PKC expression in the terminals suggests that it may down-regulate PLC, as in the rhabdomere [36].

Calcium reservoirs appear to be involved in exocytosis, since inhibition of SERCA with Thg deeply affected vesicle release. Moreover, exposure of sera2+ to the non-permissive temperature considerably decreased bouton labeling compared to permissive temperature, and we showed that this decrease cannot be explained exclusively by a temperature effect. These results strongly implicate ER Ca2+ release in photoreceptors exocytosis.

TRP and TRPL as SOCs in Photoreceptor Synaptic Terminals

The robust Ca2+ signals in the lamina after Ca2+ depletion implicated TRP/TRPL, as it was absent in trpclp animals. This supports the function of TRP/TRPL as SOCs in the synaptic terminals, allowing Ca2+ influx. This mechanism drives exocytosis, as indicated by the Ca2+-depletion protocol, where bouton labeling was significant. Interestingly, TRP and TRPL function as SOCs in heterologous expression systems [13], but not in the rhabdomere [14,15].

Mammalian homologues of Drosophila TRP, TRPC1, 2, 4 and 6, are proposed to function as SOCs in different cell types [37]. Moreover, TRPC1 operating as SOC regulates Ca2+ influx related to neurotransmission in rods and cones [38]. The Drosophila genome has one gene encoding STIMh [39], an ER Ca2+ sensor protein that forms functional SOCs in association with TRPC1 [40]. It remains to be determined whether TRP/TRPL could form equivalent presynaptic macromolecular complexes in photoreceptors.

We showed that it is improbable that in the Ca2+-depletion experiments TRPL/TRP opening could be induced by a PLC-dependent mechanism mediated by phospholipase activation by a cytoplasmic Ca2+ increase due to altered reticular release/uptake balance during Thg treatment. In these experiments PLC contribution to exocytosis was possibly by-passed. In normal conditions, this enzyme may elicit Ca2+ elevation in the synaptic terminals by DAG-mediated activation of TRP/TRPL and/or by inducing Ca2+ release.

Diversity of Ca2+ Sources in Photoreceptor Synaptic Terminals: Functional Implications

Photoreceptors synaptic transmission must accurately follow the fast photoresponses generated in the rhabdomere. As graded synapses support rapid changes in neurotransmitter release, they should undergo fast variations in internal free Ca2+ [41]. Small and fast Ca2+ increments induce correspondent changes in release, something that would be implausible if a threshold were involved, as in non-graded synapses.

Besides cacophony contribution to exocytosis, the presence of the ryanodine receptor (RyR) in the lamina [42] suggests the participation of Ca2+-inhibited Ca2+ release (CICR), but we lack direct evidence for this. CICR regulates exocytosis in rods allowing high rates of neurotransmitter release [43]. A reasonable expectation is that Drosophila photoreceptors use all available Ca2+ pathways (cacophony; TRP/TRPL; the IP3 receptor, IP3R and RyR) to satisfy the synaptic demands required by their extremely fast photoresponses [6]. Weckström et al [44] speculated that the IP3R might reinforce transmitter release, but showed no direct evidence for it. This possibility is supported by our results implicating PLC. Moreover, our observation that Ca2+ from the ER contributes to depolarization-induced exocytosis strengthens the possibility of internal release via IP3R and/or RyR.

Bouton labeling experiments were conducted under prolonged depolarization, implying that vesicle exocytosis was at steady-state. Thg experiments under such conditions show that released Ca2+ plays an essential role in neurotransmission. In tonic synapses, this mechanism may be crucial to sustain synaptic transmission for extensive periods of time.

We propose the following model for the synaptic events at the axon terminals (Fig. 8): the receptor potential activates cacophony in the axon, allowing its propagation towards the axonal terminal, where Ca2+ enters through cacophony inducing vesicle release, perhaps enhanced by CICR. Additionally, PLC activated by an unknown mechanism which may be Ca2+ itself or depolarization, generates IP3, triggering Ca2+ release through IP3Rs. ER Ca2+ depletion in turn opens TRP/TRPL by a SOC mechanism, incrementing the Ca2+ supply. These channels may also be opened by lipid and pH changes resulting of PLC activity [13]. This multi-source transient Ca2+ increment guarantees efficient, rapid and sustained neurotransmitter release. After depolarization, resting Ca2+ levels would be restored by extrusion by the Na+/Ca2+ exchanger [45] and uptake by the ER.

We think that it is important to integrate the data into a plausible working model that could be helpful for designing further experiments. Although our model accounts for the data, it is by no means the only possible one. Accordingly, some aspects of it may be interpreted differently or given a different weight. For example, the relative contributions of cacophony, CICR, IP3-induced Ca2+ depletion and TRP/TRPL to presynaptic Ca2+ for vesicle release can vary widely. Also, the activation of TRP/TRPL may rely on ER depletion and/or lipids associated to PLC activity. It may be thought that the Ca2+ influx through cacophony should be sufficient to account for exocytosis, making Ca2+ release redundant and rather unnecessary. However, in this graded synapse the level of cacophony activation will follow the graded depolarization. The
amplitude attained by the receptor potential are most likely within a small voltage range above the threshold for cacophony activation (-20 or -40 mV [20]), inconsistent with a massive cacophony-dependent Ca$^{2+}$ influx. Therefore, additional Ca$^{2+}$ sources amplifying this initial signal are likely to be required for light-induced synaptic transmission.

