Optimally approximating exponential families

Johannes Rauh

October 27, 2011

This article studies exponential families $\mathcal{E}$ on finite sets such that the information divergence $D(P\|\mathcal{E})$ of an arbitrary probability distribution from $\mathcal{E}$ is bounded by some constant $D > 0$. A particular class of low-dimensional exponential families that have low values of $D$ can be obtained from partitions of the state space. The main results concern optimality properties of these partition exponential families. Exponential families where $D = \log(2)$ are studied in detail. This case is special, because if $D < \log(2)$, then $\mathcal{E}$ contains all probability measures with full support.

1 Introduction

Let $\mathcal{X}$ be a finite set of cardinality $N$, and denote by $\mathbf{P}(\mathcal{X})$ the set of probability distributions on $\mathcal{X}$. The information divergence $D(P\|Q)$ is a natural distance measure on $\mathbf{P}(\mathcal{X})$. For any exponential family $\mathcal{E}$ on $\mathcal{X}$ (as defined in Section 2) and any $P \in \mathbf{P}(\mathcal{X})$ write $D_\mathcal{E}(P) = \inf_{Q \in \mathcal{E}} D(P\|Q)$. This article discusses the following question:

- Let $D > 0$, and choose a partial order on the exponential families. Which exponential families are minimal among all exponential families $\mathcal{E}$ satisfying $\max D_\mathcal{E} \leq D$? What is the answer to this question under further constraints on $\mathcal{E}$?

This question is related to finding the maximizers of the information divergence from an exponential family, a problem which was first formulated by Nihat Ay in [1]. See [14] for an overview and further references. The present work builds on recent progress in [15] and [12].

There are at least two partial orders of interest:

(i) The partial order induced by the dimensions of the exponential families.

(ii) The partial order by inclusion.
The partial order \((i)\) is particularly important for applications, since the dimension of an exponential family is one of the most important invariants that determine the complexity of all computations. The partial order \((ii)\) can be seen as a “local relaxation”: A candidate exponential family \(\mathcal{E}\) is only compared to “similar” exponential families, contained in \(\mathcal{E}\).

**Definition 1.** Let \(\mathcal{H}\) be a set of exponential families. An exponential family \(\mathcal{E} \in \mathcal{H}\) is called inclusion \(D\)-optimal among \(\mathcal{H}\) for some \(D \geq \max D_{\mathcal{E}}\) if every \(\mathcal{E}' \in \mathcal{H}\) strictly contained in \(\mathcal{E}\) satisfies \(\max D_{\mathcal{E}} \leq D < \max D_{\mathcal{E}'}\). An exponential family \(\mathcal{E} \in \mathcal{H}\) is called dimension \(D\)-optimal among \(\mathcal{H}\) if every exponential family \(\mathcal{E}' \in \mathcal{H}\) of smaller dimension satisfies \(\max D_{\mathcal{E}} \leq D < \max D_{\mathcal{E}'}\). Exponential families that are inclusion or dimension \(D\)-optimal among \(\mathcal{H}\) for some \(D\) are also called inclusion or dimension optimal among \(\mathcal{H}\), without reference to \(D\). If \(\mathcal{H}\) equals the set of all exponential families, then the reference to \(\mathcal{H}\) may be omitted in all definitions. Let

\[
D_{N,k}(\mathcal{H}) = \min \{ \max D_{\mathcal{E}} : \mathcal{E} \in \mathcal{H} \text{ is an exponential family of dimension } k \text{ on } [N] \}.
\]

As an example, the set \(\mathcal{H}\) may be the set of hierarchical models, the set of graphical models or the set \(\mathcal{H}_1\) of exponential families containing the uniform distribution. Obviously, any dimension optimal model is also inclusion optimal. The converse statement does not hold, see Example 27 below.

A \(D\)-optimal exponential family \(\mathcal{E}\) can approximate arbitrary probability measures well, up to a maximal divergence of \(D\). Yaroslav Bulatov proposed to use such exponential families in machine learning (personal communication), for example when using the minimax algorithm [17] by Zhu, Wu and Mumford or the feature induction algorithm [5] by Della Pietra, Della Pietra and Lafferty. Both algorithms inductively construct an exponential family by adding functions (“features”) to the tangent space in order to approximate a given distribution. Applications of the results of the present paper to machine learning will not be discussed in here, but in a future work.

One motivation to restrict the class \(\mathcal{H}\) of exponential families is that the learning system may not be able to represent arbitrary exponential families. Another motivation is given by Jaynes’ principle of maximum entropy [8], which suggests to use the class \(\mathcal{H}_1\) of exponential families with uniform reference measure.

This paper also introduces the class of partition models (see Section 3): A probability measure \(P\) belongs to the partition model associated to a partition \(\mathcal{X}' = (\mathcal{X}'_1, \ldots, \mathcal{X}'_N)\) if the restriction of \(P\) to each block \(\mathcal{X}'_i\) is uniform. Conjecture 29 relates partition models to the above question:

**Conjecture 29.** \(D_{N,k} = \log \lceil \frac{N}{k+1} \rceil\), and the dimension \(D_{N,k}\)-optimal exponential families containing the uniform distribution are partition models.

The results in Section 4 show that the conjecture is true if \(\lceil \frac{N}{k+1} \rceil \leq 2\), and Theorem 28 proves the conjecture if \(k + 1\) divides \(N\).

This paper is organized as follows: Section 2 collects the necessary preliminaries about exponential families and the information divergence. Section 3 introduces partition
models and studies their basic properties. \( \log(2) \)-optimal exponential families \( \mathcal{E} \) are studied in Section 4. Section 5 presents results on \( D \)-optimal exponential families for arbitrary \( D \).

2 Preliminaries

This section collects known facts that are needed in later sections. It starts with some notions from matroid theory before defining exponential families, the information divergence and hierarchical models. The last part discusses the function \( \overline{D}_\mathcal{E} \), which arises naturally when studying the maximizers of \( D_\mathcal{E} \).

2.1 Circuits

This section recalls some elementary notions from the theory of matroids. Only representable matroids will play a role, but nevertheless the language of abstract matroids is useful. See [13] for an introduction.

**Definition 2.** Let \( \mathcal{N} \) be a linear subspace of \( \mathbb{R}^X \). The support of \( u \in \mathcal{N} \) is defined as \( \text{supp}(u) := \{ x \in X : u(x) \neq 0 \} \). A vector \( v \in \mathcal{N} \setminus \{0\} \) is called a circuit vector if and only if for any \( u \in \mathcal{N} \) satisfying \( \text{supp}(u) \subseteq \text{supp}(v) \) there exists \( \alpha \in \mathbb{R} \) such that \( u = \alpha v \).

In other words, circuit vectors are vectors with minimal support. The support \( \text{supp}(u) \) of a circuit vector \( u \) is called a circuit. A finite set \( \mathcal{C} \subseteq \mathcal{N} \) is a circuit basis if and only if the map \( u \in \mathcal{C} \mapsto \text{supp}(u) \) is injective and maps onto the set of circuits.

**Lemma 3.** For every nonzero vector \( u \in \mathcal{N} \) and any \( x \in X \) such that \( u(x) \neq 0 \) there exists a circuit vector \( c \in \mathcal{N} \) such that \( \text{supp}(c) \subseteq \text{supp}(u) \) and \( c(x) \neq 0 \).

**Proof.** Let \( c \) be a vector with inclusion-minimal support that satisfies \( \text{supp}(c) \subseteq \text{supp}(u) \) and \( c(x) \neq 0 \). If \( c \) is not a circuit vector, then there exists a circuit vector \( c' \) with \( \text{supp}(c') \subset \text{supp}(c) \). A suitable linear combination \( c + \alpha c' \) gives a contradiction to the minimality of \( c \).

It follows that any circuit basis of \( \mathcal{N} \) contains a spanning set.

2.2 Exponential families and the information divergence

In this work only exponential families on a finite set \( X \) are studied, for the information divergence from a finite-dimensional exponential family on an infinite set is usually unbounded, cf. Theorem 28. See [2] and [3] for an introduction to exponential families and the information divergence.

