Abstract

We compute the cosmic relic (dark matter) density of the lightest supersymmetric particle (LSP) in the framework of minimal $N = 1$ Supergravity models with radiative breaking of the electroweak gauge symmetry. To this end, we re-calculate the cross sections for all possible annihilation processes for a general, mixed neutralino state with arbitrary mass. Our analysis includes effects of all Yukawa couplings of third generation fermions, and allows for a fairly general set of soft SUSY breaking parameters at the Planck scale. We find that a cosmologically interesting relic density emerges naturally over wide regions of parameter space. However, the requirement that relic neutralinos do not overclose the universe does not lead to upper bounds on SUSY breaking parameters that are strictly valid for all combinations of parameters and of interest for existing or planned collider experiments; in particular, gluino and squark masses in excess of 5 TeV cannot strictly be excluded. On the other hand, in the “generic” case of a gaugino–like neutralino whose annihilation cross sections are not “accidentally” enhanced by a nearby Higgs or $Z$ pole, all sparticles should lie within the reach of the proposed $pp$ and $e^+e^-$ supercolliders. We also find that requiring the LSP to provide all dark matter predicted by inflationary models imposes a strict lower bound of 40 GeV on the common scalar mass $m$ at the Planck scale, while the lightest sleptons would have to be heavier than 100 GeV. Fortunately, a large relic neutralino density does not exclude the possibility that charginos, neutralinos, gluinos and squarks are all within the reach of LEP200 and the Tevatron.

1. Introduction

It is by now well established \[1\] that the observed, luminous matter in the universe cannot account for its total mass. Cosmological mass densities are usually expressed as ratio $\Omega \equiv \frac{\rho}{\rho_c}$, where $\rho_c \simeq 2 \cdot 10^{-29} h^2 \text{g/cm}^3$ is the “critical” mass density that yields a flat universe, as favoured by inflationary cosmology \[2\]; $\rho < (>) \rho_c$ corresponds to an open (closed) universe, i.e. a metric with negative (positive) curvature. The dimensionless parameter $h$ is proportional to the Hubble “constant” $H$ describing the expansion of the universe: $H \equiv 100 h \text{ km/sec Mpc}$. Observations yield $0.5 \leq h \leq 1$. Even if one broadly defines luminous matter as everything that emits any kind of electromagnetic radiation, when averaged over the volume of the (visible) universe it cannot give $\Omega > 0.01$.

In contrast, from the observed orbits of hydrogen clouds around a variety of galaxies, including our own, one derives \[1\] $\Omega \geq 0.1$; and from the motion of (clusters of) galaxies within superclusters one can deduce \[2\] $\Omega \geq 0.3 - 0.4$. Finally, as indicated above, $\Omega = 1$ is predicted \[2\] by models of inflationary cosmology; such models are currently favoured, since they can solve other cosmological problems, e.g. the flatness, horizon and magnetic monopole problems.

The nature of the missing or dark matter (DM) cannot be derived directly from present observations. However, within standard (Big Bang) cosmology, the observed abundances of light elements (D, He, Li) can only be understood \[3\] if the total baryonic mass density is less than about $0.1 \rho_c$. The discrepancy between the lower bound on the total mass density and the upper bound on the baryonic one has led to speculations \[4\] that some neutral, weakly interacting stable particle might provide the bulk of the mass density today. In particular, it has been observed almost 10 years ago \[5\] that the lightest supersymmetric (SUSY) particle (LSP) is a good candidate for dark matter. Its stability is guaranteed by a discrete symmetry called R parity, which can be imposed in most phenomenologically viable SUSY models; in particular, R parity is automatically conserved in the simplest realistic SUSY model \[3\] \[6, 7\], the minimal supersymmetric standard model or MSSM. This explanation is especially attractive since the primary motivation for SUSY has nothing to do with the DM problem; rather, SUSY automatically provides a DM candidate “for free”. Moreover, for “natural” choices of parameters (to be specified below), $\Omega$ turns out to be \[6\] of approximately the right order of magnitude.

The primary motivation for the introduction of supersymmetry stems from the observation \[8\] that in SUSY models, large hierarchies between mass scales are automatically protected against (quadratically divergent) radiative corrections, in contrast \[3\] to non–supersymmetric models. In particular, within the non–supersymmetric standard model (SM) it is extremely unnatural to assume the scale of electroweak symmetry breaking, characterized by the vacuum expectation value (vev) of the Higgs field $\langle H \rangle = 175 \text{ GeV}$, to be much smaller than the scale of Grand Unification $M_X \simeq 10^{15} - 10^{16} \text{ GeV}$ or the Planck scale $M_P \simeq 10^{19} \text{ GeV}$. On the other hand, in the MSSM radiative corrections are under control, provided only that the mass scale of the superpartners is not much bigger than 1 TeV. The relation between the scale of electroweak symmetry breaking and particle...
masses is even more direct in minimal supergravity (SUGRA) models where the breakdown of electroweak gauge symmetry is induced by (logarithmic) radiative corrections to the parameters of the Higgs potential \[10, 7\]. These models also have the practical advantage that they allow to describe the whole spectrum of superparticles (sparticles) in terms of a small number of free parameters. Moreover, the resulting sparticle spectra almost automatically satisfy constraints from \(K\) and \(B\) physics \[11\], and lead to small additional contributions to electroweak observables \[12\], in agreement with LEP results \[13\]. Finally, precision measurements at LEP have shown \[14\] that the non–supersymmetric SM does not lead to a Grand Unification of the gauge couplings, whereas in the MSSM all three gauge couplings meet at scale \(M_X \simeq 10^{16}\) GeV. While this result does not depend \[15, 16\] on the constraints on the sparticle spectrum imposed by minimal SUGRA, it does lend credence to the assumption that there is no additional threshold between the weak scale and \(M_X\); this assumption is an important ingredient of SUGRA models with radiative symmetry breaking.

Quite a few papers have already been published in the last decade that contain calculations of the relic LSP density in some version of the MSSM. However, older papers \[5, 17\] often assume rather light sparticles, in conflict with recent experimental bounds. Moreover, many previous calculations \[4, 17, 18, 19, 20\] involved simplifying assumptions about the sparticle spectrum, which were often in conflict with SUGRA predictions (e.g. by assuming the LSP to have the same mass as squarks). Some computations \[21, 22, 23, 24\] do take the SUGRA relations between sfermion and gaugino masses into account, but the additional constraints on model parameters imposed by radiative gauge symmetry breaking have still been ignored in these papers. Moreover, in refs. \[21, 22, 24\] only the case of a “light” LSP, with mass below that of the \(W\) boson, has been treated. Indeed, only two calculations of the annihilations cross sections of a heavy LSP exist to date \[18, 19\], and neither of them is fully complete. In ref. \[18\] the annihilation into one Higgs boson and one gauge boson has not been included; moreover, the given expressions do not seem to be applicable if the mass of the LSP is less than half the mass of the heaviest Higgs boson. Ref. \[19\] does treat the full list of possible final states, but only considers unmixed (pure) neutralino states; we will see that this actually gives wrong results for the gaugino–like LSP even in the limit of infinite LSP mass. The results of ref. \[19\] have been used in refs. \[20, 23, 25\] as well. We have independently computed all relevant annihilation cross sections for a general, mixed LSP eigenstate. This part of our work should be useful beyond the context of the more restrictive SUGRA models. Very recently another calculation of the relic density of heavy LSPs has appeared \[26\]. The authors state that they generalized the results of ref. \[19\] by including neutralino mixing, but no explicit expressions are given; moreover, no SUGRA mass relations are assumed.

We are aware of only two calculations of relic LSP densities \[24, 24\] in which the constraints imposed by radiative gauge symmetry breaking have been taken into account. However, in these papers a specific SUSY breaking scheme, the “no–scale” ansatz \[28\], has been assumed; in this scheme the LSP density turned out to be too low to account for all dark matter. \[†\] Moreover, the Higgs sector has only been treated in the tree–level approximation. The importance of Higgs exchange contributions has been pointed out

\[†\]This result can also be derived from refs. \[22, 23\] once one makes use of the fact that these models cannot support a higgsino–like LSP; see also ref. \[24\].
in ref. [29], again using tree–level formulae for Higgs boson masses. However, radiative corrections to these masses can be [30] substantial if the top quark is heavy, \( m_t > 100 \text{ GeV} \), which now seems likely.

In this paper we compute the LSP relic density in minimal SUGRA models with radiative gauge symmetry breaking. We use 3 free parameters to describe SUSY breaking, as opposed to only 1 in refs. [27, 25]. Due to the constraints imposed by radiative gauge symmetry breaking, which in particular fix the Higgs spectrum for a given set of SUSY breaking parameters and given \( m_t \), the resulting parameter space is still sufficiently small to allow for an exhaustive scan; we thus do not have to rely on “simplifying assumptions” of often dubious validity. As indicated above, we always include neutralino mixing, as well as all kinematically accessible final states, when computing the LSP annihilation cross section. Our analysis of radiative symmetry breaking includes effects of the Yukawa couplings of the \( b \) quark and \( \tau \) lepton, which can be quite important [31, 32]. Mixing between the superpartners of left and right–handed fermions is also treated exactly. One–loop corrections to the Higgs sector are included, and all experimental constraints on sparticle masses are taken into account.

We find that the model can easily yield sufficient dark matter to close the universe, if the SUSY breaking common scalar mass \( m \) at scale \( M_X \) exceeds 40 GeV. This conclusion is closely related to the result of refs. [33, 34] that a single light slepton suffices to make the relic density of a gaugino–like LSP uninterestingly small. A qualitatively similar result has been found in ref. [24] in a more general context. On the other hand, requiring the LSP not to overclose the universe does not lead to upper bounds on sparticle masses which are both relevant for existing or planned experiments and are valid for the entire parameter space. Of course, it is quite unnatural [35, 16] to assume sparticles to be much heavier than the \( W \) and \( Z \) bosons, but naturalness arguments cannot be translated into strict upper bounds; even a rather high [18, 19] bound from cosmology would therefore have been welcome. Alas, there are two different ways in which such a bound can be circumvented. One possibility is to have a light higgsino–like LSP, with all SUSY breaking masses being very large. Note that the higgsino mass does not break supersymmetry; moreover, we argue that in such a scenario, supersymmetry would be extremely difficult to discover in laboratory experiments. The constraints from radiative gauge symmetry breaking exclude the possibility to have a higgsino–like LSP if the top quark is heavy, the precise bound on \( m_t \), depending on the ratios of the soft SUSY breaking parameters. The second possibility to allow for a very heavy sparticle spectrum is to choose the LSP mass to be close to half the mass of the pseudoscalar Higgs boson; this strongly enhances the annihilation of the LSP into SM fermions, in particular \( b \) quarks and \( \tau \) leptons. Within the framework of minimal SUGRA, this scenario necessitates a large ratio \( \tan \beta \) of the vevs of the two Higgs fields of the model, but such solutions can be realized quite easily [31, 32].

The remainder of this paper is organized as follows. In sec. 2 we briefly describe the formalism necessary to compute the DM density for a given LSP annihilation cross section. We also list all possible LSP annihilation processes, and give a short description of the parameter space of minimal SUGRA models. In sec. 3 we present illustrative examples of LSP densities in such models. The effects of \( s \)–channel poles as well as thresholds,

\footnote{Leading one–loop corrections to the Higgs sector are included in ref. [24], but only for light LSPs, and without the constraints imposed by radiative gauge symmetry breaking.}
where new annihilation channels open up, are discussed. We also explicitly demonstrate
the importance of the SUGRA imposed running of sfermion and Higgs boson masses.
Finally, we study the dependence of the DM density on the free parameters of the model
by means of several contour plots. Sec. 4 is devoted to a discussion of the bounds that
can be derived from the requirement that the LSP relic density lies in the cosmologically
interesting region. As already mentioned above, a strict upper bound on sparticle masses
can only be derived if we artificially restrict the parameter space of the model. In contrast,
a non–trivial lower bound on slepton masses can be derived from the requirement that
the LSP relic density be close to the critical density; however, the masses of the gluino,
the light chargino, and the squarks can all be near their present lower bounds. Finally,
in sec. 5 we summarize our results and draw some conclusions. Complete lists of all
LSP annihilation matrix elements are given in Appendix A, and Appendix B contains an
example of a check of some amplitudes for the production of longitudinal gauge bosons
using the equivalence theorem.

2. Formalism

In this section we describe the formalism necessary to describe the numerical results of
secs. 3 and 4. We first (sec. 2a) give a short summary of the calculation of the present day
DM density for given mass and annihilation cross section of the dark matter candidate \( \chi \).
Sec. 2b contains a brief description of the MSSM; it also contains a list of all annihilation
channels of our DM candidate. The resulting annihilation cross section will turn out to
depend on the whole sparticle and Higgs boson spectrum. In sec. 2c we therefore give a
brief summary of minimal SUGRA models, where the whole spectrum can be computed
in terms of 4 free parameters.

