ABSTRACT

We are reporting a novel approach for preparing silver nanoparticles with seed coat exudates of *Celastrus paniculatus* Willd, a medicinal plant traditionally used for the treatment of skin diseases, fever, leprosy and neurological disorders. HPTLC study revealed that aqueous, soluble seed coat exudates contain phenolics, alkaloids and flavonoids. The formation, crystalline nature and morphology of the nanoparticles were identified by UV–Vis spectroscopy, X-ray Diffraction (XRD) analysis, Transmission Electron Microscopy (TEM) and selected-area electron diffraction (SAED). Functional group stretching of aqueous soluble extracts was identified by using FTIR. Results revealed that nanosilver particles are spherical, range in size from 10 to 82 nm and crystalize in face-centered cubic structures. Surface-enhanced Raman spectra analysis showed that AgNP are capped with bioactive molecules from exudates and that they may act as precursors of the reduction of silver nitrate from the metallic state (Ag⁺) to the atomic state (Ag⁰). We also examined the minimal inhibitory concentration for bacteria *Escherichia coli* and *Bacillus subtilis* using a resazurin color assay. Nanosilver strongly inhibited the bacterial growth, leading to MIC values of 40 µg/ml and 60 µg/ml for the bacteria, respectively. The colony screening method and inhibition kinetics of biofilm formation in the *Klebsiella pneumoniae* strain were also studied using the tube method and a quantitative microplate assay. SEM analysis and quantification of the EPS revealed a fivefold decrease in concentration in treated compared to untreated. The inhibition response was duly reflected in SEM images.

Keywords: *Celastrus paniculatus* Willd, Seed Coat, Nanosilver, Bactericidal and Biofilm Inhibition.

INTRODUCTION

Many pathogenic bacteria, such as *Escherichia coli*, *Bacillus subtilis*, *Klebsiella pneumonia* and *Pseudomonas aeruginosa* have developed an enhanced resistance to standard antibiotics like streptomycin and tetracycline. The immense use of antibiotics to treat biofilm
infections has resulted in the emergence of these antibiotic resistant bacteria. Silver widely known to be highly antimicrobial and the surface-area-to-volume ratio of silver helps it to easily penetrate the bacterial cell wall. [1-3] We hypothesizing that, catalytic oxidation by metallic silver and its reaction with dissolved monovalent silver ions probably contribute to its bactericidal effect.

The biological synthesis of metal nanoparticles, silver nanoparticles in particular by many plants and microorganisms has been studied and explored. Plant parts have been found to mediate synthesis in the safest, healthiest and most effective way [4-9] due to their high number of phytoconstituents, which are involved in the formation of nanosilver. In recent years, leaf extracts such as Grewia flavescentis, Skimmia laureola, Vitex negundo and Artemesia vulgaris have been used for the synthesis of metal nanoparticles. [6-12] To the best of our knowledge, previous studies of biological synthesis involved boiling or rupturing of leaf tissue and very few reports [13-14] are available on seed coat exudates. The biological protocol we propose for synthesis is energy efficient and uses a simple extraction process, whereas non-biological methods (chemical and physical) are expensive and occasionally involve the use of hazardous chemicals. This motivated us to carry out this investigation.

In our study, nanosilver was synthesized by using the water-soluble seed coat exudates of Celastrus paniculatus Willd. C. paniculatus Willd is a woody climbing shrub and belongs to the family Celastraceae. The seeds in Ayurveda are used to treat a wide variety of ailments, particularly skin diseases, fever and neurological disorders. [15] The synthesized nanoparticles have been characterized and tested for their antimicrobial efficacy.

**MATERIALS AND METHODS**

**Materials**

Fresh *Celastrus paniculatus* Willd seeds were procured from the Sewa Aushadhi Bhandar, Indore, India. The samples were than authenticated for their correct botanical identity by scientist at Botanical Survey of India, Southern Regional Centre, Coimbatore with voucher specimen number BSI/SRC/5/23/2019/Tech./111. Reagents, solvents were purchased from Hi-Media, Mumbai and Double distilled ultrapure water was used throughout this research.

**Isolation and Screening of Phytoconstituents**

Five grams of freshly collected *C. paniculatus* seeds were transferred into an Erlenmeyer flask containing sterile distilled water (50 ml) and placed in a shaking BOD incubator with a rate of 100 rpm for 30 min at room temperature. The extract was sterilized by using an MF-Millipore Membrane Filter and stored at 4°C for further experimental work.