Let \( \mathcal{F} \) be a linear subspace of \( \mathbb{R}^X \) containing the constant function, and let \( \nu \) be a strictly positive measure on \( X \). The set \( \mathcal{E} = \mathcal{E}_{\nu, \mathcal{F}} \) of all probability measures on \( X \) of the form

\[
P_\vartheta(x) = \frac{\nu(x)}{Z_\vartheta} e^{\vartheta(x)}
\]  

(1)
is called an exponential family. ν is a reference measure, and \( \hat{T} \) will be called the extended tangent space of \( \mathcal{E} \). The extended tangent space carries its name since its image modulo the constant functions is isomorphic to the tangent space of the manifold \( \mathcal{E} \) at any point. The orthogonal complement \( \mathcal{N} := \hat{T}^\perp \) will be called the normal space of \( \mathcal{E} \). The normal space is orthogonal to the tangent space of \( \mathcal{E} \) at any point \( P \in \mathcal{E} \) with respect to the Fisher metric at \( P \). The topological closure of \( \mathcal{E} \) will be denoted by \( \overline{\mathcal{E}} \).

The exponential family \( \mathcal{E}_\nu, \hat{T} \) can be parametrized as follows: If \( a_1, \ldots, a_h \in \mathbb{R}^X \) form a spanning set of \( \hat{T} \), then \( \mathcal{E} \) consists of all probability distributions of the form

\[
P_\theta(x) = \frac{\nu(x)}{Z_\theta} \exp \left( \sum_{i=1}^h \theta_i a_i(x) \right).
\]

In this formula \( \theta \in \mathbb{R}^h \) is a vector of parameters and \( Z_\theta \) ensures normalization. The matrix \( A = (a_i(x))_{i,x} \in \mathbb{R}^{h \times X} \) is called a sufficient statistics of \( \mathcal{E} \). The linear map corresponding to \( A \) is called the moment map, denoted by \( \pi_A \). The columns of \( A \) will be denoted by \( A_x \), \( x \in X \). The normal space of \( \mathcal{E} \) equals \( N = \{ u \in \ker A : \sum_x u(x) = 0 \} \).

The convex hull of \( \{ A_x : x \in X \} \) is a polytope called the convex support \( M_A \) of \( \mathcal{E} \). This polytope is independent of the choice of \( A \) up to an affine transformation.

Any function \( u \in \mathbb{R}^X \) can be decomposed uniquely as a difference \( u = u^+ - u^- \) of non-negative functions such that \( \text{supp}(u^+) \cap \text{supp}(u^-) = \emptyset \). The following implicit description of an exponential family is useful in many contexts.

**Theorem 4.** Let \( \mathcal{E} \) be an exponential family with normal space \( \mathcal{N} \) and reference measure \( \nu \), and let \( C \) be a circuit basis of \( \mathcal{N} \). A probability measure \( P \) on \( X \) belongs to \( \mathcal{E} \) if and only if \( P \) satisfies

\[
\prod_{x \in X} \left( \frac{P(x)}{\nu(x)} \right)^{u^+(x)} = \prod_{x \in X} \left( \frac{P(x)}{\nu(x)} \right)^{u^-(x)}, \quad \text{for all } u^+ - u^- \in C.
\]

**Proof.** See [16, Theorem 10].

Let \( \mathcal{E}_1, \ldots, \mathcal{E}_c \subseteq P(X) \). The mixture of \( \mathcal{E}_1, \ldots, \mathcal{E}_c \) is the set of probability measures

\[
\left\{ P = \sum_{i=1}^c \lambda_i P_i : P_i \in \mathcal{E}_1, \ldots, P_c \in \mathcal{E}_c \text{ and } \lambda \in \mathbb{R}_+^c, \sum_{i=1}^c \lambda_i = 1 \right\}.
\]

**Corollary 5.** Let \( \mathcal{E} \) be an exponential family with normal space \( \mathcal{N} \). Let \( \mathcal{Y} \subseteq X \). If every circuit vector \( c \in \mathcal{N} \) satisfies \( \text{supp}(c) \subseteq \mathcal{Y} \) or \( \text{supp}(c) \subseteq X \setminus \mathcal{Y} \), then \( \overline{\mathcal{E}} \) equals the mixture of \( \overline{\mathcal{E}} \cap P(\mathcal{Y}) \) and \( \overline{\mathcal{E}} \cap P(X \setminus \mathcal{Y}) \).

**Proof.** For any probability measure \( P \) and subset \( \mathcal{Y} \subseteq X \) define the truncation \( P^\mathcal{Y} \) as follows: If \( P(\mathcal{Y}) > 0 \), then

\[
P^\mathcal{Y}(x) = \begin{cases} \frac{1}{P(\mathcal{Y})} P(x), & \text{if } x \in \mathcal{Y}, \\ 0, & \text{else}; \end{cases}
\]
can also be characterized as the unique probability measure 
\( P \) particular, if \( N \) measure 

For any family \( \Delta \) of subsets of \( \mathcal{X} \), let 

The corollary can be reformulated as follows, using terminology from matroid theory: If \( \mathcal{X}_1, \ldots, \mathcal{X}_n \) are the connected components of the matroid of \( \mathcal{N} \), then \( \mathcal{E} \) equals the mixture of \( \mathcal{E}_1, \ldots, \mathcal{E}_c \), where \( \mathcal{E}_i = \mathcal{E} \cap \mathcal{P}(\mathcal{X}_i)^\circ \) is an exponential family on \( \mathcal{X}_i \) for \( i = 1, \ldots, c \).

The information divergence (also known as the Kullback-Leibler divergence or relative entropy) of positive measures \( P, Q \) is defined as

\[
D(P\|Q) = \sum_{x \in \mathcal{X}} P(x) \log \left( \frac{P(x)}{Q(x)} \right),
\]

with the convention that \( 0 \log 0 = 0 \log(0/0) = 0 \). It is finite unless \( \text{supp}(P) \) is not contained in \( \text{supp}(Q) \). If \( \nu \) equals the counting measure on \( \mathcal{X} \) (i.e. \( \nu_x = 1 \) for all \( x \)), then \( D(P\|\nu) \) equals minus the Shannon entropy \( H(P) \). If \( P \) and \( Q \) are probability measures, then \( D(P\|Q) \) is strictly positive unless \( P = Q \).

Let \( \mathcal{E} \) be an exponential family. For any probability measure \( P \) on \( \mathcal{X} \) there is a unique probability distribution \( P_{\mathcal{E}} \) such that \( D(P\|P_{\mathcal{E}}) = \inf_{Q \in \mathcal{E}} D(P\|Q) \), see [H]. The measure \( P_{\mathcal{E}} \) is called the (generalized) rI-projection of \( P \) to \( \mathcal{E} \) or the (generalized) MLE. It can also be characterized as the unique probability measure \( P_{\mathcal{E}} \) such that \( P - P_{\mathcal{E}} \in \mathcal{N} \). Alternatively, \( P_{\mathcal{E}} \) minimizes the function \( D(Q\|\nu) \) on \( \{ Q \in \mathcal{P}(\mathcal{X}) : P - Q \in \mathcal{N} \} \). In particular, if \( \nu \) is the counting measure, then \( P_{\mathcal{E}} \) maximizes the entropy.

### 2.3 Hierarchical loglinear models

Let \( \mathcal{X}_1, \ldots, \mathcal{X}_n \) be finite sets of cardinality \( |\mathcal{X}_i| = N_i \), and let \( \mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_n \). For any subset \( S \subseteq [n] \) let \( \mathcal{X}_S = \times_{i \in S} \mathcal{X}_i \). The restrictions \( X_i : \mathcal{X} \to \mathcal{X}_i \) to the subsystems can be viewed as random variables, and hierarchical models can be used to study the relationship of these discrete random variables. This section summarizes the main facts which are needed in the following. See [10] and [6] for further information.