2a. Calculation of the DM density

We begin with a brief description of the calculation of the present relic mass density of
a DM candidate \( \chi \), assuming that the mass \( m_\chi \) as well as the annihilation cross section
\( \sigma_{\text{ann}}(\chi \chi \to \text{anything}) \) are known. Following the prescription of refs.[4, 18], we first intro-
duce the freeze–out temperature \( T_F \), below which the \( \chi \chi \) reaction rate is (much) smaller
than the expansion rate of the universe. It is convenient to express (inverse) temperatures
in terms of the dimensionless quantity \( x \equiv m_\chi/T \); the freeze–out temperature can then
iteratively be computed from

\[
x_F = \ln \frac{0.0764 M_P (a + 6b/x_F) c(2 + c)m_\chi}{\sqrt{g^* x_F}}.
\]

(1)

Here, \( M_P = 1.22 \cdot 10^{19} \) GeV is the Planck mass, and \( a \) and \( b \) are the first two coefficients in
the Taylor expansion of the annihilation cross section with respect to the relative velocity
\( v \) of the \( \chi \chi \) pair in its center–of–mass frame:

\[
v \cdot \sigma_{\text{ann}}(\chi \chi \to \text{anything}) = a + bv^2;
\]

(2)

notice that \( v \) is twice the velocity of \( \chi \) in the \( \chi \chi \) cms frame. Furthermore, \( g_* \) is the effective
number of relativistic degrees of freedom at \( T = T_F \). A highly relativistic boson (fermion)
contributes 1 \((7/8)\) to \(g^\ast\), whereas very nonrelativistic (slow) particles do not contribute at all. However, often \(T_F\) turns out to be close to the mass of the heavy particles of the SM (the \(c, b, t\) quark, the \(\tau\) lepton, or the \(W\) or \(Z\) boson); in this case a careful treatment of the threshold is necessary \([4]\) if ugly jumps in the curves are to be avoided. Finally, the constant \(c\) in eq.\((1)\) is a numerical parameter introduced \([4]\) to achieve smooth matching of approximate solutions of the Boltzmann equation above and below \(T_F\); following ref.\([18]\) we chose \(c = 1/2\). Given \(x_F\) and \(\sigma_{\text{ann}}\), one can compute

\[
\Omega_\chi h^2 \equiv \frac{\rho_\chi}{\rho_c} = \frac{1.07 \cdot 10^9/\text{GeV}x_F}{\sqrt{g^\ast}M_P(a + 3b/x_F)},
\]

where the rescaled Hubble constant \(h\) and the critical density \(\rho_c\) have already been introduced in sec. 1.\(^*\)

Eqs.\((1)\)–\((3)\) describe a simple, approximate solution of the Boltzmann equation that determines the abundance of any particle species. While not strictly correct \([36]\), in most cases this treatment reproduces the exact numerical solution to 10–20 \% accuracy \([1, 18]\); given that \(h^2\) in eq.\((3)\) is only known to a factor of 2, this accuracy is fully sufficient for our purposes. However, it has recently been pointed out \([37]\) that there are three cases in which this approximation fails badly: close to a threshold where a new annihilation channel opens up that dominates the total annihilation cross section; close to a very narrow \(s\)–channel resonance; and if the next–to–lightest sparticle \(\chi'\) is close in mass to the LSP, and \(\sigma_{\text{ann}}(\chi\chi' \to \text{anything}) \gg \sigma_{\text{ann}}(\chi\chi \to \text{anything})\). Unfortunately, in these three cases the proper treatment \([37]\) is considerably more cumbersome than eqs.\((1)\)–\((3)\). For reasons of computational simplicity we will therefore use the approximate treatment throughout, but we will be careful to point out the situations where it might fail, and will qualitatively describe the result of the proper treatment in such cases.

Note that \(x_F\) in eq.\((3)\) is almost independent of \(m_\chi\) and \(\sigma_{\text{ann}}\); we find \(15 \leq x_F \leq 30\) for experimentally allowed choices of parameters (see below). The number of degrees of freedom \(g^\ast\) at \(T_F \approx m_\chi/20\) increases monotonically with \(m_\chi\), but again the \(m_\chi\) dependence is quite small: \(8 \leq \sqrt{g^\ast} \leq 10\) for 20 GeV \(\leq m_\chi \leq 1\) TeV. The details of the model (particle masses and couplings) affect the prediction for \(\Omega_\chi\) therefore predominantly through the coefficients \(a\) and \(b\) describing the annihilation cross section; we now briefly describe the calculation of this cross section.

### 2b. The annihilation cross section

Within the MSSM, only the lightest neutralino is left \([38]\) as a viable DM candidate. A stable LSP has to be \([39]\) both electrically and color neutral, since otherwise it would have been found in searches for exotic isotopes. This leaves one with the lightest neutralino and the lightest sneutrino, but the latter is excluded by a combination of the bound on

\(^*\)Within the framework of inflationary cosmology, eq.\((3)\) should strictly speaking be interpreted as a calculation of the expansion rate, rather than a calculation of the density. After all, inflation predicts \([2]\) \(\Omega = 1\) to high precision, independent of the details of the particle physics model. However, only for a small range of values of the (absolute) mass density \(\rho\) does \(H\), and thus the age of the universe, come out close to the observed value.
the invisible decay width of the Z boson obtained at LEP \cite{10} and the limits derived from
the unsuccessful search for relic sneutrinos using Germanium detectors \cite{11}.

The sparticle spectrum of the MSSM contains \cite{3, 4} 4 neutralino states: The superpartners of the
B and W_3 gauge bosons, and the superpartners of the neutral Higgs bosons H_1^0 and H_2^0 with
hypercharge -1/2 and +1/2, respectively. However, after electroweak
gauge symmetry breaking these current eigenstates mix; their mass matrix in the basis
(\tilde{\theta}, B, W, Z) is given by

\[
M = \begin{pmatrix}
M_1 & 0 & -M_Z \sin\theta_W \cos\beta & M_Z \sin\theta_W \sin\beta \\
0 & M_2 & M_Z \cos\theta_W \cos\beta & -M_Z \cos\theta_W \sin\beta \\
-M_Z \sin\theta_W \cos\beta & M_Z \cos\theta_W \cos\beta & 0 & -\mu \\
M_Z \sin\theta_W \sin\beta & -M_Z \cos\theta_W \sin\beta & -\mu & 0
\end{pmatrix}
\]

where we have used the convention of refs.\cite{7, 42}, which we will follow throughout. Assuming Grand Unification of the gauge couplings implies a relation between the SUSY
breaking gaugino masses M_1 and M_2 as well as the gluino mass m_3 = |M_3|: \[M_1 = \frac{5}{3} \tan^2\theta_W M_2 = \frac{5\alpha_{em}}{3\alpha_s \cos^2\theta_W} M_3, \]

where \alpha_{em} is the electromagnetic coupling constant and \alpha_s is the strong coupling. The
angle \beta in eq.(4) is defined via tan(\beta) \equiv \langle H_2^0 \rangle / \langle H_1^0 \rangle. Finally, the parameter \mu describes the
supersymmetric contribution to the Higgs(ino) masses.

In general the LSP is a complicated mixture \cite{13, 14, 14} of the 4 current eigenstates; in our numerical calculations we take full account of this mixing by diagonalizing the
mass matrix (4) numerically. However, in the limit |M_1| + |\mu| \gg M_Z this diagonalization
can quite easily be carried out perturbatively. Since this proves helpful for a qualitative
understanding of our numerical results, we list the eigenvalues m_i and eigenvectors \vec{e}_i of
the mass matrix (4), keeping terms up to \mathcal{O}(M_Z):

m_1 = M_1;
\vec{e}_1 = \left(1, 0, \frac{M_Z \sin\theta_W (cos\beta M_1 + sin\beta \mu)}{\mu^2 - M_1^2}, \frac{M_Z \sin\theta_W (sin\beta M_1 + cos\beta \mu)}{M_1^2 - \mu^2}\right); \quad (6a)

m_2 = M_2;
\vec{e}_2 = \left(0, 1, \frac{M_Z \cos\theta_W (cos\beta M_2 + sin\beta \mu)}{M_2^2 - \mu^2}, \frac{M_Z \cos\theta_W (sin\beta M_2 + cos\beta \mu)}{\mu^2 - M_2^2}\right); \quad (6b)

m_3 = \mu (1 + \delta);
\vec{e}_3 = \frac{1}{\sqrt{2}} \left(\frac{M_Z \sin\theta_W (cos\beta + sin\beta)}{M_1 - \mu}, \frac{M_Z \cos\theta_W (cos\beta + sin\beta)}{\mu - M_2}, 1, -1 + \epsilon\right); \quad (6c)

m_4 = -\mu (1 + \delta');
\vec{e}_4 = \frac{1}{\sqrt{2}} \left(\frac{M_Z \sin\theta_W (cos\beta - sin\beta)}{M_1 + \mu}, \frac{M_Z \cos\theta_W (sin\beta + cos\beta)}{M_2 + \mu}, 1, 1 + \epsilon'\right); \quad (6d)

Note that eq.(3) implies |m_2| > |m_1|; \vec{e}_2 therefore never corresponds to the LSP. In the
limit where either $|M_1|$ or $|\mu|$ (or both) is much bigger than $M_Z$, the LSP is therefore an almost pure bino ($\vec{e}_1$), or an almost pure antisymmetric or symmetric higgsino ($\vec{e}_{3,4}$).

The corrections $\delta, \delta', \epsilon$ and $\epsilon'$ are formally $O(M_Z^2)$; however, they can be numerically quite important for a light higgsino–like LSP. They are given by

$$
\delta = \frac{M_Z^2}{2\mu} \left( \frac{\sin^2 \theta_W}{\mu - M_1} + \frac{\cos^2 \theta_W}{\mu - M_2} \right);
$$

(7a)

$$
\delta' = \frac{M_Z^2}{2\mu} \left( \frac{\sin^2 \theta_W}{\mu - M_1} + \frac{\cos^2 \theta_W}{\mu + M_2} \right);
$$

(7b)

$$
\epsilon = -\delta \frac{\cos 2\beta}{1 + \sin 2\beta};
$$

(7c)

$$
\epsilon' = -\delta' \frac{\cos 2\beta}{1 - \sin 2\beta}.
$$

(7d)

After inclusion of these terms one therefore finds that the mass splitting between the two higgsino–like states is given by (in the limit $|M_1| \gg |\mu|$):

$$
||m_3| - |m_4|| = \frac{8 M_Z^2 \sin^2 \theta_W}{3 |M_1|} \left( 1 + O\left( \frac{\mu}{M_1}, \frac{M_Z}{M_1} \right) \right).
$$

(8)

More details about neutralino masses and mixings can be found, e.g., in refs. [17, 42, 43, 44].

What are the final states into which a pair of neutralinos can annihilate? Here we only include 2–body final states that can be produced in leading order of perturbation theory. From unsuccessful sparticle searches at LEP [17] as well as the bound $m_{\tilde{g}} > 120$ GeV that follows from the preliminary gluino search limit of the CDF collaboration [46], after inclusion of “cascade decays” [17], one can derive [18] the bound $m_{\chi} \geq 20$ GeV. We see that the annihilation $\chi\chi \to f\bar{f}$ is always kinematically allowed for all light SM fermions up to and including $b$ quarks. For heavier neutralinos annihilation into a pair of gauge bosons also has to be included [18, 19]. In addition the model contains at least one neutral scalar Higgs boson $h$ with mass not much above $M_Z$, even after inclusion of radiative corrections [30]; the second neutral scalar $H$, the pseudoscalar $P$ and the charged Higgs boson $H^+$ can also be accessible. In general one therefore also has to include annihilation into two Higgs bosons [18, 19], as well as into one Higgs and one gauge boson.

We will now discuss annihilation into these final states in a little more detail, assuming $\chi$ to be either a nearly pure bino or a nearly pure higgsino. Here we only give symbolic expressions for the matrix elements, which allow to estimate the order of magnitude of the various contributions; exact expressions for the cross sections for a general $\chi$ state are listed in Appendix A. Since we expand the annihilation cross section of eq. (2) only up to $O(v^2)$, we only have to include $s$ and $p$ wave contributions. $s$ wave contributions

---

*Unless $|M_1| \simeq |\mu|$, in which case strong higgsino–bino mixing occurs. Such mixed states always lead to very small relic densities [18, 22, 33, 26].

†We note in passing that this implies a freeze–out temperature $T_F \geq 1$ GeV, well above the temperature where the quark–hadron phase transition is expected to occur. Our results do therefore not depend on the exact value of the critical temperature for this phase transition, in contrast to the case of a very light LSP [36].
start at $\mathcal{O}(v^0)$, but also contain $\mathcal{O}(v^2)$ terms that contribute to eq. (2) via interference with the $\mathcal{O}(v^0)$ terms. $p$ wave matrix elements start at $\mathcal{O}(v)$, so that we only need the leading term in the expansion. Of course, there is no interference between $s$ and $p$ wave contributions, and hence no $\mathcal{O}(v)$ term in eq. (3). Notice finally that Fermi statistics forces the $s$ wave state of two identical Majorana fermions to have $CP = -1$, while the $p$ wave has $CP = +1$; the same argument also implies that the $s$ wave has to have total angular momentum $J = 0$.

$\chi\chi \to f\bar{f}$

This reaction proceeds via the $s$–channel exchange of a $Z$ or Higgs boson, as well as via sfermion exchange in the $t$–channel. Each chirality state of $f$ has its own superpartner with in general different mass, which mix [49] if the Yukawa coupling of $f$ is not negligible. In the following expressions summation over both sfermions is always understood. Note that both the $Z - f - \bar{f}$ and fermion–sfermion–gaugino couplings conserve chirality; the sfermion and $Z$ exchange contributions to the $s$ wave matrix element $M_s$ are therefore proportional to the mass $m_f$ of the final state fermions. Contributions from Higgs exchange, from the higgsino–sfermion–fermion Yukawa interactions, and from sfermion mixing violate chirality, but have an explicit factor of $m_f$. The coefficient $a$ in the expansion (3) of the annihilation cross section is therefore always proportional to $m_f^2$ for this final state, independent of the composition of $\chi$. Moreover, since the $CP$ quantum number of the exchanged Higgs boson must match that of the initial state, only $P$ exchange contributes to $M_s$, while $h$ and $H$ exchange contribute to $M_p$. Since $M_p$ only contributes to the coefficient $b$ in eq. (2), which is suppressed by a factor $3/x_F \approx 0.1 - 0.2$, $P$ exchange is potentially much more important than the contribution from the scalar Higgs bosons.

For a bino–like LSP the matrix elements thus have the structure

$$M_s(\chi\chi \to f\bar{f})|_{\text{bino}} \propto g^2 m_f \left[ c_1 \frac{m_\chi}{m_f + m_\chi^2} Y_f^2 + c_2 \frac{M_Z^2}{M_1^2 - \mu^2} \frac{m_\chi}{M_Z^2} \right] + \sum_{i=1}^3 \frac{m_\chi}{M_i + \mu 4m_\chi^2 - m_P^2 + im_\chi \Gamma_P};$$

(9a)

$$M_p(\chi\chi \to f\bar{f})|_{\text{bino}} \propto g^2 v \left[ d_1 \frac{m_\chi}{m_f + m_\chi^2} Y_f^2 + d_2 \frac{M_Z^2}{M_1^2 - \mu^2} \frac{4m_\chi^2 - M_Z^2 + iM_\chi \Gamma_Z}{m_\chi} \right] + \sum_{i=1}^2 \frac{m_\chi}{M_i + \mu 4m_\chi^2 - M_i^2 + iM_i \Gamma_i}.\]$$

(9b)

Here the $c_i$, $d_i$ are numerical constants of order 1, and $g'$ is the $U(1)_Y$ gauge coupling, $c_3$ and the $d_{3,i}$ describe the Higgs–$f\bar{f}$ couplings, where we have introduced the notation $H_1 = H$, $H_2 = h$; in certain cases some of these couplings can be enhanced [42] by a factor $\tan\beta$ (or suppressed by $\cot\beta$).