**HPTLC**

HPTLC analysis was performed using the CAMAG HPTLC system (Switzerland). Merck 60G F254 stationary-phase, aluminum-backed, pre-coated silica gel plates with 0.2 mm thickness were used. Samples were applied as bands 10 mm from the bottom of the plates using the CAMAG ATS 4. The plates were developed up to 80 mm in ascending mode at room temperature (28 ± 2°C) in a Twin Trough Chamber (CAMAG), which had been previously saturated with mobile-phase toluene-ethyl acetate. After development, the CAMAG TLC Scanner 3 scanned the air-dried plates using a deuterium lamp with win CATS software, resulting in measurements of 254 nm and 366 nm.

**Total Phenolic Content**

Phenolics were estimated by method given by Ainsworth and Gillespie [16] and the phenolic content was calculated as gallic acid equivalents (GAEs)/grams of extract. Briefly, the test sample (0.5 ml) was mixed with 1 ml of Folin and Ciocalteu’s phenol reagent, 2 ml of a 700 mM sodium carbonate solution was added and the reaction was kept in the dark for 90 min, after which the UV-visible spectrophotometer measured the absorbance to be 765 nm.

**Synthesis of Silver Nanoparticles**

Stable nanosilver were synthesized using an earlier method by Rajasekharreddy et al [17] using different concentrations (0.5 mM and 1 mM) of nanosilver. AgNO3 solutions with aqueous seed exudates were exposed to sunlight for 60 min, and the brown color resulting is confirmed the formation of silver nanoparticles.

**Nanosilver Characterization**

The synthesis of AgNPs was monitored by scanning the maximum absorption of the reacted mixture at the wavelength between 300 and 700 nm on the UV-visible spectrophotometer (UV-2600, Shimadzu). The solution in colloidal form was centrifuged at 14,000 rpm for 10 min at room temperature and the resultant pellet was washed with sterile distilled water and dried in a desiccator. The dried pellet underwent powder X-ray diffraction (PXRD) and optical properties of the nanosilver were studied using an FTIR spectrophotometer.
spectrophotometer (PerkinElmer) in the range of 450–4000 cm⁻¹. Surface-enhanced Raman spectroscopy (SERS) was also performed using the XploRA (Jobin Yvon, HORIBA) with a 785-nm laser to confirm the molecules were present to form the nanosilver. The morphology and crystalline nature of the particles were identified by transmission electron microscope (TEM) and selected-area electron diffraction (SAED) analysis. 5µl of sample was placed onto the copper grid coated with carbon, and a thin film of the sample was made on the grid. Extra sample was removed by keeping the sample under an incandescent light bulb.

**Bactericidal activity**

**Minimum Inhibitory Concentration (MIC)**

MIC assay was carried out using Elshikh et al. [18-19] 96-well microtiter plate method with minor modifications. In this study, two of the MTCC quality control strains, namely Gram-negative Escherichia coli (MTCC-405) and Gram-positive Bacillus subtilis (MTCC-736) purchased from MTCC Chandigarh, India. Bacteria were screened against the antibiotic streptomycin (bactericidal in action), and the MIC was examined by observing and recording color changes. Serial dilution (10–100µg/ml) of the silver nanoparticles representing different concentrations of the AgNPs were added to a growth medium (10⁶ CFU/ml) in the 96 well microtiter plate. After the samples were incubated for 16 h at 37°C, resazurin dye (0.010%) obtained from Hi-Media was serially added to all wells (10µl per well), and the combined mixture was incubated for another 2 h so that we could observe a color change from blue to pink (Mechanism 2). Samples that showed no color change scored above the MIC value. A positive control of serially diluted streptomycin (10–100µg/ml) and a negative control of DMSO were also both taken in wells.

**Bacterial susceptibility to nanosilver**

**Maintenance of tested cultures**

Overnight (O/N) grown cultures in Luria broth at 37°C with continuous agitation, Absorbance was set to 0.1, corresponding to 10⁸ CFU/ml at 600 nm.

**Bacterial susceptibility to nanosilver**

E. coli and B. subtilis susceptibility was examined to antibiotics in the presence of nanosilver, we suspended the O/N incubated cells in a 0.85% NaCl buffer and then added the nanosilver at the desired concentrations: 25, 50 and 100µg/ml. After a predetermined incubation period of 3 h at room temperature, an aliquot of the suspension was inoculated on nutrient agar plates, and the plates were incubated further at 37°C in order to determine the resulting variability based on colony formation on traditional agar plates after incubation for 12 h. Silver- and antibiotic-free plates that were incubated under the same conditions were used as controls.