**Definition 6.** For any family \( \Delta \) of subsets of \([n]\) let \( \mathcal{E}_\Delta^\circ \) be the set of all probability measures \( P \in \mathcal{P}(\mathcal{X})^\circ \) that can be written in the form

\[
P(x) = \prod_{S \in \Delta} f_S(x),
\]

where each \( f_S \) is a non-negative function on \( \mathcal{X} \) that depends only on those components of \( x \) lying in \( S \). In other words, \( f_S(x) = f_S(y) \) for all \( x = (x_i)_{i=1}^n, y = (y_i)_{i=1}^n \in \mathcal{X} \) satisfying \( x_i = y_i \) for all \( i \in S \). The hierarchical exponential family \( \mathcal{E}_\Delta \) of \( \Delta \) with parameters \( N_1, N_2, \ldots, N_n \) is defined as \( \mathcal{E}_\Delta^\circ \cap \mathcal{P}(\mathcal{X})^\circ \). The closure of \( \mathcal{E}_\Delta \) (which equals the closure of \( \mathcal{E}_\Delta^\circ \)) is called the hierarchical model of \( \Delta \) with parameters \( N_1, N_2, \ldots, N_n \).
At first sight one might think that $\mathcal{E}_{\Delta}' = \mathcal{E}_{\Delta}$. Unfortunately, this is not true, see [7]. For certain applications, when the factorizability probability is important, one might want to call $\mathcal{E}_{\Delta}'$ a hierarchical model. When studying optimization problems it is more important that the models are closed.

For any $S \subseteq \{1, \ldots, n\}$ the subset of $\mathbb{R}^{\mathcal{X}}$ of functions that only depend on the $S$-components can be naturally identified with $\mathbb{R}^{\mathcal{X}_S}$. The projection $\mathcal{X} \to \mathcal{X}_S$ induces a natural injection $\mathbb{R}^{\mathcal{X}} \to \mathbb{R}^{\mathcal{X}_S}$.

It is easy to see that hierarchical exponential families are indeed exponential families: Namely, (5) implies that $\mathcal{E}_{\Delta}$ consists of all $P \in \mathcal{P}(\mathcal{X})^\circ$ that satisfy

$$(\log(P(x)))_{x \in \mathcal{X}} \in \sum_{S \in \Delta} \mathbb{R}^{\mathcal{X}_S} \subseteq \mathbb{R}^{\mathcal{X}}.$$ 

Therefore, $\mathcal{E}_{\Delta}$ is an exponential family with uniform reference measure and extended tangent space $\bar{T} = \sum_{S \in \Delta} \mathbb{R}^{\mathcal{X}_S}$. This vector space sum is not direct, since every summand contains $\mathbf{1}$. There is a natural sufficient statistics: The marginalization maps $\pi_S : \mathbb{R}^{\mathcal{X}} \mapsto \mathbb{R}^{\mathcal{X}_S}$ defined for $S \subseteq \{1, \ldots, n\}$ via

$$\pi_S(v)(x) = \sum_{y \in \mathcal{X}: y_i = x_i \text{ for all } i \in S} v(y)$$

induce the moment map

$$\pi_{\Delta} : v \in \mathbb{R}^{\mathcal{X}} \mapsto (\pi_S(v))_{S \in \Delta} \in \bigoplus_{S \in \Delta} \mathbb{R}^{\mathcal{X}_S},$$

where $\oplus$ denotes the (external) direct sum of vector spaces.

**Lemma 7.** Let $\Delta$ be a collection of subsets of $[n]$, and let $K = \cup_{J \in \Delta} J$. The marginal polytope of $\Delta$ is (affinely equivalent to) a 0-1-polytope with $\prod_{i \in K} N_i$ vertices.

**Proof.** The moment map $\pi_{\Delta}$ corresponds to a sufficient statistics $A_{\Delta}$ that only has entries 0 and 1, so $\mathcal{M}_{A_{\Delta}}$ is a 0-1-polytope. The set of vertices of $\mathcal{M}_{A_{\Delta}}$ is a subset of $\{A_x : x \in \mathcal{X}\}$. Let $x = (x_i)_{i=1}^n$, $y = (y_i)_{i=1}^n \in \mathcal{X}$. If $x_i = y_i$ for all $i \in K$, then $A_x = A_y$, so $\mathcal{M}_{A_{\Delta}}$ has at most $\prod_{i \in K} N_i$ vertices. If $x_i \neq y_i$ for some $i \in K$, then $A_x \neq A_y$, so the set $\{A_x : x \in \mathcal{X}\}$ has cardinality $\prod_{i \in K} N_i$. Since this set consists of 0-1-vectors and since no 0-1-vector is a convex combination of other 0-1-vectors, it follows that the set of vertices of $\mathcal{M}_{A_{\Delta}}$ equals $\{A_x : x \in \mathcal{X}\}$ and has cardinality $\prod_{i \in K} N_i$. \hfill $\Box$

### 2.4 The function $\overline{D}_\mathcal{E}$

The function $\overline{D}_\mathcal{E}$ is related to the function

$${\overline{D}_\mathcal{E}(u)} = \sum_{x \in \mathcal{X}} u(x) \log \frac{|u(x)|}{\nu_x}$$

defined on $\mathcal{N}$ [13]. The function $\overline{D}_\mathcal{E}$ satisfies $\overline{D}_\mathcal{E}(\alpha u) = \alpha \overline{D}_\mathcal{E}$ for all $\alpha \in \mathbb{R}$ and $u \in \mathcal{N}$. It will mostly be considered on a subset $\partial \mathcal{U}_\mathcal{N}$ of $\mathcal{N}$, defined as follows:
Definition 8. For any $v \in \mathbb{R}^X$ and $Z \subseteq X$ write $v(Z) := \sum_{x \in Z} v(x)$. Let
\[ \partial U_N := \{ u \in N : u^+(X) = u^-(X) = 1 \}. \]
The map $\Psi^+ : u \mapsto u^+$ maps $\partial U_N$ to a subset of $P(X)$. A probability distribution in the image of $\Psi^+$ is called a kernel distribution.

In the other direction there is the natural map $\Psi_E : P(X) \setminus \mathcal{E} \to N$, defined via
\[ \Psi_E(P) = \frac{P - P_E}{(P - P_E)^+(X)}. \]
The denominator makes sure that the image of $\Psi_E$ lies in $\partial U_N$. Since $P = P_E$ if and only if $P \in \mathcal{E}$, the map is well-defined on $P(X) \setminus \mathcal{E}$.

Theorem 9. Let $\mathcal{E}$ be an exponential family with normal space $N \neq 0$. The map $\Psi_E$ restricts to a bijection from the set of local maximizers of $D_E$ to the set of local maximizers of $\overline{D}_E$. An inverse is given by the restriction of the map $\Psi^+ : u \mapsto u^+$ If $P \in P(X)$ and $u \in \partial U_N$ are local maximizers of $D_E$ and $\overline{D}_E$, respectively, then
\[ D_E(P) = \log(1 + \exp(\overline{D}_E(\Psi_E(P)))) \text{ and } D_E(u^+) = \log(1 + \exp(\overline{D}_E(u))). \]
Proof. See [12, Theorem 1].

See [12] and [14] for further relations between the functions $D_E$ and $\overline{D}_E$.

Corollary 10. Let $\mathcal{E}$ be an exponential family. If $\mathcal{E} \neq P(X)$, then $\max D_E \geq \log(2)$.
Proof. Let $u \in \partial U_N$ be a global maximizer of $\overline{D}_E$. Since $\overline{D}_E(-u) = -\overline{D}_E(u)$ the maximal value $\overline{D}_E(u)$ is non-negative. Hence $D_E(u^+) = \log(1 + \exp(\overline{D}_E(u))) \geq \log(2)$.

It is straightforward to compute the first-order criticality conditions of $\overline{D}_E$:

Proposition 11. Let $\mathcal{E}$ be an exponential family with normal space $N$, let $u \in \partial U_N$ be a local maximizer of $\overline{D}_E$, and let $Y = \text{supp}(u)$. The following statements hold:

(i) $v(Y) = 0$ for all $v \in N$.