We see from eqs. (3) that the $s$–channel diagrams are all suppressed by small couplings. The $Z$ boson couples to neutralinos only via their higgsino components; more precisely,

$$g z_{i,j} \propto e_{i,3} e_{j,3} - e_{i,4} e_{j,4},$$

(10)
where $c_{i,l}$ is the $l$–th component of $\tilde{e}_i$, see eqs. (3). For a bino–like state this coupling is doubly suppressed, as indicated in eqs. (6). The Higgs boson couplings to neutralinos originate from the Higgs–higgsino–gaugino gauge interaction terms of the unmixed Lagrangian; for a bino–like neutralino this coupling involves therefore only one factor of the (small) higgsino component. Finally, the sfermion exchange contributions can only be suppressed by choosing $m_f^2 \gg m_\chi^2$ in this case.

For a higgsino–like LSP, eqs. (9) become:

$$\mathcal{M}_s(\chi\chi \to f\bar{f})|_{\text{higgsino}} \propto (g^2 + g'^2) m_f \left[ \left( c'_1 \frac{M_Z}{\mu + M} + c''_1 \frac{m_f}{M_Z} \right)^2 \frac{m_\chi}{m_f^2 + m_\chi^2} + c'_2 \frac{M_Z^2}{\mu M} \frac{m_\chi}{m_f^2 + m_\chi^2} \right] + c'_3 \frac{1}{M_1 + \mu 4m_\chi^2 - m_f^2 + im_p \Gamma_p} ;$$  \hspace{1cm} (11a)

$$\mathcal{M}_p(\chi\chi \to f\bar{f})|_{\text{higgsino}} \propto (g^2 + g'^2) v \left[ \left( d'_1 \frac{M_Z}{\mu + M} + d''_1 \frac{m_f}{M_Z} \right)^2 \frac{m_\chi^2}{m_f^2 + m_\chi^2} + c'_2 \frac{M_Z^2}{\mu M 4m_\chi^2 - M_f^2 + im_p \Gamma_p} \right] + \sum_{i=1}^2 d''_3, \frac{m_f}{M_1 + \mu 4m_\chi^2 - m_f^2 + im_p \Gamma_p} \right] ;$$  \hspace{1cm} (11b)

Notice that eqs. (11) also get contributions from SU(2) gauge interactions, which enter eqs. (9) only in higher orders in $M_Z/(M + \mu)$. On the other hand, the sfermion exchange contribution is now suppressed by either the small gaugino component of the LSP, see eqs. (6c), (6d), or by a power of the Yukawa coupling; of course, for $f = t$ the latter is hardly a suppression, and can even be an enhancement if the top quark is heavy. In contrast, Higgs exchange contributes at the same order (in $\frac{M_Z}{M + \mu}$) to the annihilation of bino–like and higgsino–like LSPs. Finally, the $Z$ exchange contribution again behaves quite differently in the two cases of eqs. (9) and (10): While in the former case, it decreases quadratically with the mass of the heavy neutralinos (whose mass is $\propto \mu$ in this case), eqs. (7) and (10) show that the $Z\chi\chi$ coupling for a higgsino–like LSP decreases only linearly with the mass of the heavy neutralinos (with mass $\propto M$). Moreover, eqs. (10) imply that the off–diagonal $Z\chi\chi'$ coupling is not suppressed at all if $\chi = \tilde{e}_3$, $\chi' = \tilde{e}_4$ or vice versa. If $Z$ exchange gives the dominant contribution (which is true for light higgsinos, except in the vicinity of the $h$ pole), one therefore has

$$\sigma(\chi\chi' \to f\bar{f}) \propto \left( \frac{M_1 \mu}{M_Z^2} \right)^2 \sigma(\chi\chi \to f\bar{f}) ;$$  \hspace{1cm} (12)

\footnote{The fact that the Higgs coupling to a mixed neutralino is unsuppressed explains to a large part the big annihilation cross sections, and hence small relic densities, of this kind of LSP.}

\footnote{Unitarity implies that the $Z\chi\chi$ coupling must be suppressed at least like $1/m_\chi$ as $m_\chi \to \infty$. The $Z$ exchange contribution to $\mathcal{M}_h$ behaves like $g_{Z\chi \chi} m_f m_\chi / M_Z^2$. This contribution cannot be cancelled by $f$ or $P$ exchange because one can always choose $m_f, m_p \gg m_\chi$; since this does not increase any couplings, the heavy states simply decouple in this limit. The $Z$ coupling itself therefore has to compensate for the factor of $m_\chi$.}
In this case $\chi\chi'$ co-annihilation \cite{37} can be quite important \cite{26}; we will come back to this point later.

$\chi\chi \to W^+W^-, ZZ$

These final states can be produced via $t-$channel chargino or neutralino exchange, as well as $s-$channel exchange of scalar Higgs bosons; in case of the $W^+W^-$ final state $s-$channel $Z$ exchange also contributes. It is important to realize here that the cross sections behave quite differently for longitudinal and transverse gauge bosons. For each longitudinal gauge boson the amplitude gets an enhancement factor $\gamma_V = E_V/M_V \simeq m_\chi/M_V$. Unitarity then requires strong cancellations between different contributions to the matrix element if the couplings of $\chi$ to $V$ are not suppressed. On the other hand, these enhancement factors can give finite matrix elements in the limit $m_\chi \to \infty$ even if the couplings do vanish in this limit. These effects can also be understood from the equivalence theorem \cite{50}, which states that in the high energy limit, the matrix element for the production of a longitudinal gauge boson is identical to the one for the production of the would-be Goldstone boson that gets “eaten” when the gauge boson acquires its mass. The couplings of these Goldstone modes to neutralinos and charginos originate from the Higgs–higgsino–gaugino gauge interactions of the unmixed Lagrangian. This means that a pair of would–be Goldstone bosons can be produced with full gauge strength from pure gaugino as well as pure higgsino initial states, by exchange of higgsinos or gauginos, respectively. On the other hand, since the relevant couplings are gauge couplings, the matrix element must be well behaved in the limit where any mass becomes very large. Notice finally that neither a pair of longitudinal gauge bosons nor a combination of one longitudinal and one transverse gauge boson can exist in a $J = 0$ state with $CP = -1$; these final states are therefore only accessible to the $p-$wave initial state.

For a bino–like LSP, the coupling to gauge bosons does indeed decrease like $1/m_\chi$, see eq.(6a). The above discussion then shows that only the amplitude for the production of two longitudinal gauge bosons survives, which is purely $p-$wave: $(V = W, Z)$:

$$\mathcal{M}_p(\chi\chi \to V V) \big|_{\text{bino}} \propto g^2 v \left[ d_4 \frac{M_Z^2}{M_1^2 + \mu^2} \frac{m_\chi}{\mu} + \sum_{i=1}^{2} d_{5,i} \frac{M_Z}{M_1 + \mu} \frac{m_\chi M_V}{4m_\chi^2 - m_H^2 + im_H \Gamma_H} \right] \frac{m_\chi^2}{M_V^2}. \quad (13)$$

Because of the enhancement factor $\gamma_V^2$, the annihilation of heavy bino–like LSPs into (longitudinal) gauge bosons does not vanish for $m_\chi \to \infty$, unless one has $|M_1| \ll |\mu|$. Considering \cite{19} an exact bino state therefore does not give the right answer in this case. As discussed above, this can also be understood from the equivalence theorem, since the production of two Goldstone modes can only be suppressed by making the exchanged higgsino very heavy. (This argument is made more rigorous in Appendix B, where numerical factors from the diagonalization of the Higgs sector etc. are treated properly.) Finally, we mention that the coefficient $d_{5,1}$ is often quite small, since the heavy Higgs scalar decouples \cite{12} from $W$ and $Z$ bosons when its mass is large. In contrast the exchange of the light Higgs boson actually gives the dominant contribution in the limit $|\mu| \gg |M_1|$.
For a higgsino–like LSP one has

\[
\mathcal{M}_s(\chi\chi \rightarrow VV)_{\text{higgsino}} \propto (g^2 + g'^2)c'_4; \\
\mathcal{M}_p(\chi\chi \rightarrow VV)_{\text{higgsino}} \propto (g^2 + g'^2)v|d'_4 + \sum_{i=1}^{2} d'_{6,i} \frac{M_Z}{M + \mu} \frac{m_{\chi} M_V}{4m_{\chi}^2 - m_{H_i}^2 + im_{H_i} \Gamma_{H_i} M_V^2} + m_{\chi}^2 M_Z^2].
\] (14a)

Notice that in this case there is no propagator suppression of the \(t\)–channel diagrams for \(V_T V_T\) production, because the exchanged (other) higgsino state is almost mass degenerate with the LSP. Since the (off–diagonal) couplings to gauge bosons are not suppressed in this case, cancellations between \(t\)–channel (and \(Z\) exchange, for \(V = W\)) diagrams are necessary to restore unitarity for \(V_L V_L\) production. The equivalence theorem shows that in the limit \(|M_1| \gg |\mu|\) the contribution from longitudinal gauge bosons is even suppressed, since the production of Goldstone bosons necessitates the exchange of heavy gaugino–like states, or the exchange of \(Z\) or Higgs bosons whose diagonal couplings are also suppressed in this limit. Moreover, the production of \(V_L V_L\) final states is suppressed by neutralino mixing factors. However, the production of transverse gauge bosons, and hence the total cross section, is not suppressed in the limit where the masses of the heavier neutralinos becomes very large; this is again in contrast to the case of a bino–like LSP.\(^4\)

\(\chi\chi \rightarrow Zh\)

This final state can be produced via neutralino exchange in the \(t\)–channel as well as \(s\)–channel exchange of \(Z\) and \(P\) bosons. Notice that now a longitudinal \(Z\) boson can be produced both from the \(s\)– and \(p\)–wave; since we always need at least one neutralino mixing factor, the matrix element would go to zero in the limit of large LSP mass without the enhancement factor \(\gamma_Z\). For the case of a bino–like LSP, the matrix elements have the form:

\[
\mathcal{M}_s(\chi\chi \rightarrow Zh)_{\text{bino}} \propto g'^2 \frac{m_{\chi}}{M_1 + \mu} \frac{M_Z^2}{m_P + M_Z^2} \left[ c_6 + c_7 \frac{m_{\chi}^2}{4m_{\chi}^2 - m_P^2 + im_{H} \Gamma_{H_i} M_V^2} \right];
\] (15a)

\[
\mathcal{M}_p(\chi\chi \rightarrow Zh)_{\text{bino}} \propto g'^2 v d_6 \frac{m_{\chi}^2}{M_1^2 + \mu^2}.
\] (15b)

Both \(c_6\) and \(d_6\) get contributions from neutralino as well as \(Z\) exchange diagrams; in the important limit \(m_P^2 \gg M_Z^2\), \(\mathcal{M}_s\) is strongly suppressed, due to a cancellation between the two classes of diagrams. In this limit the \(ZhP\) coupling also becomes small \(^{12}\), suppressing the \(P\) exchange contribution as indicated. Only the \(p\)–wave amplitude (15b) therefore survives in the limit \(m_P^2 \gg M_Z^2\). Notice, however, that the amplitude as a whole does not vanish in the limit of large sparticle masses and small neutralino mixing, unless

\(^4\) The \(V_L V_L\) final states have not been treated properly in ref.\(^{19}\). However, since they only contribute to \(p\)–wave annihilation, they are numerically not very important. This is even true for bino–like LSP’s where the production of transverse gauge bosons does not contribute, since here the total annihilation cross section is dominated by the \(ff\) final state.
\( |\mu| \gg |M_1| \); once again this is due to the production of a longitudinal gauge boson, giving rise to an enhancement factor \( m_\chi/M_Z \).

For a higgsino–like LSP eqs. (13) become:

\[
\mathcal{M}_s(\chi\chi \to Zh)\big|_{\text{higgsino}} \propto (g^2 + g'^2) \frac{m_\chi}{M + \mu} \left[ c'_6 + c'_7 \frac{M_Z^2}{m_Z^2 + M_Z^2} \right] \left( \frac{m_H^4}{M^2 + \mu^2} \right) \tag{16a}
\]

\[
\mathcal{M}_p(\chi\chi \to Zh)\big|_{\text{higgsino}} \propto (g^2 + g'^2)v d_7^2 \frac{m_\chi^2}{M^2 + \mu^2}. \tag{16b}
\]

Note that in this case the \( \mathcal{O}(v^0) \) term from the \( t \)–channel and \( Z \) exchange diagrams is not suppressed for \( m_P^2 \gg M_Z^2 \). Just as in the case of a bino–like LSP the total amplitude is only suppressed if the heavier neutralinos are much heavier than \( m_\chi \), i.e. if \( |M_1| \gg |\mu| \) in this case.

\( \chi\chi \to hh \)

Here only \( t \)–channel neutralino exchange and \( s \)–channel scalar Higgs exchange diagrams contribute. Since two identical scalars cannot be in a state with \( J = 0 \) and \( CP = -1 \), annihilation can only proceed from the \( p \)–wave. The amplitude thus has the general form:

\[
\mathcal{M}_p(\chi\chi \to hh) \propto g'^2 v \left[ d_8 \frac{m_\chi}{M + \mu} + d_9 \frac{M_Z^2}{M^2 - \mu^2} + \sum_{i=1}^{2} d_{10,i} \frac{M_Z}{M + \mu} \frac{M_Z m_\chi}{4 m_\chi^2 - m_{H_i}^2 + i m_{H_i} \Gamma_{H_i}} \right]. \tag{17}
\]

This form holds for both bino–like and higgsino–like LSP’s. The contribution \( \propto d_8 \) comes from the exchange of the heavier neutralinos, which occurs with full gauge strength but is suppressed by small propagators; the term \( \propto d_9 \) originates from neutralino mixing. In case of a bino–like LSP the coefficient \( d_8 \) is suppressed if \( \tan \beta \gg 1 \) and \( |\mu| \gg |M_1| \):

\[
d_{8,\text{bino}} = d_8 \frac{M_1 + \mu \sin 2\beta}{\mu}. \tag{18}
\]

This possible additional suppression is absent for the case of a higgsino–like LSP; in this case the amplitude also gets contributions from \( SU(2) \) gauge interactions, as do all other higgsino annihilation amplitudes.