We provide novel evidence for TRP/TRPL function in Drosophila photoreceptors. For the first time, we show that these channels have dual roles in separate regions of the same cell, namely the rhabdomere and the synapse, apparently involving different mechanisms. More generally, the observations reported herein shed light on the mechanism controlling presynaptic events in graded synapses.

Materials and Methods

Drosophila Fly Strains

The following Drosophila melanogaster strains were used: wild type (w+ Oregon Red, w; trp$^{343}$, w; trpl$^{302}$, w; cn; trp$^{CM}$, w; trpl$^{343}$ and w; mopd. We confirmed the integrity of the retinae of these flies with the pseudopupil test [46] and electroretinogram. We also used the stocks GMR-Gal4,UAS-mCD8-GFP/Cyo, GMR-Gal4/Cyo, UAS-GaMP. The thermosensitive mutants cac$^{TS2}$ and dac$^{TS}$ were kindly provided by R.W. Ordway and S. Sanyal, respectively. For Ca$^{2+}$ fluorescence experiments, UAS-GaMP flies were crossed to GMR-Gal4/Cyo and the progeny of 2–4 days post-eclosion was utilized. Flies were reared at 18°C under dim light conditions.

Drosophila Brain Slices

Adult male and female flies were anesthetized in CO$_2$ and kept in ice for sectioning with a vibratome (Vibratome, 1000 plus) under continuous illumination. For each experiment, around 10 flies were stuck to the stainless steel tray with 1 μL of cyanoacrylate ester glue. Flies were immersed in chilled extracellular solution containing (in mM): 120 NaCl, 5 KCl, 1 MgSO$_4$, 1 CaCl$_2$, 25 L-proline, 1.25 NaH$_2$PO$_4$ and 25 NaHCO$_3$, 2.5 sucrose, 10 HEPES. This solution was bubbled with a mixture of 95% O$_2$, 5% CO$_2$, which maintained the pH at 7.15. The whole body was sectioned in transversal slices (200 μm thick), yielding one slice per individual. These slices were suitable for both immunofluorescence and functional analysis. In the latter case, slices were kept in iced Ringer in the dark, for at most 2 hours, before imaging. The experiments were carried out at room temperature [approximately 20°C]. We considered depolarization-induced FM4-64 or Rhod-2 AM loading into axonal varicosities as a criterion for slice functionality. In mutants where depolarization-induced loading was disrupted, we performed internal positive controls using pharmacological tools to show that the terminals can effectively be loaded. All functional experiments were performed in chilled medium, except for those with the temperature-sensitive mutants at non-permissive temperatures and experiments in wt at 37/41°C to evaluate the effect of temperature.

Antibodies and Reagents

The α-TRP monoclonal antibody MAb83F6 developed by Seymour Benzer was purchased from the Developmental Studies Hybridoma Bank (DSHB) under the auspices of the NICHD and maintained by The University of Iowa, Department of Biological Sciences, Iowa City. A second α-TRP monoclonal antibody was kindly provided by Craig Montell (Johns Hopkins University); both antibodies were tested for specificity in the double mutant trp$^{343}$; trpl$^{302}$. The α-TRP/TRPL polyclonal antibody AB5912 was obtained from Chemicon and the pan α-N-type Ca$^{2+}$-1B polyclonal antibody (L-17), from Santa Cruz [47]. Polyclonal antibodies directed against PLC, PKC, INAD [48,7], G$_s$-protein and Rh1 were kindly provided by Charles Zuker (Columbia University). Specificity of the latter four antibodies was previously tested [49]. Alexa-Fluor 546 conjugated goat α-mouse and goat α-rabbit, Texas Red-X phalloidin, Bodipy TR-X rhapsgargin, TO-PRO-3 iodide Alexa 633 and the calcium ionophore A-23187 were from Molecular Probes, Invitrogen. The spider toxin Plectreurystoxin II (PLTX-II) was purchased from Alomone Labs.

Immunohistochemistry

Flies were anesthetized in CO$_2$ and fixed for 48 h in 4% formaldehyde in phosphate buffer saline (PBS) at 4°C. 200 μm
thick horizontal head sections were cut with a vibratome in chilled PBS under illumination, as described above. The sections were incubated for 2 h at room temperature (20–22°C) in blocking solution containing: 50% goat serum, 10% bovine serum albumin (BSA) in PBST (PBS +0.1% Triton X-100; Sigma). Primary antibodies were incubated overnight at the appropriate dilution in blocking solution at 4°C (α-TRP 1:200, α-TRPL 1:1000, α-GaM, α-PLC and α-INAD 1:300). Slices were washed 4×20 min in PBS and incubated with secondary antibody (1:200) for 1 h at room temperature. Either goat α-rabbit AlexaFluor594 or goat α-mouse AlexaFluor488 conjugated IgG antibodies were used. Sections were then washed (4×20 min) in PBS and stored in glycerol at 4°C. For imaging, slices were enclosed between two coverglasses and immersed in mounted media (Fluoromount, Electron Microscopy Sciences) and 20% glycerol.