(ii) Let $P_E$ be the $rI$-projection of $u^+$ and $u^-$, and let $v \in N$. Then
\[ \sum_{x \in X \setminus Y} v(x) \log \frac{|v(x)|}{v_x} \leq v^+(Z')D_E(v_0). \quad (6) \]
Proof. See [12] or [14, Proposition 3.21].
3 Partition models

Partition exponential families are convex exponential families. The information divergence from convex exponential families has been studied in [11]. Apart from this, partition exponential families do not seem to have been studied before, despite their peculiar properties. In other contexts the name “partition model” is used for other mathematical objects, but there seems to be little danger of confusion.

**Definition 12.** A partition $\mathcal{X}'$ of $\mathcal{X}$ is a family $\mathcal{X}' = \{\mathcal{X}_1, \mathcal{X}_2, \ldots, \mathcal{X}_{N'}\}$ of nonempty subsets $\mathcal{X}_i \subset \mathcal{X}$ such that $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2 \cup \cdots \cup \mathcal{X}_{N'}$ and $\mathcal{X}_i \cap \mathcal{X}_j = \emptyset$ for all $1 \leq i < j \leq N'$. The subsets $\mathcal{X}_i \subseteq \mathcal{X}$ are called the blocks of the partition $\mathcal{X}'$. For any $x \in \mathcal{X}$ the block $\mathcal{X}_x$ containing $x$ is denoted $\mathcal{X}_x$.

The coarseness $c(\mathcal{X}')$ of a partition $\mathcal{X}'$ is the cardinality of the largest block of $\mathcal{X}'$. A partition $\mathcal{X}'$ is called homogeneous if all blocks of $\mathcal{X}'$ have the same cardinality $c(\mathcal{X}')$.

Partitions are in bijection with equivalence relations, the blocks of a partition corresponding to the equivalence classes. The equivalence relation induced by the partition $\mathcal{X}'$ is denoted $\sim_{\mathcal{X}'}$. In other words $x, y \in \mathcal{X}$ satisfy $x \sim_{\mathcal{X}'} y$ if and only if $x$ and $y$ lie in the same block of $\mathcal{X}'$.

**Definition 13.** Let $\mathcal{X}'$ be a partition of $\mathcal{X}$. Denote $\mathbb{R}^{\mathcal{X}'}$ the set of functions $\vartheta : \mathcal{X} \to \mathbb{R}$ such that $x \sim_{\mathcal{X}'} y$ implies $\vartheta(x) = \vartheta(y)$. The exponential family $\mathcal{E}_{\mathcal{X}'}$ with uniform reference measure and extended tangent space $\mathbb{R}^{\mathcal{X}'}$ is called the partition exponential family of $\mathcal{X}'$, and $\overline{\mathcal{E}_{\mathcal{X}'}}$ is the partition model of $\mathcal{X}'$.

Partition models are, in fact, also linear families: $\overline{\mathcal{E}_{\mathcal{X}'}}$ equals the intersection of $\mathcal{P}(\mathcal{X})$ with the linear space $\mathbb{R}^{\mathcal{X}'}$. In particular, partition exponential families are convex exponential families. Convex exponential families have been studied by Ay and Matúš in [11], which contains more detailed arguments for the following calculations. It follows from [11, Proposition 1] that a convex exponential family is a partition exponential family if and only if it contains the uniform distribution.

**Remark 14.** Partition models can be used to model symmetries. This was first noted by Juríček, who used this idea to compute the global maximizers of $D_2$ for the multinomial models [9]. If a symmetry group $G$ acts on $\mathcal{X}$, then it induces a partition $\mathcal{X}^G$ of $\mathcal{X}$ into orbits $\mathcal{X}_1, \ldots, \mathcal{X}_{N'}$. The action of $G$ extends naturally to an action on $\mathbb{R}^\mathcal{X}$. Any exponential family that consists of $G$-invariant probability measures is a subfamily of $\mathcal{E}_{\mathcal{X}^G}$ (such exponential families are called $G$-exchangeable in [9]). Conversely, an arbitrary partition model $\overline{\mathcal{E}_{\mathcal{X}'}}$ arises in this way from the group of all permutations $g$ of $\mathcal{X}$ such that $g(\mathcal{X}') = \mathcal{X}'$ for all $\mathcal{X}' \in \mathcal{X}'$.

**Lemma 15.** An exponential family with uniform reference measure and sufficient statistics $A \in \mathbb{R}^{h \times \mathcal{X}}$ is a partition exponential family if and only if its convex support is a simplex with vertex set $\{A_x : x \in \mathcal{X}\}$.

**Proof.** A sufficient statistics of $\mathcal{E}_{\mathcal{X}'}$ is given by the characteristic functions $a_i = 1_{\mathcal{X}_i}$ of the blocks of $\mathcal{X}'$. Any column of $A = (a_i(x))_{i,x}$ is a unit vector, and therefore the convex support is a simplex.
In the other direction define an equivalence relation \( \sim \) on \( \mathcal{X} \) via \( x \sim y \) if and only if \( A_x = A_y \). Then \( \mathcal{E} \) agrees with the partition exponential family of this equivalence relation.

For partition models the mapping \( P \mapsto P_\mathcal{E} \) is easy to compute: The equation \( AP = AP_\mathcal{E} \) translates into \( P(\mathcal{X}^i) = P_\mathcal{E}(\mathcal{X}^i) \) for \( i = 1, \ldots, N' \). Therefore,

\[
P_\mathcal{E}(x) = P_\mathcal{E}^{\mathcal{X}^x}(x)P(\mathcal{X}^x), \quad \text{for all } x \in \mathcal{X},
\]

where \( P_\mathcal{E}^{\mathcal{X}^x} \) denotes the truncation of \( P_\mathcal{E} \) to \( \mathcal{X}^x \). Since \( P_\mathcal{E} \) maximizes the entropy subject to (7), it follows that \( P_\mathcal{E}^{\mathcal{X}^x} = \frac{1}{|\mathcal{X}^x|}1_{\mathcal{X}^x} \) is the uniform distribution on \( \mathcal{X}^x \). Hence the \( ri \)-projection map \( P \mapsto P_\mathcal{E} \) averages over the blocks of the partition. It follows that

\[
D_\mathcal{E}(P) = \sum_{i=1}^{N'} P(\mathcal{X}^i)D(P^{\mathcal{X}^i}||\frac{1}{|\mathcal{X}^i|}1_{\mathcal{X}^i}) = \sum_{i=1}^{N'} P(\mathcal{X}^i) \left( \log |\mathcal{X}^i| - H(P^{\mathcal{X}^i}) \right).
\]

As a consequence:

**Lemma 16.** If \( \mathcal{E} \) is a partition model of a partition \( \mathcal{X}^1, \ldots, \mathcal{X}^{N'} \) of coarseness \( c \), then \( \max D_\mathcal{E} = \log(c) \). A probability measure \( P \in \mathcal{P}(\mathcal{X}) \) maximizes \( D_\mathcal{E} \) if and only if the following two conditions are satisfied:

(i) \( P(\mathcal{X}^i) > 0 \) only if \( |\mathcal{X}^i| = c \).

(ii) \( P^{\mathcal{X}^i} \) is a point measure for all \( i \) such that \( |\mathcal{X}^i| = c \) and \( P(\mathcal{X}^i) > 0 \).

**Corollary 17.** Let \( \mathcal{E} \) be the partition model of a partition \( \mathcal{X}' \) of coarseness \( c \), and let \( Z \) be the union of the blocks of \( \mathcal{X}' \) of cardinality \( c \). Then any \( Q \in \mathcal{E} \) with support contained in \( Z \) is the \( ri \)-projection of some global maximizer of \( D_\mathcal{E} \). In particular, if \( \mathcal{X}' \) is homogeneous, then any \( Q \in \mathcal{E} \) is the \( ri \)-projection of some global maximizer of \( D_\mathcal{E} \).