This concludes our qualitative discussion of the annihilation matrix elements for the most important final states. In principle the heavier Higgs bosons \( H, P, H^\pm \) could also be produced in \( \chi\chi \) annihilation, either in pairs or in association with a gauge boson. However, we will see in the next subsection that in minimal supergravity models these heavy states are usually not accessible. We do therefore not discuss the relevant matrix elements here; of course, they are included in the list of matrix elements in Appendix A.
2c. The particle spectrum

The basic assumption of minimal Supergravity (SUGRA) models is that supersymmetry breaking can be described \[7\] in terms of just three parameters: A universal scalar mass \(m\), a universal gaugino mass \(M\), and a universal parameter \(A\) characterizing the strength of nonsupersymmetric trilinear scalar interactions. If the particle spectrum is restricted to that of the MSSM, which we always assume in this paper, one in addition has to introduce a supersymmetric contribution \(\mu\) to Higgs boson and higgsino masses; the masses \(\mu_1\) and \(\mu_2\) of the two Higgs doublets are then given by

\[
\mu_1^2 = \mu_2^2 = m^2 + \mu^2, \quad (19)
\]

while the Higgs mixing term \(\mu_3^2\) is given by

\[
\mu_3^2 = (A - m) \cdot m. \quad (20)
\]

This simple form of the particle spectrum is assumed to emerge after integrating out the fields of the “hidden sector” \[7\] where local supersymmetry is broken spontaneously. Since the decoupling of these fields occurs at the Planck or GUT scale the spectrum will be this simple only at ultra–high energies \(Q \geq M_X\); in particular, eq.(19) will only hold at these very high energies.

Of course, present day experiments, as well as DM annihilation, occur at much smaller energy scales. The particle spectrum at energies of the order of the weak or sparticle mass scale can be obtained by solving a set of coupled renormalization group equations (RGE)\[10\]; for given \(m, M, A, \mu\) and Yukawa couplings \(h_t, h_b\) (with \(h_b = h_\tau\) at the GUT scale), minimal SUGRA specifies the boundary conditions at \(Q = M_X\), which uniquely determine the particle spectrum at lower energies. In this scheme leading logarithms are automatically summed, i.e. all terms of order \((\alpha/\pi \ln M_X/M_Z)^n\) are automatically included, where \(\alpha\) is a generic gauge or Yukawa coupling. It has been recognized quite early \[10, 51\] that the radiative corrections described by the RGE can induce spontaneous breaking of the \(SU(2) \times U(1)_Y\) gauge symmetry by driving some combination of the squared Higgs mass parameters \(\mu_i^2\) of eq.(19) to negative values. This is due to the effect of the Yukawa couplings, which tend to reduce the squared masses of scalar fields. The Yukawa sector therefore plays a crucial role in these models.

In a recent paper \[32\] we studied radiative gauge symmetry breaking and the particle spectrum in minimal SUGRA in some detail, taking care to incorporate the effects of the Yukawa couplings of the \(b\) quark and \(\tau\) lepton, which can be quite important if \(|\tan\beta| \gg 1\). We later showed \[52\] how to incorporate the “finite” (i.e., without \(\ln M_X/M_Z\) enhancement) radiative corrections to the Higgs sector in this scheme. In particular we demonstrated that for most purposes these radiative corrections can be made negligibly small by a proper choice of the scale \(Q_0\) where the RG running is terminated; the only exception is the mass \(m_h\) of the light Higgs scalar where the corrections have to be included explicitly. (A similar result had been obtained previously in ref.\[53\].) For more details we refer the reader to these papers, as well as to earlier work on this subject \[10, 51\]; here we only give a brief summary of the relevant properties of the spectrum.

As stated above, the squared mass of all sfermions at the GUT scale is simply given by \(m^2\). In case of the superpartners of the first two generations the only sizable radiative
corrections to the masses involve the gauge interactions. The breakdown on \(SU(2) \times U(1)_Y\) gauge symmetry also has some effect on sfermion masses. All these contributions can quite easily be computed analytically; one has

\[
m_{\tilde{f}}^2 = m^2 + d_i M^2 + \cos 2\beta (I_{3,i} - Q_i \sin^2 \theta_W) M^2_Z,
\]

where \(I_{3,i}\) and \(Q_i\) are the third component of the weak isospin and electric charge of the sfermion \(\tilde{f}_i\), respectively. The positive constant \(d_i\) is determined by the gauge quantum numbers of the sfermion; numerically, it is about 6 for squarks, 0.5 for \(SU(2)\) doublet sleptons and 0.15 for \(SU(2)\) singlet sleptons with hypercharge 1.

The gaugino masses \(M_i\) are all equal to \(M\) at scale \(M_X\); their \(Q\) dependence is identical to that of the gauge couplings \(\alpha_i\):

\[
M_i(Q) = \frac{\alpha_i(Q)}{\alpha_i M_X} M,
\]

which immediately implies eq.(5). Numerically, \(M_3 \simeq 3M\), \(M_2 \simeq 0.84M\) and \(M_1 \simeq 0.43M\).

Eqs.(21) and (22) have been taken into account in some previous analyses [21, 22, 24, 25] of LSP relic densities. Unfortunately the effects of the Yukawa couplings are not so easily treated analytically. These effects are important for the masses of third generation sfermions as well as Higgs bosons. Indeed, Yukawa couplings affect sfermion masses already at tree level [49]; they lead to mixing between \(SU(2)\) doublet and singlet sfermions, and give rise to additional supersymmetric diagonal mass terms. These effects are especially important for stop squarks, which obviously have the largest Yukawa couplings; this has been included in the analysis of ref.[23]. However, for \(|\tan \beta| \gg 1\), sbottom and especially stau mixing also becomes important [32]. Moreover, the Yukawa couplings reduce the nonsupersymmetric diagonal mass terms from the values predicted by eq.(21). The net effect is that the lighter stop and stau eigenstates can be substantially lighter than the other squarks and sleptons, respectively; indeed, no strict lower bound on these masses could be given even if the masses of first generation sfermions were known. The maximal reduction of the light sbottom mass is not quite as large, but can still amount to \(20 - 30\%\) if \(|\tan \beta| \simeq m_t/m_b\). Since tree–level and loop effects tend to cancel for the heavier eigenstates of third generation sfermions, their masses are usually not very different from those of the corresponding sfermions of the first two generations.

The Yukawa couplings also affect the Higgs masses via the RGE; as explained above, this effect is at the heart of the radiative gauge symmetry breaking mechanism. First of all, it should be noted that the masses of the heavier Higgs bosons are related to the sfermion masses via eq.(19); this equation only holds at scale \(M_X\), but it shows that in SUGRA models one cannot treat Higgs boson and sfermion masses as independent free parameters. As well known [54], the masses of the \(P\), \(H\) and \(H^+\) states are essentially determined by \(m_P\), which is simply given by

\[
m_P^2 = \mu_1^2(Q_0) + \mu_2^2(Q_0);
\]

\(^\ast\)In our numerical calculations we use proper on–shell masses, i.e. \(m_{\tilde{f}_i} = m_{\tilde{f}_i}(Q = m_{\tilde{f}_i})\) and similar for gluinos. The coefficients in eqs. (21) and (22) then depend on the masses themselves, rather than being simple constants. This can change the masses of strongly interacting sparticles by as much as 20%; e.g. for 1 TeV gluinos, \(m_3 \simeq 2.5|M|\), rather than 3|M|. 

14
as discussed above, eq. (23) also holds to good approximation after inclusion of 1–loop radiative corrections if the scale \( Q_0 \) where the RG running is terminated is chosen properly, i.e. \( Q_0 \approx m_\tilde{q} \). Notice that only the Higgs doublet \( H_2 \) couples to top quarks; moreover, the requirement

\[
\langle H^0_1 \rangle^2 + \langle H^0_2 \rangle^2 = 2M_W^2/g^2
\]

immediately implies \( \mu^2(Q_0) > -M_Z^2/2 \). If the \( b \) and \( \tau \) Yukawa couplings are neglected, the nonsupersymmetric contribution to \( \mu^2 \) runs just like an \( SU(2) \) doublet slepton mass, i.e. it increases when going from \( Q = M_X \) to \( Q = Q_0 \); in addition the positive supersymmetric contribution \( \mu^2 \) has to be added \( \dagger \). This argument shows that \( m_P \) can only be smaller than the slepton masses if the \( b \) and \( \tau \) Yukawa couplings are sizable, i.e. if \( |\tan \beta| \gg 1 \). The exact numerical expression for \( m_P \) can be approximated by \( \S2 \):

\[
m_P^2 = \frac{M_\tilde{Z}^2}{2} (\cot \beta - 1) + \left( m^2 + 0.52 M^2 + \mu^2(Q_0) \right) \left( \frac{1}{\sin^2 \beta} - \frac{a^2}{\cos^2 \beta} \right),
\]

where \( a \approx 1/45 - 1/35 \) depends on the ratios \( M/m, A/m \) as well as on the top mass \( m_t \). \( \S2 \)

The mass of the lightest Higgs scalar \( h \) in general depends on all parameters of the model in a complicated way. However, in the important limit \( m_P^2 \gg M_\tilde{Z}^2 \) the situation simplifies greatly, and one finds \( \S2 \):

\[
m_h^2 = M_\tilde{Z}^2 \cos^2 2\beta + \Delta_{22} \sin^2 \beta + O \left( \frac{M_\tilde{Z}^2}{m_P^2}, \frac{m_b^2}{m_\tilde{t}^2} \right).
\]

Here \( \Delta_{22} \) describes the leading radiative corrections from top–stop loops. It grows like the fourth power of \( m_t \), but depends only rather mildly on the values of the SUSY breaking parameters; in the limit \( m_\tilde{q}^2 \gg m_\tilde{t}^2 \) it grows \( \propto \ln m_\tilde{q}/m_t \).

The SUGRA–imposed constraint that is most difficult to treat analytically follows from the almost obvious observation that in the radiative gauge symmetry breaking scenario the vevs of the Higgs fields can be computed from the input parameters at the GUT scale, i.e. \( \langle H^0_{1,2} \rangle \) are functions of \( m, M, A, \mu \) and the set of Yukawa couplings \( h_t, h_b, h_\tau \). The condition \( \S2 \) therefore leads to a relation between these parameters. This relation cannot be expressed in closed form once the effects from \( h_{b,\tau} \) are included, but it can approximately be written as \( \S2 \):

\[
\mu^2(Q_0) \simeq \frac{\tan^2 \beta + 1}{\tan^2 \beta - 1} X_2 - m^2 - 0.52 M^2 - M_\tilde{Z}^2/2, \tag{27}
\]

where \( X_2 \) describes the effect of the RG–running due to the top quark Yukawa coupling. An approximate expression for \( X_2 \) is

\[
X_2 \simeq \left( \frac{m_t}{150 \text{ GeV}} \right)^2 \left\{ 0.9 m^2 + 2.7 M^2 + \left[ 1 - \left( \frac{m_t}{190 \text{ GeV}} \right)^3 \right] (0.24 A^2 + MA) \right\}. \tag{28}
\]

\( \dagger \)Note that this is the square of the real parameter \( \mu \), which renormalizes multiplicatively; \( \mu^2 \) is therefore indeed always positive.

\( \S2 \)In ref. \( \S2 \) we gave a somewhat larger numerical value of \( a \), because we under–estimated the effect of the running of the \( b \) quark mass between \( Q_0 \) and \( m_b \). Since a smaller \( m_b(Q_0) \) also implies a larger upper bound on \( |\tan \beta| \), our results for sparticle masses, including \( m_\tilde{q} \), remain valid if one rescales \( \tan \beta \rightarrow 1.15 \tan \beta \) in the region \( |\tan \beta| \gg 1 \).

\( \S2 \)In ref. \( \S2 \) we gave a somewhat larger expression for \( X_2 \), since we had chosen a rather small value for \( Q_0 \), i.e. \( Q_0 = M_Z \); eq. (28) is valid for \( Q_0 \approx 300 \text{ GeV} \).
Eq. (27) usually works to 10% accuracy, but eq. (28) might deviate by as much as 20% from the exact numerical result; nevertheless these expressions are quite useful to gain some insight into the relation between the input parameters.

Strictly speaking, eq. (27) does not provide the searched-for relation between input parameters at scale $M_X$ on the one hand and $M_Z$ on the other, since it still depends on $\tan \beta$, which is itself a complicated function of the input parameters. (In fact, this is where the dominant effect from the other Yukawa couplings enters.) However, $\mu^2$ becomes essentially independent of $\tan \beta$ if $\tan^2 \beta \gg 1$, in practice for $|\tan \beta| > 3$ or so. Another complication arises because a given set of $m$, $M$, $A$ and $m_t$ often allows up to three different solutions of the equation that determines $\tan \beta$ (and hence the Yukawa couplings); these solutions differ in both sign and magnitude of $\tan \beta$. We therefore present results always for fixed $\tan \beta$, $M$ and $m$, rather than fixing the values of the SUSY breaking parameters. Since consistent solutions only exist for $h_t > h_b$, the allowed range of $\tan \beta$ in this model is restricted to $1 < |\tan \beta| < m_t/m_b$.

Unfortunately another two-fold ambiguity occurs when $\mu$ and $A$ are adjusted such that $M_Z$ and $\tan \beta$ have their desired values. In one of these solutions $\mu$ is of the order of $m$ and $M$. However, unless $m_t$ is very large there is also a second solution with $\mu^2 \ll m^2$, $M^2$; indeed, this is the “small $\mu$” solution which has been discussed in the first analyses of radiative gauge symmetry breaking. However, by now this kind of solution is quite severely constrained. First of all, we know from SUSY searches at LEP that $|\mu(Q_0)| > 40$ GeV; since these solutions typically have $|\mu|$ much smaller than $m$ and $M$, this constraint implies that most sparticles must be quite heavy for these solutions to be acceptable. Moreover, for $m_t > 155$ GeV the small$-\mu$ solutions disappear altogether, since then the effect of the top Yukawa coupling always drives $\mu^2(Q_0)$ below $-M_Z^2/2$ unless it receives a sizable, positive contribution $+\mu^2$, see eq. (19).