**Biofilm inhibition effects of Nanosilver**

**Tube Method**

Tube method is a qualitative analysis for detection of biofilm form determined by Christensen et al. [20] Overnight (O/N) grown Klebsiella isolate was inoculated on culture plates, incubated for 24 h at 37°C. The isolates of which biofilm formed on the test tube were stained with 0.1% crystal violet for 1h, after planktonic cells are discharged by rinsing twice with phosphate-buffered saline (PBS). Then, crystal violet stained test tubes is rinsed twice with PBS to discharge stain. After air drying of the test tube process, occurrence of visible lines at the bottom of the test tube indicates biofilm production.

**Microplate Quantitative Assay**

Microplate quantitative assay is a quantitative method to determine biofilm production by microplate reader. Klebsiella inoculum was inoculated with different concentrations in the range of 25, 50, 75 and 100µg/ml of nanosilver and antibiotic streptomycin (control). Aliquots of 200µl of bacterial suspension are inoculated into 96 well flat-bottomed polystyrene microtiter plates (Tarsions). Microplates are incubated at 24 h at 37°C, then each well is stained by adding 25µl of crystal violet for 15 min. Planktonic cells in wells of the microplate are discharged by washing with 200µl PBS. The crystal violet absorbed by the biofilm was extracted later with two washes of 200µl ethyl alcohol and degree of biofilm formation was measured by taking the absorbance at 540 nm.

**Microscopic Observation**

Effect of nanosilver against biofilm formation by Klebsiella pneumoniae was examined by using light and a confocal laser scanning microscope (CLSM). Biofilm formation were allowed on 1 × 1 cm glass slides, which were placed into 24 well microtiter plates (in triplicate), incubated at 37°C for 24 h. The glass slides were washed with distilled water after being removed from incubation.

Cells bound to the glass slides were stained with 200µl of 0.1% (v/v) crystal violet for 15 min and viewed under a light microscope at 100x magnification and the image was documented by the digital camera attached to the microscope (Carl Zeiss, Jena, Germany). [21] Biofilms formed on the 1 × 1 cm glass slides were stained with 0.01% acridine orange (w/v) for 5 min, followed by a brief wash in distilled water. After air drying, the slides were observed under the CLSM (LSM 710, Carl Zeiss, Germany). The 488-nm Ar laser and 500–640 nm band emission filter were used to excite and detect the stained cells (Nithya et al. 2010). [22] Biofilms formed on the glass slides was fixed with 2.5% glutaraldehyde for 2 h at 4°C and washed with 0.1 M of a sodium acetate buffer (pH 7.3). Finally, the dehydrated samples were dried, gold sputtered and examined with the VEGA3 microscope (TESCAN). [21]

**Quantification of Exopolysaccharide (EPS)**

EPS was extracted from both treated and untreated pathogens and quantified by using Nithya et al. [22-23] Glass slides immersed in bacterial culture in 24 well polystyrene plates were used to estimate the extra poly saccharide formation. The glass slides were removed
and washed with 0.9% NaCl (0.5 ml) after incubation. An equal volume of concentrated H₂SO₄ were added to the cell suspension, incubated for 1 h in the dark and centrifuged at 10,000 rpm for 10 min. The absorbance of the supernatant was measured at 490 nm.

**Statistical Analysis**
All experiments were carried out independently at least six times. Bars representing standard deviation values with average of mean were created using SPSS software, and graphs were plotted using GraphPad Prism 6.1.

---

**RESULTS AND DISCUSSION**

**Phytochemical Screening**
Tannins, phenolics and alkaloids present in the seed exudates of *C. paniculatus* was analyzed using preliminary phytochemical analysis method (data not shown). For further identification, HPTLC separation of active constituents was done. Different mobile systems for TLC analysis were also tested (Fig. 1). Toluene-ethyl acetate (9:1 ratio) was identified as a suitable mobile phase and RF values were calculated. Recent reports by [2, 24-25] suggest that the reduction of silver ions (Ag⁺) to silver atoms (Ag⁰) in the presence of reducing agents is mediated by secondary metabolites and they also play a role of capping agents in the process of stabilizing nanoparticles. These results agree with previous reports [20], in which they clearly recognize that seed coat exudates are a key source of phenolics for the preparation of nanoparticles. Remarkably, in our research, as evidenced in Fig. 2, we observed that there is tremendous decrease in phenolics by the increase in the concentration of nanoparticles.