**Proof.** For any \( \mathcal{X}^i \in \mathcal{X}' \) of cardinality \( c \) choose a representative \( x_i \in \mathcal{X}^i \). Define \( P \in \mathcal{P}(\mathcal{X}) \) by \( P(\mathcal{X}^i) = Q(\mathcal{X}^i) \) and \( P^{\mathcal{X}^i} = \delta_{x_i} \), for all \( i \) such that \( |\mathcal{X}^i| = c \). Then \( P_\mathcal{E} = Q \), so the statement follows from Lemma 16.

**Remark 18.** Composite systems have natural homogeneous partitions, which lead to hierarchical models as defined in Section 2. Suppose that \( \mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_n \) and let \( K \subseteq \{1, \ldots, n\} \). Then \( K \) induces an equivalence \( \sim_K \) on \( \mathcal{X} \) via \( x \sim_K y \) if and only if \( x_i = y_i \) for all \( i \in K \). The equivalence classes of \( \sim_K \) form a homogeneous partition \( \mathcal{X}^K \) of \( \mathcal{X} \) of coarseness \( \prod_{i \in K} N_i \). The corresponding partition model \( \mathcal{E}_K \) consists of those probability distributions \( P \) satisfying \( P(x) = P(y) \) whenever \( x \sim_K y \). Therefore, \( \mathcal{E}_K \) equals the hierarchical exponential family \( \mathcal{E}_{\{K\}} \). Conversely, any homogeneous partition \( \mathcal{X}' \) can be used to find a bijection of \( \mathcal{X} \) with a composite system \( \mathcal{X}_1 \times \mathcal{X}_2 \), where \( \mathcal{X}_1 = \mathcal{X}' \) and \( \mathcal{X}_2 \in \mathcal{X}' \). Then the partition \( \mathcal{X}' \) arises from \( \sim_K \), where \( K = \{1\} \).
4 Exponential families with \( \max D_\mathcal{E} = \log(2) \)

By Corollary 10 the maximal value of \( D_\mathcal{E} \) is at least \( \log(2) \) unless \( \mathcal{E} = \mathcal{P}(X) \). This section studies exponential families \( \mathcal{E} \) where \( \max D_\mathcal{E} = \log(2) \). For such an exponential family, any kernel distribution is a local maximizer of \( D_\mathcal{E} \). Furthermore, \( D_\mathcal{E}(u) = 0 \) for all \( u \in \mathcal{N} \) (even if \( u \notin \partial U_\mathcal{N} \)). The main results are:

**Theorem 19.** Let \( \mathcal{E} \) be an exponential family on a finite set \( X \) of cardinality \( N \). If \( \max D_\mathcal{E} = \log(2) \), then the dimension of \( \mathcal{E} \) is at least \( \left\lceil \frac{N}{2} \right\rceil - 1 \).

**Theorem 20.** Let \( X \) be a finite set of cardinality \( N \), and let \( \mathcal{E} \) be an exponential family on \( X \) of dimension \( \left\lceil \frac{N}{2} \right\rceil - 1 \) satisfying \( \max D_\mathcal{E} = \log(2) \). If \( N \) is even, then \( \mathcal{E} \) is a partition model. If \( N \) is odd, then there is a set \( Z \subseteq X \) of cardinality three, a partition model \( \mathcal{E}_{X \backslash Z} \) on \( X \backslash Z \) and a one-dimensional exponential family \( \mathcal{E}_Z \) on \( Z \) such that \( \max D(\cdot \| \mathcal{E}_{X \backslash Z}) = \log(2) = \max D(\cdot \| \mathcal{E}_Z) \), and the closure \( \overline{\mathcal{E}} \) equals the mixture of \( \mathcal{E}_{X \backslash Z} \) and \( \mathcal{E}_Z \). If \( \mathcal{E} \) contains the uniform distribution, then \( \overline{\mathcal{E}} \) is a partition model.

**Proposition 21.** Let \( X = \{1, 2, 3\} \). For any \( u \in \mathbb{R}^X \) such that \( u_1 + u_2 + u_3 = 0 \) there exists a unique exponential family \( \mathcal{E} \) on \( X \) with normal space \( \mathcal{N} = \mathbb{R}u \) such that \( \max D_\mathcal{E} = \log(2) \).

The proofs of the results will be given below after a series of preliminary lemmas. Under the additional assumptions that \( N \) is even Theorem 20 has a simpler proof, see Theorem 28.

Let \( \mathcal{E} \) be an exponential family with sufficient statistics \( A \) and normal space \( \mathcal{N} \).

**Lemma 22.** For any \( v_0, v_1, \ldots, v_s \in \mathcal{N} \) let \( Z = \text{supp}(v_0) \cup \bigcup_{j=1}^s \text{supp}(v_j) \). Suppose that \( \max D_\mathcal{E} = \log(2) \). Then
\[
\sum_{x \in Z} v(x) \log \frac{|v(x)|}{v_x} = 0 \quad \text{and} \quad \sum_{x \in Z} v(x) = 0 \quad \text{for all } v \in \mathcal{N}.
\]

**Proof.** The proof is by induction on \( s \). Let \( s = 0 \). Any \( v_0 \in \mathcal{N} \) satisfies \( D_\mathcal{E}(v_0) = 0 \) and is a local maximizer of \( D_\mathcal{E} \). The equality \( v(Z) = 0 \) for all \( v \in \mathcal{N} \) follows from Proposition 11(i). Let \( Z' = X \setminus Z \). Proposition 11(ii) implies that
\[
\sum_{x \in Z'} v(x) \log \frac{|v(x)|}{v_x} \leq v^+(Z') D_\mathcal{E}(v_0) = 0
\]
for all \( v \in \mathcal{N} \). Together with the same inequality with \( v \) replaced by \( -v \) it follows that
\[
\sum_{x \in Z} v(x) \log \frac{|v(x)|}{v_x} = 0. \quad \text{Hence} \quad \sum_{x \in Z} v(x) \log \frac{|v(x)|}{v_x} = D_\mathcal{E}(v) - \sum_{x \in Z} v(x) \log \frac{|v(x)|}{v_x} = 0.
\]
If \( s \geq 1 \), then let \( Y = X \setminus \text{supp}(v_s) \). Let \( \mathcal{E}^Y \) be the exponential family on \( Y \) with reference measure the restriction \( v|_Y \) of \( v \) to \( Y \) and normal space \( \mathcal{N}' = \{ v|_Y : v \in \mathcal{N} \} \). The case \( s = 0 \) implies \( D_\mathcal{E}(w) = D_\mathcal{E}(v) - \sum_{x \in \text{supp}(v_s)} v(x) \log \frac{|v(x)|}{v_x} = 0 \) for all \( w = v|_Y \in \mathcal{N}' \). Therefore, the statement follows from induction.

\[ \square \]
Let $X = \{ x \in X : v(x) \neq 0 \text{ for some } v \in \mathcal{N} \}$. Define a relation $\sim$ on $X$ via

$$x \sim y \iff v(y) \neq 0 \text{ for all } v \in \mathcal{N} \text{ such that } v(x) \neq 0.$$ 

It is easy to see that $\sim$ is an equivalence relation: If there exist $v, w \in \mathcal{N}$ such that $v(y) \neq 0 = v(x)$ and $w(x) \neq 0 \neq w(y)$, then $u := v(y)w - w(y)v \in \mathcal{N}$ satisfies $u(y) = 0 \neq u(x)$, and so $\sim$ is symmetric. Transitivity can be shown similarly. In the language of matroid theory the equivalence classes are the coparallel classes.

**Lemma 23.** A subset $Z \subseteq X$ is an equivalence class of $\sim$ if and only if there exist circuits $\sigma_0, \sigma_1, \ldots, \sigma_s$ of $\mathcal{N}$ such that

$$Z = \sigma_0 \setminus \cup_{j=1}^s \sigma_j,$$

and such that $Z \setminus \sigma \in \{ \emptyset, Z \}$ for all circuits $\sigma$ of $\mathcal{N}$.