At this point some comments on fine tuning might be appropriate. It should be quite obvious that the “natural” scale for the vevs of the Higgs fields is set by the dimensionful parameters of the Higgs potential, which in turn are roughly of the order of typical sparticle masses, as can be seen from eqs. (23) and (27). Therefore some fine tuning of parameters will be necessary to achieve $M_Z^2 \ll m^2 + M^2$. This provides a strong argument that sparticles should not be much heavier than $O(1$ TeV), but this argument cannot be translated into strict upper bounds on sparticle masses. Since one of the motivations of this study is to see whether cosmology might provide us with such bounds, we do not impose any “a priori” upper bounds on the SUSY breaking parameters in our analysis. One might also argue that large ratios of the mass parameters of the model are “unnatural”, but the Yukawa sector shows that large ratios of “fundamental” parameters can indeed occur. Of course, one ultimately hopes to understand the origin of the dimensionful parameters $m$, $M$, $A$ and $\mu$ better, e.g. in the framework of superstring theories. However, at present it seems safer to pursue an “agnostic” approach, and try to cover the entire experimentally allowed parameter space.

In this scheme the sign of $\tan \beta$ is is determined dynamically via the RGE. On the other hand, the couplings listed in ref. 8 and 42 have been derived under the assumption $\tan \beta > 0$. Fortunately the masses and mixings of the neutralino and chargino eigenstates only depend on the sign of the product $M \cdot \mu \cdot \tan \beta$; a sign in $\tan \beta$ can therefore always be “rotated” into $M$ or $\mu$. 

16
This allowed region is defined via the following experimental constraints:

\[ m_{\tilde{\epsilon}_{R,L},\tilde{\tau}_1,\tilde{\chi}^\pm} > 45 \text{ GeV}; \]  
\[ m_{\tilde{\nu}} > 40 \text{ GeV}; \]  
\[ \sum_{i,j=1}^4 Br(Z \rightarrow \tilde{\chi}^0_i \tilde{\chi}^0_j) < 5 \cdot 10^{-5}; \]  
\[ \Gamma(Z \rightarrow \tilde{\chi}^0_1 \tilde{\chi}^0_1) < 12 \text{ MeV}; \]  
\[ m_{\tilde{g}} > 120 \text{ GeV}; \]  
\[ m_{\tilde{\tau}_1} \geq m_{\chi}. \]  

The bounds (29a)–(29d) directly follow from LEP limits on sparticle production [45] as well as on the invisible width of the Z boson; here \( \tilde{\chi}^\pm \) and \( \tilde{\chi}^0 \) stand for a generic chargino and neutralino state, with \( \tilde{\chi}^0_1 \equiv \chi \). The bound (29e) is a conservative interpretation of the preliminary CDF search limits [46] after inclusion of cascade decays [47]. Finally, (29f) follows directly from the requirement that the LSP should not be charged, as discussed in the introduction. Further experimental constraints follow from the unsuccessful search of Higgs bosons; we have incorporated a parametrization of the ALEPH bound [56] in our list of conditions.

In addition to imposing these experimental constraints, we also discard combinations of parameters that lead to deeper lying minima of the scalar potential that break charge and/or color; this requirement excludes combinations with \( A^2 / (m^2 + M^2) \gg 1 \) [57]. Finally, we demand that the scalar potential should be bounded from below at scale \( Q = M_X \), which implies \( \mu_1^2 + \mu_2^2 \geq 2|\mu_3^2| \); eq. (20) shows that this excludes the region

\[ \frac{|B|}{2} - \sqrt{\frac{B^2}{4} - 1} < |\mu(M_X)| < \frac{|B|}{2} + \sqrt{\frac{B^2}{4} - 1}, \]  

if \( |B| \equiv |A - m| \geq 2m \). This constraint is effective at small \( |\tan \beta| \), which implies large \( \mu \), see eq. (27), and thus large and positive squared Higgs mass parameters (21). One then needs large \( |A/m| \) to achieve spontaneous gauge symmetry breaking, since this accelerates the RG running of the mass parameters; however, large \( |B/m| \) also imply a large excluded region (30).

### 3. Examples

We are now in a position to present some numerical results. The discussion of sec. 2c showed that the model has 4 free parameters, which we chose to be \( m \), \( M \), \( m_t \) and \( \tan \beta \); \( \mu \) and \( A \) are then fixed by the equations describing the minimization of the Higgs potential, up to a possible discrete ambiguity. Without loss of generality \( m_t \) and \( m \) can be chosen to be positive, but \( M \) and \( \tan \beta \) can have either sign.

Figs. 1 a–d show a first partial exploration of the parameter space of the model. In these figures we have fixed \( m = 300 \) GeV, which leads to cosmologically interesting DM densities for a wide range of the remaining parameters. In addition, in each figure we have
kept $m_t$ and $\tan \beta$ fixed, and varied $M$. We find that for the chosen values of parameters only one experimentally allowed solution for $A$ and $\mu$ exists. Moreover, since in all these cases the mass of the LSP increases monotonically with $|M|$, we present our results as a function of $m_{\chi}$; this simplifies the identification of the various $s$–channel poles and of the thresholds where new annihilation channels open up. The starting point of all curves in figs. 1 is determined by the LEP constraints (29a), (29c) and (29d).

We see that in the limit of large $m_{\chi}$ all curves become almost identical. The reason is that in this case we always have $|\mu| > |M_1| \gg M_Z$, so that the LSP is bino–like. The dominant annihilation channel is then $\chi\chi \rightarrow l^+l^-$ via $\tilde{l}$ exchange, where $\tilde{l}$ is any lepton. Eq. (1) shows that squark exchange is suppressed [22] by their large mass (21), and the $\chi\chi$ dominant annihilation channel is then suppressed by powers of $\mu$. As discussed in sec. 2, the production of longitudinal gauge bosons $V_L$ and of the light Higgs boson $h$ are not suppressed by powers of $M_Z/m_\chi$, but are suppressed by powers of $|M_1/\mu| \simeq 1/4 - 1/2$ for the examples of figs. 1; moreover, all neutralino couplings relevant for these final states originate (either directly or via the equivalence theorem) from the Higgs–higgsino–gaugino $U(1)_Y$ gauge interaction, which involve fields with hypercharge $|Y| = 1/2$, while the $SU(2)$ singlet leptons have $Y = 1$. The gauge and Higgs boson final states therefore only contribute a few % in the region $m_{\chi} > 200 \text{ GeV}$ ($> 300 \text{ GeV}$ for the dashed curve in fig. 1c; see below).

The behaviour of the curves in this region can therefore be understood semi–quantitatively from the $\tilde{l}_R$ exchange contribution alone:

$$
\sigma_{\text{ann}} \propto \frac{m_\chi^2}{(m_{\tilde{l}_R}^2 + m_\chi^2)^2} \left[ \left( 1 - \frac{m_\chi^2}{m_{\tilde{l}_R}^2 + m_\chi^2} \right)^2 + \frac{m_\chi^4}{(m_{\tilde{l}_R}^2 + m_\chi^2)^2} \right],
$$

(31)

where the parenthesis results from the Taylor expansion of the propagator in powers of the velocity $v$. SUGRA predicts $m_{\tilde{l}_R}^2 \simeq m^2 + 0.83m_\chi^2$ for the given case of a bino–like LSP; see eqs. (27) and (28); eq. (31) then leads to a maximum of the annihilation cross section, i.e. a minimum of the relic density, at $m_{\chi} \simeq 0.6m \simeq 180 \text{ GeV}$ for the parameters of figs. 1. This maximum is very broad; the $\tilde{l}_R$ exchange contribution falls to 50% of its maximal value at $m_{\chi} \simeq 1.52m$, just beyond the end of the region shown in figs. 1. Indeed, in Figs. 1a,b, $\Omega h^2$ at $m_{\chi} = 430 \text{ GeV}$ is about twice as large as at the minimum. Eq. (11) also predicts the annihilation cross section to fall at small values of $m_{\chi}$, dropping to half the maximum value at $m_{\chi} \simeq 0.25m$. However, in many cases our assumption that $\tilde{l}_R$ exchange dominates the total annihilation cross section is no longer valid in this region.

Going towards smaller values of $m_{\chi}$, the first prominent structure one encounters is the $t\bar{t}$ threshold. It is most prominent for the dashed curve in fig. 1c, since this combination of parameters leads to the smallest value of $|\mu|$; for a given value of $M$, a smaller $|\mu|$ means larger higgsino admixtures to the LSP, see eq.(6a), and hence larger couplings to $h$ and $Z$ bosons. For most of cases shown in figs. 1 the contribution of the $t\bar{t}$ final state is suppressed by destructive interference between $\tilde{l}$ and $Z$ exchange contributions, which have approximately equal magnitude but opposite signs here. On the other hand, top production is not $p$–wave suppressed unless $m_{\chi} > m_t^2$, unlike the production of massless fermions. The importance of the $t\tilde{t}$ final state compared to light fermions is therefore enhanced by a relative factor $x_F/3 \simeq 10$, see eq.(4).
In the region below the $t\bar{t}$ threshold the differences between the various curves start to become more pronounced. Many of these differences can be understood from eqs. (27) and (28), which show that increasing $m_t$ and decreasing $\tan\beta$ both imply larger values of $\mu$, which leads to smaller couplings of the LSP to Higgs and gauge bosons, and suppresses contributions from the $t$–channel exchange of higgsino–like, heavier neutralinos. This explains why the $WW$ and $ZZ$ thresholds, as well as the minima at $m_\chi = M_Z/2$ and at $m_\chi = m_h/2$, are more prominent in fig. 1a than in 1b, and why $\Omega h^2$ at small $m_\chi$, where $Z$ exchange diagrams dominate the annihilation cross section, is considerably smaller in figs. 1c,d than in 1a,b. Moreover, $m_h$ increases with increasing $m_t$ and increasing $|\tan\beta|$, so that the position of the $h$–pole tends to move to larger values of $m_\chi$ as we go from fig. 1a to 1d.

The depth and width of the minimum at $m_\chi = m_h/2$ depends quite sensitively on the choice of parameters. Eq. (23) shows that in figs. 1 we always have $m_\chi^2 \gg M_Z^2$; in this limit the $h\chi\chi$ coupling [42] becomes for a bino–like LSP:

$$g_{h\chi\chi} = \frac{\alpha'}{2} \frac{M_Z \sin\theta_W (M_1 + \mu \sin2\beta)}{M_1^2 - \mu^2} + \mathcal{O} \left( \frac{M_Z^2}{M_1^2 - \mu^2}, \frac{M_Z^2}{m_P^2} \right).$$

(32)

Notice that the two terms in the numerator tend to cancel if $M_1 \cdot \mu \cdot \tan\beta < 0$; this explains why the minimum at $m_\chi = m_h/2$ is narrower and shallower for the dashed curves in figs. 1 than for the solid ones. However, we remind the reader that estimating $\Omega h^2$ from eqs. (1)–(3) can lead to large errors in the vicinity of a very narrow pole. A more careful treatment [37] would lead to shallower minima, which are broadened in the region below $m_h/2$; if $m_h > M_Z$, the relative maximum between the two minima should therefore also be somewhat lower than indicated in figs. 1. On the other hand, the $h$–pole clearly affects only a very limited region of parameter space; our overall conclusions do therefore not depend on an accurate treatment of this pole.

Finally, the strength of the $Z\chi\chi$ coupling also depends quite sensitively on the choice of parameters, including their signs. In this case the ordering of the curves for $M > 0$ and $M < 0$ even depends on $\tan\beta$. For $\tan\beta = 2$, a cancellation occurs [13, 14] in the neutralino (and chargino) mass matrix if $M_1 \cdot \mu \cdot \tan\beta > 0$; the LSP then has substantial higgsino components if $m_\chi \leq M_Z/2$. In contrast, for small $\tan\beta$ and $M_1 \cdot \mu \cdot \tan\beta < 0$ the LSP remains dominantly a gaugino even if $m_\chi$ is very small. On the other hand, for $M < 0$, $\tan\beta = 15$, $\mu(Q_0)$ is quite small due to a strong cancellation in the r.h.s. of eq.(27), especially for $m_t = 130$ GeV, fig. 1c. At larger $|M|$, i.e. larger $m_\chi$, this cancellation is less complete, but for this choice of parameters $\chi$ remains dominantly a higgsino for $m_\chi \leq 60$ GeV, and reaches 90% bino–content only for $m_\chi \geq 120$ GeV; for $M > 0$ and the same values of $m_t$ and $\tan\beta$, the LSP has already 97% bino–content at this mass. This explains why the two curves in fig. 1c differ quite strongly even at rather large values of $m_\chi$.

The strong dependence of some of the annihilation cross sections on the model parameters is further illustrated by fig. 2, which shows a blow–up (on a linear scale) of the $VV$ and $Zh$ threshold region for two of the curves of figs. 1. Both curves show small shoulders at the $WW$ and $ZZ$ thresholds. As explained above, these thresholds are somewhat less pronounced for the case $m_t = 160$ GeV, due to the larger value of $\mu$. However, since for fixed $m_\chi$, $\mu$ only increases by approximately 25% as $m_t$ is increased.
from 130 to 160 GeV, this effect is not very large; see also eq.\((\ref{13})\). This rather small change of parameters suffices, however, to reduce the $\chi\chi \rightarrow hh$ cross section by as much as a factor of 6! For $m_t = 130$ GeV, the exchange of the lighter, gaugino–like and heavier, higgsino–like neutralinos gives contributions of approximately equal size and equal sign to the matrix element. In other words, the terms $\propto d_8$ and $\propto d_9$ in eq.\((\ref{17})\) have about equal magnitude here; notice that the larger $SU(2)$ gauge coupling can only enter via $d_9$ in case of a bino–like LSP. Going to larger $m_t$ does not only increase $\mu$ for fixed $M$, it also increases $m_h$ via the radiative correction $\Delta_{22}$ of eq.\((26)\); this necessitates an increase of $M$, and thus a further increase of $\mu$, in order to reach the $hh$ threshold. The contributions $\propto d_9$ are therefore almost negligible for the dashed curve in fig.2. Indeed, the decrease of this curve after the maximum at $m_\chi = 62$ GeV has nothing to do with any thresholds; rather it is caused by the increase of the slepton exchange contribution to the $l^+ l^-$ final state, see eq.\((31)\). Finally, we remind the reader that a cancellation occurs in the contribution to the $hh$ final state from higgsino exchange if $M_1 \cdot \mu \cdot \tan \beta < 0$, see eq.\((18)\); this contribution is also suppressed for large $\tan \beta$ if $|\mu| \gg |M_1|$. The $hh$ threshold is therefore all but invisible in most curves in figs. 1.