**Synthesis and Characterization of Silver Nanoparticles**
*C. paniculatus* seed coat exudate was mixed into 0 mM (without silver nitrate), 0.5 mM and 1-mM silver nitrate solutions and was incubated at room temperature for 1 h. The formation of nanoparticles is indicated by the change of colorless silver nitrate solution to brown (Fig. 3a). UV-Vis spectroscopy showed the excited surface plasmon resonance (SPR) band [27], with a maximum 420 nm indicating the existence of silver nanoparticles. Fig. 3b shows that increasing reaction time also increased the peak area this process was clearly observed up to 35 min. PXRD methods were used to evaluate the crystalline nature of the silver nanoparticles. The PXRD profile of the AgNPs, presented in Fig. 4a, exhibits characteristic peaks at scattering angles (2θ) of 37.87, 44.07, 64.26 and 77.12, corresponding with scattering from the (1 1 1), (2 0 0), (2 2 0) and (3 1 1) planes respectively [28]. These diffraction peaks represent a face-centered, cubic structure of crystalline silver nanoparticles. All the peaks in the XRD pattern can be indexed as standard Ag crystals, which shows the high purity of the synthesized crystalline silver nanoparticles (JCPDS card no. 89-3722).

FTIR analysis was summarized in Table 1 and Fig. 3c. An evaluation of these results in comparison with earlier reports by Poovizhi et al [29] indicates that phenolics, alkanes and carboxylic acids may be participating in the nanoparticle synthesis and stabilization. The SERS spectrum of nanosilver is shown in Fig. 4b, which identifies the active biomolecules of the extract involved in this process.

**Table 1: Spectral Positions of FTIR peaks.**

| Center (cm⁻¹) | Assignments                        |
|--------------|------------------------------------|
| 3431         | N-H stretching of 1º and 2º amines |
| 2924         | O-H stretching of nitro group      |
| 2850         | C-H stretching of alkanes          |
| 1561         | N-O stretching of nitro compounds  |
| 1401         | C-C for aromatics                  |

TEM measurements revealed the size and shape of the synthesized nanoparticles (Fig. 5). Their spherical shape was further defined by TEM images of the AgNPs.

Fig. 4: Characterization of Nano silver by using (a) XRD pattern of silver nanoparticles. (b) SERS spectra for silver nanoparticles.

Fig. 5: TEM, SAED patterns of nanoparticles (0.5 mM) of C. paniculatus Willd. seed exudates
The lattice fringes in processed TEM images show that the AgNPs are single crystals and also reveal that the particles have a latticed spacing of 2.37 Å in the (1 1 1) plane, matching the d-spacing in the (1 1 1) plane of Ag with a face-centered cubic shape (FCC). SAED of a single spherical particle also confirmed the monocrystalline nature of AgNPs (Fig. 5). Size-dependent histograms of seed exudate nanosilver showed spherical AgNPs with varying sizes between 20–50 nm, and the mean particle size was ~50 nm. However, the availability of phytochemicals and metal salt concentration defines the particles size. [11]

**Minimal Inhibitory Concentration**

Using available reports [18, 30-33] as a basis, our study set out to find the MIC value for selected Gram-negative *E. coli* (MTCC-405) and Gram-positive *B. subtilis* (MTCC-736) by adding resazurin dye, which shows blue in its oxidized state and pink in its reduced state. [30] Figure 6 shows 96-well plates labeled L₁ to L₅, in which different concentrations of nanosilver were applied in relation to the antibiotic. The presence of nanosilver shows that the MIC value is 40µg/ml for Gram-negative bacteria (L₁) and 60µg/ml for Gram-positive bacteria (L₂) (Fig. 6) being more effective than streptomycin.

**Bactericidal Kinetics in the Presence of Nanosilver**

The efficacy of nano-silver to combat bacteria growth is based on more than the known antibiotic concentration. Colony screening method was done using different concentrations (25, 50, 75 and 100µg/ml) of nanosilver for the gram-negative and gram-positive bacteria to evaluate the effect of nanosilver on their growth. The kinetics of bacterial growth on agar plates (initial bacterial concentration 10⁶ CFU/ml) with different concentrations was monitored. Figure 7 depicts the trend of a decreasing number of bacterial colonies with the increasing concentration of nanosilver. Upto 10-fold
reduction was observed with increase in nanosilver concentration. The effect was more in *E. coli* (gram negative bacteria). This may be due to greater penetration of the cell wall by the nanosilver; in gram-positive bacteria, the S-layer is attached to a thick peptidoglycan layer and teichoic acid, whereas in gram-negative bacteria, the S-layer is directly attached to the bacterial cell wall.