**Proof.** If $x \neq y$ for some $y \in X$, then there exists a $v \in \mathcal{N}$ such that $v(x) \neq 0$ and $v(y) = 0$. By Lemma 3 there exists a circuit with the same property. Conversely, if $y \sim x$, then $y \in \sigma$ for any circuit $\sigma$ such that $x \in \sigma$. \qed

Let $C \in \mathbb{R}^{c \times X}$ be a matrix such that the rows $c_1, \ldots, c_c$ of $C$ form a circuit basis of $\mathcal{N}$. Since each circuit basis contains a basis, the rank of $C$ equals the dimension of $\mathcal{N}$. The columns of $C$ are denoted by $\{C_x\}_{x \in X}$.

**Lemma 24.** Let $Z$ be an equivalence class of $\sim$. The rank of the submatrix $C|_Z$ consisting of those columns $C_x$ indexed by $Z$ is one.

**Proof.** Let $Z \subseteq X$. If the rank of $C|_Z$ is larger than one, then there exist two circuit vectors $c_1, c_2$ such that $c_1|_Z$ and $c_2|_Z$ are linearly independent and have support $Z$. Let $x \in Z$. Let $v = c_2(x)c_1 - c_1(x)c_2 \in \mathcal{N}$. Then $v|_Z \neq 0$ and $\text{supp}(v|_Z) \subseteq Z \setminus \{x\}$. Therefore, $Z$ is not an equivalence class of $\sim$. \qed

The main argument of the last proof can be reformulated in terms of the elimination axiom of oriented matroid theory, cf. [13]. In the language of matroid theory Lemma 24 states that the coparallel classes of a matroid have corank one.

**Proof of Theorem 14.** Suppose $\max D_E = \log(2)$. By Lemma 21 the rank of $C$ is bounded from above by the number of equivalence classes of $\sim$. Let $Z$ be an equivalence class of $\sim$. By definition, the submatrix $C|_Z \in \mathbb{R}^{c \times Z}$ is not the zero matrix. By Lemmas 22 and 23 the rows $c_i|_Z$ of $C|_Z$ satisfy $\sum_{x \in Z} c_i(x) = 0$. Hence each equivalence class must contain at least two elements. Therefore, the rank of $C$, which equals the codimension of $E$, is bounded from above by $\lceil N/2 \rceil$, and so the dimension of $E$ is bounded from below by $N - 1 - \lceil N/2 \rceil = \lceil N/2 \rceil - 1$. \qed

**Lemma 25.** If the dimension of $\mathcal{N}$ equals the number of equivalence classes of $\sim$, then the equivalence classes are the circuits of $\mathcal{N}$. In other words, the circuit vectors $c_1, \ldots, c_c$ of a circuit basis are in bijection with the equivalence classes $Z_1, \ldots, Z_c$, such that $Z_i = \text{supp}(c_i)$. Hence $\mathcal{E}$ is the mixture of $\mathcal{E}_1, \ldots, \mathcal{E}_c$, where $\mathcal{E}_c$ is the exponential family $\mathcal{E} \cap \mathcal{P}(Z_i)^0$. 

11
Proof. Let \( \mathcal{Z}_1, \ldots, \mathcal{Z}_c \) be the set of equivalence classes of \( \sim \). Reorder \( \mathcal{X} \) such that the equivalence classes are given by consecutive numbers. Let \( \tilde{C} \) be the matrix obtained from \( C \) by doing a Gauss elimination through row operations. By assumption \( \tilde{C} \) has \( \dim \mathcal{N} = c \) nonzero rows. By Lemma 24 the \( i \)th row \( \tilde{c}_i \) of \( \tilde{C} \) has support contained in \( \mathcal{Z}_i \cup \cdots \cup \mathcal{Z}_c \). In particular, \( \text{supp}(\tilde{c}_i) = \mathcal{Z}_c \). Therefore, \( \tilde{c}_c \) is a circuit vector. If \( v \in \mathcal{N} \) has \( v(x) \neq 0 \) for some \( x \in \mathcal{Z}_c \), then \( \tilde{v} = v - \frac{u(x)}{\tilde{c}_c(x)} \tilde{c}_c(x) \) satisfies \( \text{supp}(\tilde{v}) = \text{supp}(v) \setminus \mathcal{Z}_c \). Hence no other circuit intersects \( \mathcal{Z}_c \). By induction, \( \text{supp}(c_i) \) equals an equivalence class of \( \sim \) for each \( i \). The first statement follows from \( \text{supp}(c_i) \neq \text{supp}(c_j) \) for \( 1 \leq i < j \leq c \). The last statement is a consequence of Corollary 3. \( \square \)

Proof of Theorem 20. Assume that the dimension of \( \mathcal{E} \) equals \( \left\lfloor \frac{N}{2} \right\rfloor - 1 \). By the proof of Theorem 19 there must be \( m := \left\lfloor \frac{N}{2} \right\rfloor \) equivalence classes of \( \sim \). If \( N \) is even, then each equivalence class has cardinality two. If \( N \) is odd, then there may be one equivalence class \( \mathcal{Z} \) of cardinality three. In this case, reorder \( \mathcal{X} \) such that \( \mathcal{Z} = \{N-2, N-1, N\} \). By Lemma 25 there exists a circuit vector \( c \in \mathcal{N} \) such that \( \text{supp}(c) = \mathcal{Z} \). Assume without loss of generality that \( c_{N-2} \) and \( c_{N-1} \) are positive and that \( c_N = -(c_{N-1} + c_{N-2}) = -1 \). Then

\[
\sum_{i=N-2}^{N} c_i \log |c_i| = -h(c_{N-1}, c_{N-2}) \neq 0,
\]

where \( h(p, q) \) is the entropy of a binary random variable with probabilities \( p, q \). Therefore, if \( N \) is even or if 1 is a reference measure of \( \mathcal{E} \), then all equivalence classes of \( \sim \) have cardinality two.

By Lemma 25 there are exponential families \( \mathcal{E}_1, \ldots, \mathcal{E}_c \) such that \( \mathcal{E}_i \subseteq \mathcal{P}(\mathcal{Z}_i)^\circ \) for \( i = 1, \ldots, c \) and such that \( \mathcal{E} \) is the mixture of \( \mathcal{E}_1, \ldots, \mathcal{E}_c \). For \( i = 1, \ldots, c \) there is a unique circuit vector with support \( \mathcal{Z}_i \), hence \( \mathcal{E}_i \neq \mathcal{P}(\mathcal{Z}_i)^\circ \), so \( \mathcal{E}_i \) has dimension \( |\mathcal{Z}_i| - 1 \). If \( |\mathcal{Z}_i| = 2 \), then \( \mathcal{E}_i \) consists of the uniform distribution \( \frac{1}{2} \mathbf{1}_{\mathcal{Z}_i} \) on \( \mathcal{Z}_i \), so \( \mathcal{E}_i \) is a partition model, and also the mixture of \( \mathcal{E}_i \) for those \( i \) satisfying \( |\mathcal{Z}_i| = 2 \) is a partition model. \( \square \)

Proof of Proposition 21. Let \( \mathcal{E} \) be a one-dimensional exponential family with normal space \( \mathbb{R}u \). Without loss of generality assume that \( u^+ \) and \( u^- \) are probability measures. By Theorem 9 the set of local maximizers of \( D_{\mathcal{E}} \) consists of \( u^+ \) and \( u^- \), and both are projection points. \( \mathcal{E} \) satisfies \( \max D_{\mathcal{E}} = \log(2) \) if and only if \( (u^+)_{\mathcal{E}} = (u^-)_{\mathcal{E}} = \frac{1}{2}(u^+ + u^-) \), which happens if and only if \( u^+ + u^- \) is a reference measure of \( \mathcal{E} \), proving existence and uniqueness of \( \mathcal{E} \). \( \square \)