It has been noted in ref.\([37]\) that our estimate of $\Omega h^2$ eqs.\((1)\)–\((3)\), becomes unreliable in the vicinity of a threshold for a final state which quickly dominates the total annihilation cross section. The example given there was exactly the $hh$ final state, which for certain combinations of parameters can dominate the total cross section by a large factor. However, we find that such a situation never occurs for bino–like or mixed LSP’s in minimal SUGRA; in this case the $hh$ threshold, as well as all other thresholds, is never much more pronounced than for the solid curve in fig. 2, and usually the thresholds are much less important, as can be seen from figs. 1. We do therefore not expect the error introduced by our approximate treatment to exceed 10% just below threshold, and it should be much smaller everywhere else.

So far we have concentrated on examples where the LSP is dominantly a bino, the exception being the dashed curve in fig. 1c. Since the LSP will only be higgsino–like if $|\mu| < |M_1| \simeq 0.43|M|$, one obviously needs quite large values of $|M|$ to get a higgsino–like LSP with mass substantially above $M_Z$. The SUGRA constraints then imply that one also needs large $m$, since for $M^2 \gg m^2$ eqs.\((27)\) and \((28)\) always yield $|\mu| \geq |M_1|$ for experimentally allowed values of $m_t$. In fig. 3 we have therefore chosen $m = 2$ TeV, and present results for two different choices of $M$ and $m_t$. In this figure, $\mu$, $A$ and $\tan \beta$ all vary along the $x$–axis, with $m_\chi \simeq |\mu|$. As in figs. 1, we see that $\Omega h^2$ is essentially independent of most parameters if the LSP is a heavy, almost pure state, here an almost pure higgsino. Of course, once $|\mu| > |M_1|$ the LSP will become bino–like again, and will thus have a very small annihilation cross section, since the very large $m$ implies very heavy sfermions; this explains the steep rise of the dashed curve at $m_\chi \simeq 430$ GeV.

Notice that this curve does not have a relative minimum in the region $|\mu| \simeq |M_1|$, even though here both the higgsino and gaugino components of the LSP are large; this seems to be in conflict with results of refs.\([18, 26]\). However, in our case eq.\((23)\) implies that all Higgs bosons except $h$ are very heavy, so that most final states containing Higgs bosons are not accessible; moreover, contributions from $P$–exchange in the $s$–channel are suppressed, even though the $P \chi \chi$ coupling is large for a mixed LSP. The $\chi \chi \rightarrow f \bar{f}$ cross section does show a maximum in the region where $\chi$ is a mixed state, due to the
contributions from $Z$ and $h$ exchange, but this is not sufficient to compensate the rapid decrease of the $VV$ and $Zh$ cross sections.

For $m_\chi < M_W$ the annihilation of higgsino–like LSP’s is dominated by $Z$–exchange diagrams. Eqs.\((14)\) and \((j)\) show that $g Z_{\chi \chi} \propto M_Z^2/\mu M_1$ in this case; the $\chi \chi$ annihilation cross section is therefore about 4 times smaller for $M = 2$ TeV than for $M = -1$ TeV. However, the results of fig. 3 are quite misleading in this region. We had already mentioned above that eqs.\((1)\)–\((3)\) are not valid \([37]\) close to a threshold where a new channel opens up which quickly dominates the total annihilation cross section, as is the case for the $WW$ threshold here; this is because we ignored the possibility that LSP’s with mass below $M_W$ can annihilate into $WW$ pairs if they have sufficient kinetic energy. Therefore we have overestimated the relic density in the region just below and at the $WW$ threshold.

Moreover, as already discussed in sec. 2b, a light higgsino–like LSP always implies the existence of a second higgsino–like state $\chi'$ whose mass is quite close to that of the LSP. Since the $Z\chi\chi'$ coupling is not suppressed, unlike the $Z\chi\chi$ coupling, the $\chi\chi'$ co-annihilation cross section is much larger than $\sigma_{\text{ann}}(\chi\chi)$, see eq.\((12)\). Furthermore, $\chi\chi'$ co-annihilation is not $p$–wave suppressed even if the final state fermions are massless. Using the formalism of ref.\([37]\), we estimate that inclusion of $\chi\chi'$ co-annihilation would reduce $\Omega h^2$ by a factor

$$K \simeq \left(1 + \frac{\epsilon^2}{3} e^{-x_F \Delta} \right) \bigg(1 + e^{-x_F \Delta} \bigg)^2 .$$

(33)

Here $\Delta \equiv |(m_3 - |m_4|)/\mu|$ is given by eq.\((8)\) and $\epsilon$ by eq.\((7)\). The exponential factor describes the Boltzmann suppression of the $\chi'$ density at freeze–out; we find $x_F \simeq 25$ in this case. The factor of $x_F/3$ in front of the second term in the numerator of eq.\((33)\) has been included to estimate the $s$–wave enhancement (or, more accurately, lack of $p$–wave suppression) of the co-annihilation process, and the 2 is a statistics factor \([37]\). Numerically we find $K \simeq 4 \, (80)$ for $|M| = 1$ TeV and $|\mu| = 50 \, (80)$ GeV; for $|M| = 2$ TeV the corresponding numbers are 230 and 1500, respectively. Of course, these estimates could easily be off by a factor of 2 or so; nevertheless, taken together with sub–threshold $\chi\chi$ annihilation into $W$ pairs, these large suppression factors allow us to conclude that the relic density of higgsino–like LSP’s will always be uninterestingly small unless $m_\chi \geq 500$ GeV or so.\(^*$

\(^*$Of course, co–annihilation will also occur for $m_\chi > M_W$; indeed, the relative mass splitting $\Delta$ between the higgsino states, and hence the Boltzmann suppression of the co-annihilation contribution, will be (much) smaller than for light higgsinos. On the other hand, $\sigma_{\text{ann}}(\chi\chi')$ should not be much bigger than $\sigma_{\text{ann}}(\chi\chi)$ in this case, since $\sigma_{\text{ann}}(\chi\chi)$ is dominated by annihilation into a pair of gauge bosons, which occurs with full gauge strength; in the region $m_\chi > M_W$ co–annihilation should therefore not change the result of fig. 3 much.

We had seen in figs. 1 that over a wide region of parameter space the relic density of a heavy, bino–like LSP depends only very little on $m_t$, $\tan \beta$ and the sign of $M$. However, as already pointed out in ref.\([32]\), this is no longer true for very large values of $|\tan \beta|$. This is illustrated in fig. 4, where we show $\Omega h^2$ as a function of $\tan \beta$ for fixed $m$, $M$ and $m_t$; the parameters are chosen such that $\chi$ is bino–like. The full line shows the SUGRA prediction including the contributions from the $b$ and $\tau$ Yukawa couplings to the neutralino–fermion–sfermion interactions as well as to the RGE. These latter contributions reduce $m_P$, as
shown in eq.\((25)\); they also reduce the masses of the lighter $\tilde{b}$ and $\tilde{\tau}$ eigenstates by mixing between $SU(2)$ singlet and doublet states, and by reducing the diagonal entries of their mass matrices.

Fig. 4 shows that both these effects are quite important. When $\tan\beta$ is increased sufficiently, one eventually has $m_P = 2m_{\chi_i}$; for the parameters of fig. 4 this happens at $\tan\beta \approx 35$. This results in a very strong enhancement of the $\chi\chi \rightarrow b\tilde{b}$, $\tau^+\tau^-$ cross sections via the exchange of a pseudoscalar Higgs boson. Note that the $Pb\tilde{t}$ and $P\tau^+\tau^-$ couplings increase $\propto \tan\beta$, so that the total decay width $\Gamma_P \propto \tan^2\beta$. For $\tan\beta = 35$ the mass to width ratio of $P$ is therefore similar to that of the $Z$ boson, so that our estimate of $\Omega h^2$ should be quite reliable even in the pole region $^{37}$.

The long dashed curve has been obtained by artificially keeping $m_P$ constant at the value SUGRA predicts for $\tan\beta = 2 \left(\approx 780 \text{ GeV}\right)$; this also implies that $m_{H^+}$ and $m_H$ are kept (approximately) constant. However, the $\tilde{b}$ and $\tilde{\tau}$ masses are still allowed to vary with $\tan\beta$ as predicted by SUGRA, and the Yukawa contributions to the neutralino couplings are included; we see that this suffices to reduce $\Omega h^2$ by approximately a factor of 3 at the largest allowed value of $\tan\beta$. The reduction of $m_{\tilde{\tau}_i}$ is the dominant effect here, since for the given choice of $m$ and $M$ the $\tilde{b}$ squarks are almost twice as heavy as the $\tilde{\tau}$ sleptons, and have smaller hypercharge. Because for the given choice of parameters one has $m_{\tilde{\chi}}^2 \ll m_{\tilde{f}}^2$, the annihilation cross section is essentially proportional to $\sum_i Y_{i\chi}^4/m_{i\chi}^4$ here, where $i$ is a generation index; at small $\tan\beta$, all three generations contribute almost equally, but for large $\tan\beta$ the sum is dominated by the contribution from the 3rd generation. The reduction of $\Omega h^2$ by a factor of 3 then corresponds to a reduction of $m_{\tilde{\tau}_i}$ by only a factor of 1.63. An even larger reduction of the $\tilde{\tau}$ mass is not possible here since a further increase of $\tan\beta$ would lead to $m_P^2 < 0$; as shown in ref.\(^{22}\), this constraint implies $|\tan\beta| \leq m_t(Q_0)/m_b(Q_0)$. Finally, the short dashed curve has been obtained by ignoring all effects from the $b$ and $\tau$ Yukawa couplings; it is a few % above the other curves even at small $\tan\beta$ since the effects of sfermion mixing are not entirely negligible even here. We see that in this case, which approximates the usual analyses based on a global SUSY model with independent sparticle masses at the weak scale, $\Omega h^2$ does indeed only depend very little on $\tan\beta$.

Using the insight gained from figs. 1–4 it is now quite straightforward to interpret the contour plots of figs. 5 and 6. Each of these figures is for fixed values of $m$ and $m_t$ and for a given choice of the signs of $M$ and $\tan\beta$. In figs. 5 a–d we choose $m = 250 \text{ GeV}$, $m_t = 140 \text{ GeV}$, and explore the plane of $M$ and $\tan\beta$ for all 4 combinations of signs. Solid and long dashed lines are contours of constant $\Omega h^2 = 1$ and 0.25, respectively. The short dashed curves in fig. 5a are lines of constant $\Omega h^2 = 0.025$; since these contours cluster very narrowly around the $Z$, $h$ and $P$ poles, in the other figures we have merely indicated the position of these poles with the short dashed lines.

Finally, the region outside the dotted curves is excluded by the experimental and theoretical constraints discussed at the end of sec. 2c. In the region of small $|M|$ the most important constraints are the LEP search limits \((29a)–(29d)\) as well as the gluino mass bound \((29f)\); for small $|\tan\beta|$ the LEP limit on the production of the light scalar Higgs boson also plays a role. The lower bound on $|\tan\beta|$ is determined by the Higgs search bound as well as the requirement that the Higgs potential should be bounded from below even at the GUT scale, as discussed in sec. 2c below eq.\((30)\). The region of large
$|\tan\beta|$ and small and moderate values of $|M|$ is limited by the LEP bounds on associate $hP$ production, which is practically equivalent to requiring $m_P^2 > 0$ here, since the overall mass scale ($m$) is chosen quite high in these figures. Finally, in the region of large $|M|$ (or, more accurately, large $|M/m|$) the parameter space is limited by the requirement of a neutral LSP, eq. (29f); this bound is especially important for large $|\tan\beta|$, since $m_{\tilde{\tau}_1}$ is smaller there, as discussed in connection with fig. 4.

The gross features are the same in all 4 figures. At large $|M|$, $\Omega h^2$ exceeds 1, as already shown in figs. 1; this also happens at small $|\tan\beta|$ and small $|M|$, below the $Z$ and $h$ poles. Finally, there is a third region where the $\chi$ relic density is unacceptably large, covering the region between the $Z$ and $h$ poles and the $VV$, $Zh$ and $hh$ thresholds at small and moderate values of $|\tan\beta|$. The extension of these last two excluded regions does depend on the signs of $M$ and $\tan\beta$, however. We have already seen that the contribution from $h$ exchange and the annihilation cross section into the $hh$ final state are much smaller if $M_1 \cdot \mu \cdot \tan\beta < 0$, fig. 5b,c; in this case the line $\Omega h^2 = 0.25$ can even cross the $h$ pole. Moreover, for $|M| \leq 300$ GeV negative values of $\tan\beta$ (figs. 5b,d) require rather large, positive values of $A_1$; if in addition $M > 0$, $X_2$ of eq. (28) and hence $|\mu|$ become large, leading to small higgsino components of the LSP and thus large values of $\Omega h^2$ in fig. 5b. In fig. 5d we have $M < 0$, however, which results in a partial cancellation in $X_2$ and much smaller values of $|\mu|$; together with sizable contributions from $h$ exchange and $hh$ production this explains the smallness of the cosmologically excluded region for this choice of signs. On the other hand, small or moderately positive values of $\tan\beta$ imply $A_1 \simeq 0.5$ in the region $|M| \leq m$, reducing the impact of this parameter on $X_2$ and $\mu$; furthermore, choosing $M > 0$ now results in larger contributions from the light Higgs boson. The differences between figs. 5a and 5c in the experimentally allowed region are therefore smaller than those between figs. 5b and 5d.