**Statistics**

For all quantifications we utilized as statistical tests one or two-way ANOVA with Dunnett’s and Bonferroni post-test, p<0.05. Error bars represent ± S.E.M.

**Ca²⁺ Imaging**

*Drosophila* slices from GMR-Gal4/UAS-G-CaMP flies were covered with low melting point agarose (type IX-A, Sigma-Aldrich) to prevent movement. They were constantly perfused with normal extracellular solution (1 mL/min, bubbled with 95% O₂-5% CO₂) and a glass micropipette positioned on the lamina was used for local application of high-K⁺ solution (in mM: 35 NaCl, 90 KCl, 8 MgSO₄, 1 CaCl₂, 25 L-proline, 1.25 NaH₂PO₄ and 25 NaHCO₃, pH 7.15). Ca²⁺ signals were recorded by the fluorescent protein G-CaMP, ectopically expressed in the photoreceptors of GMR-Gal4/UAS-G-CaMP flies. This approach was not used in *tppl* mutants because in GMR-Gal4 flies the *gal4* construct localizes in the same chromosome as *tppl*. This could be addressed by making GMR-Gal4, *tppl*/*tppl* recombinants and UAS-GaMP,*tppl*/*tppl* segregant. Since this is a rather demanding and time consuming approach, we circumvented it by measuring Ca²⁺ in *tppl*;*tppl* mutants and *wt* flies with the fluorophore Rhod-2-AM. The slices were incubated for 30 minutes in the dye (10 μM in normal extracellular solution) and then washed for 10 minutes. In the SOC protocol, after Rhod-2-AM loading, Ringer solution was replaced by 0-Ca²⁺ Ringer supplemented with 10 μM Thg for 10 min; after this, normal Ringer was restored. Confocal z-stacks images were acquired before, during and after stimulation. See SI for details on image capture and analysis.

**Vesicle Exocytosis (FM4-64 Imaging)**

Vesicle exocytosis in the lamina was evaluated by the membrane fluorophore FM4-64 imaging in brain slices. Synaptic terminals were labeled with FM4-64 (10 mM) in an activity-dependent manner [50]. Discrete boutons were clearly distinguishable in *wt* and mutant flies. Loading procedure was as follows: in darkness, slices were stimulated in ice with high K⁺ extracellular solution (90 mM) in the presence of FM4-64 for 10 minutes and then washed for 5 minutes in normal extracellular solution. In store-depletion experiments, FM4-64 was applied after 8 min of thapsigargin (Thg, 10 μM) pre-treatment and washed out with Ringer. Basal dye labeling was evaluated without stimulation, in the presence of FM4-64 for 10 minutes. Along the paper the notation “control” refers to basal labeling of FM4-64 or other dyes. Only slices with morphological preservation of the lamina were used. See below and SI for details on image acquisition and analysis.

**Image Capture and Analysis**

Acquisition of the different types of fluorescence images obtained in this study is described in detail in SI. Raw confocal image stacks were deconvolved by Huygens Scripting software (Scientific Volume Imaging, Hilversum, Netherlands) using an algorithm based on the Classic Maximum Likelihood Estimator. Image-processing routines were developed in SCIAN laboratory (www.scian.d) based on interactive data language (IDL, ITT, Boulder, Colorado). These procedures were used for ROI segmentation, quantification, and to determine colocalization coefficients (see below).

**Quantification of FM4-64 Labeled Synaptic Boutons**

A semi-automated analysis was developed to quantify synaptic boutons in an unbiased manner (see SI for details on gradient and size filters). The selected ROIs were automatically quantified by IDL. Results are expressed as mean number of fluorescently labeled boutons (mean ± standard error, SEM) from several projection images, each from a different fly. One- and two-way ANOVA with Dunnett’s and Bonferroni post-test statistical analysis was performed using GraphPad Prism 4 for Windows (GraphPad Software, San Diego California USA).

**Colocalization Analysis**

The confined displacement algorithm (CDA) was performed according to Ramirez et al. [22], segmented cartridges confined the displacement area. Briefly, with correlation techniques it is possible to shift one channel and its corresponding image mask (which confines radial displacement to the defined axonal section) relative to the second channel. Random colocalization of two fluorescent signals in the x/y plane was estimated by calculating its probability of occurrence within the cartridges (M1ROF(random), see SI). M1ROF(random) was subtracted from the Manders colocalization coefficient calculated without any displacement M1ROF(d=0) and referred to as effective colocalization M1ROF(effective). Expressed as a percentage, Eff-Colocalization (%) = M1ROF(effective) * 100.

**Supporting Information**