5 Optimal exponential families

Corollary 10 says that max \( D_{\mathcal{E}} \geq \log(2) \) for all exponential families \( \mathcal{E} \neq \mathcal{P}(\mathcal{X})^\circ \). Therefore \( D \)-optimality is only interesting for \( D \geq \log(2) \). The case \( D = \log(2) \) was studied in Section 4, where it was shown that \( D_{N,k} = \log(2) \) if and only if \( \left\lfloor \frac{N}{k+1} \right\rfloor - 1 \leq k < N \). This condition is equivalent to \( \left\lfloor \frac{N}{k+1} \right\rfloor = 2 \). Many \( \log(2) \)-dimension optimal exponential families are partition exponential families.
Example 26. Any zero-dimensional exponential family $\mathcal{E} = \{\nu\}$ is dimension-optimal. The function $P \mapsto D(P\|\nu)$ is convex on the probability simplex $\mathbf{P}(\mathcal{X})$ and attains its maximum at a vertex of $\mathbf{P}(\mathcal{X})$, which corresponds to a point distribution. Therefore,
\[
\max D_{\mathcal{E}} = \max \{-\log(\nu_x) : x \in \mathcal{X}\} \geq \log |\mathcal{X}|.
\]
Hence $D_{N,1} = \log(N)$, and $\mathcal{E}$ is $D$-optimal if and only if $\nu_x \geq e^{-D}$ for all $x \in \mathcal{X}$. Zero-dimensional exponential families are the dimension $D$-optimal exponential families for $D \geq \log|\mathcal{X}|$. In general, they are not the only inclusion $D$-optimal exponential families, see Example 27.

Example 27. Let $\mathcal{X} = \{1, 2, 3\}$. Any zero-dimensional exponential family $\mathcal{E} = \{\nu\}$ satisfies $\max D_{\mathcal{E}} \geq \log(3)$. Therefore, if $\log(2) \leq D < \log(3)$, then the dimension $D$-optimal exponential families are one-dimensional. The normal space $\mathcal{N}$ of any one-dimensional exponential family $\mathcal{E}$ is spanned by a single element $u$, which can be taken to be normalized, such that $\partial \mathbf{U}_\mathcal{N} = \{\pm u\}$. By Theorem 9 the set of local maximizers of $D_{\mathcal{E}}$ equals $\{u^+, u^-\}$. Let $P_\mathcal{E} = (u^+)_{\mathcal{E}} = (u^-)_{\mathcal{E}}$, then $P_\mathcal{E} = \mu u^+ + (1 - \mu)u^-$ for some $0 < \mu < 1$. Hence $D_{\mathcal{E}}(u^+) = -\log \mu$ and $D_{\mathcal{E}}(u^-) = -(1 - \mu)$. It follows that $\mathcal{E}$ is dimension $D$-optimal if and only if $e^{-D} \leq \mu \leq 1 - e^{-D}$. Alternatively, using Theorem 9 $\mathcal{E}$ is dimension $D$-optimal if and only if $-\log(e^D - 1) \leq D_{\mathcal{E}}(u) \leq \log(e^D - 1)$.

If $D \geq \log(3)$, then the dimension $D$-optimal exponential families are zero-dimensional, consisting of a single point $\{\nu\}$ such that $\min\{\nu_1, \nu_2, \nu_3\} \geq e^{-D}$. There are also one-dimensional inclusion $D$-optimal exponential families: Consider, for example, the exponential family $\mathcal{E}$ with sufficient statistics $A = (0, 1, 2)$ and reference measure $\nu = (1, 4, 1)$. The two local maximizers are $u^+ = \delta_2$ and $u^- = \frac{1}{2}(\delta_1 + \delta_3)$. Their $rI$-projection is $P_\mathcal{E} = \frac{1}{6}\nu$. Hence $D_{\mathcal{E}}(u^+) = \log \frac{2}{3}$ and $D_{\mathcal{E}}(u^-) = \log 3$, and so $\max D_{\mathcal{E}} = \log 3$. The monomial parametrization of $\mathcal{E}$ is
\[
P_\mathcal{E} = \frac{1}{Z_\mathcal{E}}(1, 4\xi, \xi^2),
\]
where $\xi \in \mathbb{R}_+$ and $Z_\mathcal{E} = 1 + 4\xi + \xi^2$. Consequently, $\mathcal{E}$ does not contain the uniform distribution. Therefore, any point $P \in \mathcal{E}$ satisfies $\max D(\cdot\|P) > \max D_{\mathcal{E}}$.

The following theorem generalizes the special case of Theorem 20 when $N$ is even.

**Theorem 28.** Let $\mathcal{X}$ be a finite set of cardinality $N$. Then $D_{N,k} \geq \log(N/(k + 1))$ for all $0 \leq k < N$. If $\mathcal{E}$ is a $k$-dimensional exponential family that satisfies $\max D_{\mathcal{E}} = \log(N/(k + 1))$, then $\mathcal{E}$ is a partition model of a homogeneous partition of coarseness $N/(k + 1)$. In particular, if $N$ is divisible by $(k + 1)$, then $D_{N,k} = \log(N/(k + 1))$, and the dimension $D_{N,k}$-optimal models are partition models.

**Proof.** First assume that $\mathcal{E} \in \mathcal{H}_1$. Let $A$ be a sufficient statistics of $\mathcal{E}$. The moment map $\pi_A$ maps the uniform distribution $Q = \frac{1}{N}1$ to a point in the relative interior of $\mathbf{M}_A$. By Carathéodory's theorem there are $k + 1$ vertices $A_n, \ldots, A_{x_k}$ of $\mathbf{M}_A$ and $\lambda_0, \ldots, \lambda_k \in \mathbb{R}_+$ such that $\pi_A(Q) = \sum_{i=0}^k \lambda_i A_x$, and $\sum_{i=0}^k \lambda_i = 1$. Let $P = \sum_{i=0}^k \lambda_i \delta_x$, then $Q = P_{\mathcal{E}}$. By
the Pythagorean theorem, $\max D_{\mathcal{E}} \geq D_{\mathcal{E}}(P) = H(Q) - H(P) \geq \log(N) - \log(k+1)$, proving the first assertion.

If equality holds, then $\lambda_0 = \cdots = \lambda_k = \frac{1}{k+1}$. Let $x \in \mathcal{X} \setminus \{x_0, \ldots, x_k\}$. For $i \in \{0, \ldots, k\}$ let $C_i$ be the convex hull of $A_{x_0}, \ldots, A_{x_{i-1}}, A_{x_{i+1}}, \ldots, A_{x_k}$ and $A_x$. By Carathéodory’s theorem the sets $C_i$ cover the convex hull of $A_{x_0}, \ldots, A_{x_k}$ and $A_x$. In particular, $\pi_A(Q) \in C_j$ for some $j \in \{0, \ldots, k\}$, so $\pi_A(Q) = \sum_{i \neq j} \lambda_i A_{x_i} + \lambda_j A_x$.

By the same argument as above it follows that $\lambda_0 = \cdots = \lambda_k = \frac{1}{k+1}$. Therefore, $A_x = (k+1)\pi_A(Q) - \sum_{i \neq j} A_{x_i} = A_{x_j}$.

Let $\sim$ be the equivalence relation on $\mathcal{X}$ defined by $x \sim y$ if and only if $A_x = A_y$, and let $\mathcal{X}' = (\mathcal{X}', \ldots, \mathcal{X}^N)$ be the corresponding partition into equivalence classes. Then $N' \leq k+1$ by what was shown until now. From $\dim(\mathcal{E}) = \dim(M_A)$ one concludes $N' = k+1$, and $M_A$ is a simplex of dimension $k$. By Lemma 10, $\mathcal{E}$ equals the partition model of $\mathcal{X}'$. Lemma 11 implies that the coarseness of $\mathcal{X}'$ equals $\frac{N}{k+1}$, which must be an integer. Furthermore, $\mathcal{X}'$ is homogeneous.