Because of the cancellation in the neutralino mass matrix discussed in connection with figs. 1, LEP constraints from neutralino searches lead to a more stringent limit on $|M|$ if $M_1 \cdot \mu \cdot \tan\beta > 0$; this explains why the experimentally allowed, but cosmologically excluded region of small $|M|$ is larger in figs. 5b,c than in 5a,d. Finally, as shown in ref. [32], one can only achieve $|\tan\beta| \gg 1$ for sizable values of $\mu$ if $A > 0$, and usually $A > m_1$; choosing $M < 0$ then reduces the effect of the Yukawa coupling on the running of scalar masses, as exemplified by $X_2$, eq. (28). Somewhat paradoxically, this reduces $m_P$, because in the relevant limit $\tan^2\beta \gg 1$ eqs. (26) and (27) imply $m_P^2 \propto X_2$. A smaller $X_2$ also implies smaller $\mu$ and hence less stau mixing, which again increases $m_{\tilde{\tau}_1}$. altogether we thus see that choosing $M < 0$ leads to smaller values of $m_P$ and larger $m_{\tilde{\tau}_1}$ in the region of large $|\tan\beta|$. The region of parameter space to the right of the $P$ pole that is allowed by the requirement $m_\chi \leq m_{\tilde{\tau}_1}$ is therefore somewhat larger for $M < 0$, figs. 5b,d, than for $M > 0$, 5a,c. One even finds another smaller region with $\Omega h^2 > 0.25$ at very large $|\tan\beta|$ and $M \simeq -800$ GeV.

In figs. 6 we have chosen $M$ and $\tan\beta$ to be positive, and study the effects of varying $m_t$ (figs. 6a,b) or $m$ (6c,d). We have already seen that increasing $m_t$ increases $|\mu|$ and thus also $\Omega h^2$ if $\chi$ is bino–like. Indeed we find larger cosmologically excluded regions in fig. 6a than in fig. 5a. Moreover, the fraction of the plane with $M < 200$ GeV where $\Omega h^2 > 0.25$ is now much larger than before. This partly due to the increase of the mass of the light Higgs boson caused by the increase of $\Delta_{22}$ in eq. (20). For $\tan\beta \geq 5$ the $h$
and $Z$ poles are now sufficiently far apart to allow for a new region with cosmologically interesting DM density in between these poles. Larger values of $|\mu|$ also imply more $\tilde{\tau}$ mixing, which reduces $m_{\tilde{\tau}_1}$; at the same time increasing $|\mu|$ implies larger values of $m_P$, see eq. (25). The neutral LSP constraint (29f) therefore does no longer allow to choose $|\tan\beta|$ so large that $m_P \simeq 2m_T$, except for a small stretch at $M \simeq 130$ GeV; the effect of the reduction of $m_P$ and $m_{\tilde{\tau}_1}$ at large $\tan\beta$ is nevertheless still quite pronounced in fig. 6a. Finally we mention that the requirement that the top Yukawa coupling remains finite up to scale $M_X$ implies $|\tan\beta| \geq 2$ for $m_t = 170$ GeV.

Reducing $m_t$ from 140 to 110 GeV, fig. 6b, has obviously the opposite effect as increasing it to 170 GeV. $|\mu|$ is now so small that the whole region of small and moderate $|M|$ is cosmologically safe; however, this also implies larger couplings of the lighter neutralino states to the $Z$ boson, so that the LEP search limits rule out a much larger part of the plane than in fig. 5a. (Recall that the signs of the parameters are such that cancellations occur in the determinant of the neutralino mass matrix.) We already saw in fig. 2 that the $hh$ contribution depends very sensitively on $M$, $\mu$ and $\tan\beta$; in the given case it is large enough to create a small “island” with $\Omega h^2 < 0.25$ at $\tan\beta \simeq 2$, $M \simeq 200$ GeV. Moreover, for given values of $M$ and $\tan\beta$, $m_{\tilde{\tau}_1}$ is now larger and $m_P$ is smaller than in fig. 5a, so that a sizable region of parameter space to the right of the $P$ pole is again allowed, including a substantial region where $\Omega h^2 > 0.25$. The relatively light pseudoscalar here even affects the cosmologically excluded region at very large $M$, leading to a much steeper slope of the uppermost solid line than in fig. 5a. Finally, the reduction of $|\mu|$ also implies that the requirement (30) of a bounded Higgs potential at scale $M_X$ now excludes a large region of parameter space at large $|M|$ and small $\tan\beta$.

In figs. 6c,d we have again chosen $m_t = 140$ GeV, but have varied $m$ compared to the value of fig. 5a. A larger $m$ means larger sfermion masses and hence smaller contributions from sfermion exchange diagrams, which are dominant at large $|M|$, as we have seen above. Indeed, we see that the uppermost contour with $\Omega h^2 = 1$, which (at least for small $|\tan\beta|$) occured essentially in the same place in the previous 6 figures, depends very strongly on $m$: For $m = 400$ GeV the cosmologically safe region above the $VV$, $Zh$ and $hh$ thresholds has disappeared completely; on the other hand, for $m = 125$ GeV, fig. 6d, all experimentally allowed combinations of $M$ and $\tan\beta$ give $\Omega h^2 < 1$, so that the requirement that the relic LSP density should not overclose the universe doesn’t constrain the parameter space any further. Recall that an increase of $m$ also implies an increase of $|\mu|$ via eq. (27); this explains the differences in the region of small $M$, below and around the $h$ pole, between figs. 5a, 6c and 6d, even though sfermion exchange contributions are essentially negligible here. Finally, for $m = 125$ GeV we observe a region with very small relic density, $\Omega h^2 < 0.25$, in approximately the same place that leads to $\Omega h^2 > 1$ for $m = 250$ GeV; this once again demonstrates the strong dependence of the contributions from gauge and Higgs final states on the parameters of the model.

This concludes our discussion of samples of the parameter space of the model. We now attempt to derive bounds on sparticle masses or model parameters from computations of the DM density.
4. Bounds

We have seen in the previous section that very heavy LSPs tend to have small annihilation cross sections. This is not surprising, since unitarity requires the cross section to fall off at least like \(1/m^2\) as \(m_\chi \to \infty\), for fixed values of the other parameters. Indeed, we see from figs. 5 that for given \(m\) and \(m_t\) the requirement \(\Omega h^2 \leq 1\) imposes an upper bound on \(|M|\). Moreover, in the important case of a bino–like LSP away from all \((Z\) and Higgs) poles, the resulting bound depends essentially only on \(m\) and \(m_\chi\), as shown in figs. 1, 5 and 6.

The SUGRA relations for sfermion masses (22) imply that the sfermions with the largest hypercharge, the superpartners \(\tilde{t}_R\) of the right–handed leptons, also have the smallest masses; they will therefore dominate the annihilation cross section unless \(M^2 \ll m^2\), as already pointed out in the previous section. From eqs.(22) and (31) and the numerical result of figs. 1 that \(\Omega h^2 \simeq 1\) for \(m = 300\) GeV, \(m_\chi = 180\) GeV if \(\chi\) is bino–like, one then derives the approximate bound

\[
\frac{\left( m^2 + 1.83m_\chi^2 \right)^2}{m_\chi^2 \left[ \left( 1 - \frac{m_\chi^2}{m^2 + 1.83m_\chi^2} \right)^2 + \left( \frac{m_\chi^2}{m^2 + 1.83m_\chi^2} \right)^2 \right]} \leq 1 \cdot 10^6 \text{ GeV}^2;
\]

(34)

this bound is only valid for a bino–like LSP away from poles. We already mentioned in the previous section that for fixed \(m\) the l.h.s. of (34) has a minimum at \(m_\chi = 0.6m\). Plugging this into the bound (34) gives

\[
m \leq 300 \text{ GeV}
\]

(35)

for any value of \(m_\chi\); this can also be read off figs. 1. Similarly, for given \(m_\chi\) the l.h.s. of (34) is minimized by choosing \(m\) as small as allowed by the constraint \(m_{\tilde{t}_R} \geq m_\chi\), i.e. for \(m^2 + 0.83m_\chi^2 = m_\chi^2\). This immediately gives the bounds

\[
m_\chi \leq 350 \text{ GeV};
\]

(36a)

\[
|M| \leq 825 \text{ GeV},
\]

(36b)

for any \(m\). The bound (36a) is considerably stronger than the bound of 550 GeV given in ref.[18], because in that paper all sfermions were allowed to have mass \(m_{\tilde{f}} = m_\chi\), which is not possible in minimal SUGRA. In particular, a light stop greatly enhances the annihilation into \(t\bar{t}\) pairs, which also makes a sizable contribution to the \(s\)–wave, \(O(v^0)\) cross section.

We emphasize again that the bounds (34) – (36) only hold for a bino–like LSP away from poles. In particular, the bound (34) on \(m\) can be violated even for small \(|\tan \beta|\) if \(m_\chi\) is close to \(M_Z/2\) or \(m_h/2\), see fig. 6c; in this case no useful bound on \(m\) can be given. Moreover, figs. 5 and 6 show that for a given combination of \(m\), \(m_t\) and \(\tan \beta\), the upper bound on \(|M|\) is weakest in the region close to the \(P\) pole, if \(m \geq 150\) GeV. More precisely, \(|M|\) reaches its maximal allowed value at the point where the contour for \(\Omega h^2 = 1\) (which has a positive slope with increasing \(|\tan \beta|\)) meets the line \(m_{\tilde{\tau}_1} = m_\chi\) (which has a negative slope). The location of this crossing point obviously depends on how large \(m_{\tilde{\tau}_1}\), \(m_P\) and the \(P\chi\chi\) coupling \(g_{P\chi\chi}\) are for a given choice of \(M\) and \(\tan \beta\). We have
already mentioned in the previous section that both $|\mu|$ and $m_P$ grow with increasing $X_2$, eq. (28). Moreover, choices of parameters that maximize $X_2$ also maximize the reduction of the diagonal elements of the $\tau$ mass matrix due to the effect of the $\tau$ Yukawa coupling on the RGE. Finally, increasing $|\mu|$ further reduces $m_{\tilde{\tau}_1}$ by increasing $\tilde{\tau}_L - \tilde{\tau}_R$ mixing, and reduces $g_{P\chi\chi}$ by reducing the higgsino component of $\chi$, see eq.(6a). Combinations of parameters that increase $X_2$ therefore push the $P$ pole to larger values of $|\tan\beta|$, and also make it narrower and shallower; at the same time they strengthen the upper bound on $|\tan\beta|$ that results from the requirement $m_{\tilde{\tau}_1} \geq m_{\chi}$. The combined effect of these changes is to move the crossing point of the lines $m_{\tilde{\tau}_1} = m_{\chi}$ and $\Omega h^2 = 1$ to smaller $|M|$ and smaller $|\tan\beta|$.

We already discussed in connection with figs. 5 that in the region of large $|\tan\beta|$ one has $A > 0$, so that $X_2$ is smaller for $M < 0$ than for $M > 0$. The absolute bound on $|M|$ for given $m$ and $m_t$ is therefore reached if $M$ and $\tan\beta$ are both negative, see fig. 5d. The resulting upper bound on $|M|$ as a function of $m$ is shown in fig. 7 for three different choices of $m_t$. For $m \leq 125$ GeV the upper bound on $|M|$ only comes from the requirement $m_{\tilde{\tau}_1} \geq m_{\chi}$; for these small values of $m$ the constraint (34) is satisfied even for the extreme case $m_{\chi} = m_{\tilde{l}_R}$. Here the maximal allowed $|M|$ occurs at rather small values of $|\tan\beta|$, where $m_{\tilde{\tau}_1} \simeq m_{\tilde{l}_R}$ only depends on $m$ and $M$; for small $m$ the bound on $|M|$ is therefore almost independent of $m_t$. However, once the condition $\Omega h^2 \leq 1$ starts to impose nontrivial constraints on the allowed parameter space, the bound on $|M|$ comes from the region of large $|\tan\beta|$ and does depend quite strongly on $m_t$. For light top quark and thus small $X_2$ (short dashed curve), the DM constraint reduces $|M|_{\text{max}}$ only marginally from the value of 5.7$m$ that follows from the simple requirement $m_{\tilde{l}_R} > m_{\chi}$. On the other hand, if the top quark is very heavy (long dashed curve), a relatively large ratio $|m/M|$ is needed to get sufficiently close to the $P$ pole without reducing $m_{\tilde{\tau}_1}$ below $m_{\chi}$. Finally, $|M|_{\text{max}}$ also depends quite sensitively on the chosen combination of signs; for instance, if $M$ and $\tan\beta$ are both positive one finds $M < 2150$ (1210, 620) GeV for $m = 500$ GeV and $m_t = 110$ (140, 170) GeV, respectively.

The rise of the curves in fig. 7 cannot persist indefinitely. Right on the pole, for $m_{\chi} = m_P/2$, the annihilation cross section is proportional to $g_{P\chi\chi}^2/\Gamma_P^2$. The decay width $\Gamma_P$ is proportional to $m_P$, and thus also to $m_{\chi}$; moreover, the $P\chi\chi$ coupling decreases $\propto 1/m_{\chi}$ if $\chi$ is bino–like, see eq.(6a). As a result, the annihilation cross section for a bino–like LSP on the $P$ pole decreases $\propto 1/m_{\chi}^4$. We estimate that $\Omega h^2$ will be larger than 1 even right on the pole if $m_{\chi} \geq 3.5$ (1.7) TeV for $m_t = 140$ (170) GeV. If the top quark is lighter, one can arrange $m_{\chi} = m_P/2$ even for a mixed LSP, i.e. if $|M_1| \simeq |\mu|$. In this case $g_{P\chi\chi}$ is not suppressed by small mixing angles, which increases the cross section by a factor $(m_{\chi}/M_Z)^2$ compared to the case of a bino–like LSP. The relic density of a mixed LSP with $m_{\chi} = m_P/2$ will therefore only exceed 1 if $m_{\chi} > \mathcal{O}(100)$ TeV or so! One can hardly speak of “weak scale” supersymmetry if the lightest superparticle is thousand times heavier than the weak gauge bosons; in particular, the model can no longer provide a solution of the naturalness problem.