**Antibiofilm Activity of Nanosilver**

Biofilm infectious diseases account for 80% of microbial infections in the body [34] in which female urinary tract infections (UTIs) are one of the major recurrent and chronic infections caused by the formation of *Klebsiella* biofilm. [19, 35] For these reasons, we selected the *Klebsiella* strain to study their biofilm inhibition under different concentrations of silver nanoparticles. It is evident from our experiments that the biofilm ring formation decreased as the concentration of nanosilver increases (Fig. 8) where as in antibiotic-treated tubes, biofilm inhibition was relatively lower.

### Table 2: Kinetics of inhibition of *Klebsiella pneumoniae* biofilm by different concentrations of nano-silver and antibiotics.

| Concentration (µg/ml) | Untreated (µg/ml) | Nanosilver (µg/ml) | Streptomycin (µg/ml) |
|-----------------------|-------------------|--------------------|----------------------|
|                       | Absorbance (a.u.) | 0.35 ± 0.06        | 0.30 ± 0.00          | 0.23 ± 0.06          |
| 0                     | 0.96 ± 0.02       | 0.17 ± 0.02        | 0.50 ± 0.00          | 0.32 ± 0.02          |
| 25                    | 0.06              | 0.02               | 0.04                 | 0.03 ± 0.10          |
| 50                    | 0.06              |                    |                      |                     |
| 75                    | 0.06              |                    |                      |                     |
| 100                   | 0.06              |                    |                      |                     |

Values represent mean of data collected from three independent experiments. Mean values of triplicate independent expression of Mean ± SD are shown.

The growth kinetics of *Klebsiella* was assayed with different concentrations of nanosilver using a microplate assay developed by Maldonado et al. with small modifications, and the capability of nanosilver to inhibit the biofilm was studied by taking the OD at 540 nm. The results are summarized in Table 2. Recently Ahmed et al. reported clinically isolated *Klebsiella* biofilm inhibition by preventing early colonization, and our results correlate with these previous reports of Shakibaie et al. At this stage, we cannot explain the mechanism behind nanosilver’s ability to inhibit biofilm formation, but recently Beyth et al. explained that nanosilver may electrostatically interact with bacteria, causing membrane disruption and leading to the formation of more free radicles. Ultimately, this leads to protein destruction.

EPS synthesis plays a major role in creating a matrix to form biofilms. We performed EPS quantification to learn the effects of nanosilver treatment on biofilm formation. The results showed that EPS was reduced to one-fifth of the control (*P*<0.05) with an increase in concentration of nanosilver (0, 25, 50, 100µg/ml) (Fig. 9). Even though EPS is essential to the formation of biofilm, to date, very few studies are available on preventing EPS formation to reduce *Klebsiella* biofilm. Though our results are comparable to the previous study wherein essential oil from *C. tamala* and bacterial extracts from marine sources inhibit biofilm activity by reducing EPS formation, present results are different in the extent of EPS reduction. Figure 10 shows the results of a microscopic analysis, which confirmed that the maximum reduction of biofilm occurred when the nanosilver was at its highest concentration levels. CLSM was also performed to confirm the morphology and inhibition of biofilm in support of light microscopy data, and the inhibition of biofilms was evident in the treated samples when compared with the control (Fig. 11).

Due to its high magnification and resolution, SEM revealed that there is destruction in biofilm formation after treatment with nanosilver (Fig. 12). To the best of our knowledge, this is the first report on preformed biofilm inhibition of *Klebsiella*; earlier studies have merely reported that the prevention of EPS synthesis will stop biofilm formation in other genera. Based on the present results to further validate the effect of nano-particles and the use of seed exudates, it is recommended that additional studies be carried out with:

- More number of gram positive and gram-negative bacteria
- Seed coat exudates from other plant sources
- Nanoparticles other than silver.
ACKNOWLEDGEMENTS

Author is grateful to the CSIR for providing CSIR Senior Research Fellowship (09/475(0201)/2018-EMR-I) and the support is duly acknowledged. We also thank Dr. D. Saravanan, Coordinator and application specialist Ms. Kavitha, National College Instrumentation Facility (NCIF) for helping in SEM analysis and also, we grateful to the CLSM facility provided by the DST-PURSE scheme [SR/FT/LS-113/2009] to Bharathidasan University.