It remains to prove $\max D_{\mathcal{E}} > \log(N/(k+1))$ in the case $\mathcal{E} \notin \mathcal{H}_1$. Let $P_{\mathcal{E}}$ be the $rI$-projection of the uniform distribution, and let $\mathcal{N}_1$ be the set of probability distributions that $rI$-project to $P_{\mathcal{E}}$. The function $D_{\mathcal{E}}$ is convex on $\mathcal{N}_1$, hence $D_{\mathcal{E}}$ is maximal at the vertices of $\mathcal{N}_1$. Let $P$ be a vertex of $\mathcal{N}_1$. Assume that $v \in \mathcal{N}$ satisfies $\text{supp}(v) \subseteq \text{supp}(P)$. Then there exists $\epsilon > 0$ such that $P \pm \epsilon v \in \mathcal{N}_1$ and $P = \frac{1}{2}(P + \epsilon v) + \frac{1}{2}(P - \epsilon v)$. Hence $v = 0$. Therefore, the set $\{A_x : P(x) > 0\}$ is linearly independent. In particular $|\text{supp}(P)| \leq \dim(\mathcal{X}') + 1$.

Denote by $\mathcal{E}_1$ the exponential family with uniform reference measure and with the same normal space as $\mathcal{E}$. On $\mathcal{N}_1$ the difference

$$\delta(P) := D_{\mathcal{E}}(P) - D_{\mathcal{E}_1}(P) = -\sum_{x \in \mathcal{X}} P(x) \log P_{\mathcal{E}}(x) - \log N$$

is an affine function that is positive at the uniform distribution. Hence there exists a vertex $P$ of $\mathcal{N}_1$ such that $\delta(P) > 0$, and so $D_{\mathcal{E}}(P) > D_{\mathcal{E}_1}(P) = \log N - H(P) \geq \log(N/(k+1))$. \hfill $\Box$

The value of $D_{N,k}$ is unknown when $k+1$ does not divide $N$. The situation is known for $N = 3$, see Example 27. If $1 \leq k < 3$, then $D_{N,k} = \log(2)$, and all dimension $D_{N,1}$-optimal exponential families that contain the uniform distribution are partition models. The following conjecture generalizes this example and Theorems 20 and 28.

**Conjecture 29.** $D_{N,k} = \log\left[\frac{N}{k+1}\right]$, and the dimension $D_{N,k}$-optimal exponential families containing the uniform distribution are partition models.

The following weaker statement holds:

**Lemma 30.** Let $\mathcal{X}' = \{\mathcal{X}', \ldots, \mathcal{X}^N\}$ be a partition of coarseness $c < N$ such that $\mathcal{X}'$ has cardinality $l \leq c$ and all other components $\mathcal{X}^i$ for $i > 1$ have cardinality $c$. Then the partition model $\mathcal{E}$ of $\mathcal{X}'$ is log$(c)$-inclusion optimal.

**Proof.** The fact that $\max D_{\mathcal{E}} = \log(c)$ follows from Lemma 16. It remains to prove the optimality. Let $\mathcal{E}' \subseteq \mathcal{E}$ be an exponential family contained in $\mathcal{E}$. Let $Z$ be the union
of all blocks of $\mathcal{X}'$ of cardinality $c$. Assume that there exists a probability measure $Q \in \mathcal{E} \setminus \mathcal{E}'$ with support contained in $\mathcal{Z}$. By Corollary 17 there exists $P \in \mathcal{P}(\mathcal{Z})$ such that $Q = P_\mathcal{Z}$ and $D(P\|Q) = \log(c)$. Let $Q' = P_\mathcal{Z}' \in \mathcal{E}$. Then $D(P\|Q') = D(P\|Q) + D(Q\|Q') > \log(c)$ by the Pythagorean identity. Otherwise, if $\mathcal{E} \cap \mathcal{P}(\mathcal{Z}) = \mathcal{E}' \cap \mathcal{P}(\mathcal{Z})$, then $\dim(\mathcal{E}) = \dim(\mathcal{E} \cap \mathcal{P}(\mathcal{Y}')) + 1 = \dim(\mathcal{E} \cap \mathcal{P}(\mathcal{Y})) + 1 \leq \dim(\mathcal{E}')$, so $\mathcal{E} = \mathcal{E}'$. \hfill \qed

Theorem 28 can be applied to the hierarchical models $\mathcal{E}_K$ for $K \subseteq [n]$ introduced in Remark 18. By Theorem 28 the hierarchical model $\mathcal{E}_K$ is dimension optimal with max $D(\cdot\|\mathcal{E}_K) = \sum_{i \in [n] \setminus K} \log(N_i)$. If $N_n = 2$, then the choice $K = \{1, \ldots, n - 1\}$ yields an exponential family of dimension less than $|\mathcal{X}|/2$ such that max $D(\cdot\|\mathcal{E}_K) = \log(2)$, and Theorem 13 implies that $\mathcal{E}_K$ is dimension optimal. The following proposition says that the exponential families $\mathcal{E}_K$ are the unique dimension $D$-optimal hierarchical models for many values of $D$.

**Proposition 31.** Let $\mathcal{X} = \mathcal{X}_1 \times \cdots \times \mathcal{X}_n$, where $N_i = |\mathcal{X}_i| < \infty$. For any $K \subseteq [n]$ let $D_K = \sum_{i \in K} \log(N_i)$. The hierarchical model $\mathcal{E}_K$ is dimension $D_K$-optimal.

Let $l$ be any divisor of $N := |\mathcal{X}| = \prod_{i=1}^n N_i$. If $\mathcal{E}$ is any hierarchical model that is dimension $\log(N/l)$-optimal, then there is a subset $K \subseteq [n]$ such that $\mathcal{E} = \mathcal{E}_K$.

The proposition implies that if $l$ is not of the form $\prod_{i \in K} N_i$ for some subset $K \subseteq [n]$, then there exists no hierarchical model that is dimension $\log(N/l)$-optimal.

**Proof.** It only remains to prove the last statement. If $\mathcal{E}$ satisfies the assumptions, then $\mathcal{E}$ is a partition model by Theorem 28. Therefore, it suffices to prove that any hierarchical model that is also a partition model is of the form $\mathcal{E}_K$.

Let $\Delta$ be a simplicial complex on $[n]$ such that $\mathcal{E} = \mathcal{E}_\Delta$, and let $K = \cup_{J \in \Delta} J$. Then $\mathcal{E}$ is a submodel of $\mathcal{E}_K$. Let $A$ be a sufficient statistics of $\mathcal{E}$. By Lemma 7 the convex supports of $\mathcal{E}$ and $\mathcal{E}_K$ have the same number of vertices. By Lemma 15 both are simplices, hence they have the same dimension, so $\mathcal{E} = \mathcal{E}_K$. \hfill \qed

### 6 Discussion

Conjecture 29 would imply that the partition models of Lemma 30 are dimension optimal among all exponential families. If the conjecture were true, then it would suggest the following interpretation: In many cases the information divergence $D(P\|Q)$ can be interpreted as the information which is lost when $P$ is the true probability distribution, but computations are carried out with $Q$. For example, in the case of the independence model $\mathcal{E}_1$ of two variables, $D_{\mathcal{E}_1}$ equals the mutual information and measures the amount of information that one variable carries about the other variable. If a probability measure is replaced by its $rI$-projection, then this information is lost.

For the exponential families $\mathcal{E}_K$ the loss equals $D_K = \sum_{i \in K} \log(N_i)$, which is precisely the maximal information that the random variables that are not in $K$ can carry. Assuming that the conjecture is true, if the model is smaller than $\mathcal{E}_K$, then, in general, more information can be lost. In this interpretation the fact that max $D_\mathcal{E} \geq \log(2)$ unless
\( \mathcal{E} = \mathbf{P}(\mathcal{X})^\circ \) means that for any exponential family \( \mathcal{E} \neq \mathbf{P}(\mathcal{X})^\circ \) in general at least one bit is necessary to compensate the approximation of arbitrary probability measures.