It can be argued that finetuning is needed to achieve $|\tan\beta| \gg 1$, because this occurs only over a narrow range of values of $A$. Moreover, in minimal supersymmetric $SU(5)$ the proton decay width increases $\propto \tan^2\beta$, since in this model proton decay is mostly mediated by the exchange of superheavy higgsinos, whose Yukawa couplings grow $\propto \tan\beta$.
|tanβ|; large values of |tanβ| are then disfavored (although “accidental” cancellations might still lead \[58\] to an acceptable nucleon lifetime even if |tanβ| ≫ 1). Fig. 7 therefore also includes curves (dotted) where we have required |tanβ| ≤ 15. This rather mild constraint does not affect the curve for \(m_t = 110\) GeV at all, but for a heavier top quark it leads to a substantial reduction of \(|M|_{\text{max}}\). Since \(m_\chi \simeq m_P/2\) is no longer possible in this case, the only possibility to achieve large values of \(|M|\) is to choose parameters such that the LSP is higgsino–like.

We have already seen in fig. 3 that the relic density of such a state is quite small. By extrapolation of the curves of this figure it is clear that a higgsino–like LSP is cosmologically safe up to \(m_\chi = 2\) TeV at least; this has already been shown in refs. \[18\] and \[19\]. The LSP will obviously only be higgsino–like if \(|M|_{\text{max}} \simeq 0.43|M| \geq |\mu|\), but this requirement might clash with the constraints imposed by radiative gauge symmetry breaking, eqs.\((27)\) and \((28)\). Clearly \(\mu^2(Q_0)\) can be minimized by choosing \(A\) such that \(X_2\) is minimal, \(A \simeq -2.08M\). For \(\tan^2\beta \gg 1\), eqs.\((27)\) and \((28)\) then give the following lower bound on \(|\mu|\):

\[
\mu^2(Q_0) \geq m^2 \left[ 0.9 \left( \frac{m_t}{150 \text{ GeV}} \right)^2 - 1 \right] + M^2 \left\{ \left( \frac{m_t}{150 \text{ GeV}} \right)^2 \left[ 2.7 - 1.04 \left( 1 - \left( \frac{m_t}{190 \text{ GeV}} \right)^3 \right) \right] - 0.52 \right\}. \tag{37}
\]

Notice that the coefficient of \(M^2\) is positive for \(m_t \geq 95\) GeV; it surpasses \((M_1/M)^2 \simeq 0.18\) for \(m_t \geq 95\) GeV, i.e. in almost the entire experimentally allowed region. The condition for having a higgsino–like LSP, \(|\mu(Q_0)| \leq |M_1|\), is therefore most easily fulfilled if \(|M|\) (and thus \(|M_1|\)) is itself very small. However, the coefficient of \(m^2\) in eq.\((37)\) also turns positive for \(m_t > 158\) GeV. For such a heavy top quark a higgsino–like LSP can therefore not be realized in minimal SUGRA. For this reason the lower dotted curve in fig. 7, which is valid for \(m_t = 170\) GeV, is essentially just given by the bound \((34)\) in the region where DM constraints are relevant and the condition \((33)\) is fulfilled; for \(m > 300\) GeV this curve simply follows the \(h\) pole, \(m_\chi \simeq 0.43|M| \simeq m_h/2\).

For \(m_t = 140\) GeV (upper dotted curve) a higgsino–like LSP is still possible provided \(|M/m| \leq 0.5\) or so. The actual bound on \(|M|\) is in many cases substantially above this value since for moderately large \(m\) the total \(\chi\chi\) annihilation cross section is still sufficiently large even if the higgsino component of \(\chi\) is sub–dominant; in particular the contribution from the \(t\bar{t}\) final state plays an important role here. However, increasing \(m\) decreases the sfermion exchange contribution to the total annihilation cross section; this has to be compensated by increasing the higgsino content of \(\chi\), i.e. by reducing \(|\mu/M|\), which via eq.\((37)\) reduces the bound on \(|M/m|\). As a result the bound on the absolute value of \(|M|\) is almost independent of \(m\) for \(400\) GeV ≤ \(m\) ≤ \(1\) TeV; for even larger values of \(m\) the LSP can be an almost pure higgsino even for \(M > 0.5\) TeV, and one has \(|M|_{\text{max}} \simeq 0.6m\). Finally, we mention that a further sharpening of the bound on \(|\tan\beta|\), e.g. requiring \(|\tan\beta| \leq 5\), would suppress the bound on \(|M|\) for \(m_t = 140\) GeV to a value very close to the one for \(m_t = 170\) GeV. This is because solutions with \(\mu^2 \ll m^2\) always have \(\tan^2\beta \gg 1\), unless one has \(|A| \gg m\); however, eqs.\((27)\) and \((28)\) show that large \(|A/m|\) require \(|\mu|\) to be larger than \(|M_1|\), unless \(m_t\) is near its present lower bound \([59]\) of
91 GeV.

This completes our discussion of possible upper bounds on mass parameters of the model that can be derived from the requirement $\Omega h^2 \leq 1$. What about lower bounds? In principle the bound (34) also implies a lower bound on the mass of a bino–like LSP if $m$ is fixed within the region allowed by the limit (35). Recall, however, that these bounds are only valid if $\chi$ is a nearly pure bino and $m_\chi$ is not close to a pole. Both these conditions can be violated quite easily especially if $m_\chi$ is not large. Indeed, figs. 5 and 6 show that for most combinations of $m$, $m_t$ and $\tan \beta$ the lower bound on $|M|$ is determined from laboratory search limits alone, the exception being the region of small $|\tan \beta|$ and $m > 200$ GeV. In particular, inclusion of the DM constraint does not strengthen the bound $m_\chi > 20$ GeV that follows [48] from the combination of the gluino, chargino and neutralino search limits.

On the other hand, we have seen in fig. 6d that the LSP relic density becomes quite small if $m$ is small, for all experimentally allowed combinations of the remaining parameters. Imposing an upper bound on $m$ therefore leads to an upper bound on $\Omega h^2$; conversely, requiring the neutralino relic density to be larger than some minimal value can give a lower bound on $m$. We have already seen that for fixed $m$ the annihilation cross section of a bino–like LSP becomes small both at very small and at very large $m_\chi$. In the experimentally allowed [48] region $m_\chi \geq 20$ GeV and for $m \leq 140$ GeV, $\Omega h^2$ is maximized if $|M|$ is chosen as large as is allowed by the condition $m_{\tilde l_R} \geq m_\chi$. Since $m_{\tilde l_R}$ decreases at large $|\tan \beta|$, $\Omega h^2$ will be maximal at small values of $|\tan \beta|$ where all three $SU(2)$ singlet sleptons are essentially mass degenerate. On the other hand, $m_{\tilde l_R} = m_\chi$ allows $M^2 \gg m^2$, which means that all other sparticles will be too heavy to contribute significantly to the annihilation cross section, so that eq.(31) applies. Normalizing the cross section from numerical results of fig. 1 as before, we find

$$\Omega h^2 \leq 0.47 \left( \frac{m}{100 \text{ GeV}} \right)^2 + 0.085,$$

where the constant term comes from the $D-$term contribution to $m_{\tilde l_R}$, which can be significant for small values of $m$; we have checked numerically that the true bound deviates from (38) by only 10% or so. For $m > 140$ GeV the maximum of $\Omega h^2$ for fixed $m$ is reached if $m_\chi$ is at its experimental lower bound; however, in this region eq.(38) already allows $\Omega h^2 \geq 1$ anyway.

As discussed above, the bound (38) is saturated if $m_\chi = m_{\tilde l_R}$, which implies $m_\chi = 2.42 m$ or $M = 5.7 m$; all sparticle masses would then be substantially larger than $m$. We have therefore also studied the question how an upper bound on a physical sparticle mass affects the upper bound on $\Omega h^2$. We find that fixing the mass of the gluino, of the lighter stop, or of the lightest neutralino or chargino state does not induce a significant upper bound on $\Omega h^2$. On the other hand, we have seen repeatedly that $SU(2)$ singlet sleptons have an important effect on the LSP relic density. Since bino–like LSPs annihilate predominantly via $\tilde l_R$ exchange, a light $\tilde l_R$ implies a small neutralino relic density; this has already been observed by Roszkowski [33].

If $\chi$ is a pure bino, the annihilation cross section (31) is minimized and $\Omega h^2$ is maximized for given $m_{\tilde l_R}$ if $m_\chi$ is as small as experimentally allowed [48], $m_\chi = 20$ GeV. For small $m_\chi$ and correspondingly small $|M|$ the mass splitting between sfermions need not
be large; the contributions from all \( f \bar{f}_R \) final states will then have to be included in eq. (31), properly weighted with the fourth power of the hypercharge of the exchanged sfermion, and with the sfermion masses given by eq. (22). The resulting prediction for the maximum of \( \Omega h^2 \) as a function of \( m_{\tilde{\ell}} \) is shown by the dotted curve in fig. 8. The other curves in this figure are results from numerical scans of the entire allowed parameter space, using the program MINUIT of the CERN program library.

We see that the extended version of eq. (31) does describe the overall trend of the numerical results; however, the deviation from the full numerical bounds can be as large as a factor of 2 here. In particular, for small values of \( m_{\tilde{\ell}} \), \( \Omega h^2 \) can be substantially larger than one would expect for a pure bino. This occurs if \( \chi \) is a light, strongly mixed state. Such a light state exists [43] if \(|M|\) and \(|\mu|\) are both \( O(M_Z) \) and \( M_1 \cdot \mu \cdot \tan \beta > 0 \). In this case the \( SU(2) \) and \( U(1)_Y \) components of \( \chi \) can have opposite signs (unlike the familiar case of a photino); moreover, the squared bino component of this state only amounts to typically 50%. As a result, its couplings to charged sleptons are strongly suppressed [43]. On the other hand, such a state always has sizable higgsino components and thus couples to gauge and Higgs bosons. For \( m_t \geq 130 \) GeV and present experimental bounds on sparticle masses the suppression of the slepton masses is the more important effect if \( m_{\tilde{\ell}} \leq 150 \) GeV; since the existence of such a light mixed LSP also implies [43] a rather light chargino the actual numerical value of the upper bound on \( \Omega h^2 \) is in this region largely determined by the LEP chargino and neutralino search limits (29a) and (29c). For \( m_{\tilde{\ell}} > 150 \) GeV the enhancement of the \( Z\chi\chi \) and \( h\chi\chi \) couplings over–compensates the suppression of the couplings to sleptons; in this case choosing \( \chi \) to be bino–like does indeed maximize \( \Omega h^2 \), and the full numerical result comes out quite close to the simple approximation based on eq. (31).

The curve for \( m_t = 110 \) GeV looks quite different from those for larger values of \( m_t \). One reason is that for \( m_{\tilde{\ell}} \leq 75 \) GeV the Higgs search limits now force one to choose \(|\tan \beta|\) substantially larger than 1; this increases the \( Z\chi\chi \) coupling, which vanishes for \(|\tan \beta| = 1 \). In this region \( \Omega h^2 \) is therefore again maximized by choosing \( \chi \) to be bino– or photino–like. For larger values of \( m_{\tilde{\ell}} \), the constraints imposed by the Higgs search limits are less severe, since the Higgs boson masses tend to increase with the overall SUSY breaking scale; for \( 80 \) GeV \( \leq m_{\tilde{\ell}} \leq 130 \) GeV the curve for \( m_t = 110 \) GeV is therefore close to those for a heavier top quark. However, for even larger values of \( m_{\tilde{\ell}} \), \( \Omega h^2 \) is maximized for such small values of \(|M/m|\) that radiative gauge symmetry breaking with a light top quark can only be achieved if \( |A/m| \) is quite large, which greatly reduces the mass of the lighter stop eigenstate; the bound \( m_{\tilde{\ell}} \geq 45 \) GeV then rules out large regions of parameter space, causing the curve for \( m_t = 110 \) GeV to again fall below those for larger values of \( m_t \) if \( m_{\tilde{\ell}} > 130 \) GeV.

In all cases we find that the upper bound on \( \Omega h^2 \) for light \( \tilde{\ell}_R \) is determined not only by \( m_{\tilde{\ell}} \) itself, but also by the experimental bounds on the masses of the other sparticles and Higgs bosons. This dependence is further illustrated by the long–short dashed curve in fig. 8, which is valid for \( m_t = 140 \) GeV after we impose the (hypothetical) bounds \( m_{\tilde{\ell}} \geq 80 \) GeV and \( m_\tilde{g} \geq 200 \) GeV. This is meant to approximate the bounds that would emerge if LEP200 and the tevatron fail to find evidence for supersymmetry (other than perhaps light sleptons). The constraints from searches for Higgs bosons and neutralinos will also become more severe in the next few years, but the final bounds depend quite strongly
on the energy and luminosity that will be achieved in the LEP upgrade. The increased bound on the chargino mass excludes a mixed LSP unless \( m_\chi \geq 40 \text{ GeV} \), which is quite close to the \( Z \) pole; the upper bound on \( \Omega h^2 \) is therefore now always saturated if \( \chi \) is a bino– or photino–like state. The increased lower bound on the gluino mass implies \( m_\chi \geq 35 \text{ GeV} \) for such a state, see eq.\((23)\): this enhances the annihilation cross section by approximately a factor of 2, compared to the present bound \( m_\chi \geq 20 \text{ GeV} \). Since \( \chi \) is now always gaugino–like, the bound that can be derived from eq.\((31)\) reproduces the long–short dashed curve to an accuracy of about 20%.

5. Summary and Conclusions

In this paper we have computed the relic density \( \Omega h^2 \) of LSPs produced during the Big Bang, within the framework of minimal \( N = 1 \) Supergravity models with radiative gauge symmetry breaking. In sec. 2 we briefly described the calculation of the relic density for a given LSP annihilation cross section. We then discussed the various contributions to this cross section, including final states composed of gauge and Higgs bosons that become accessible for a “heavy” LSP, \( m_\chi > M_W \). Expressions for all these cross sections are given in the Appendix, for a general neutralino eigenstate; to our knowledge such a complete list does not exist in the literature. In sec. 2b we discussed the qualitative features of the most important contributions to the annihilation cross section for the important special cases that the LSP is an almost pure higgsino or bino. In particular, we pointed out that, even though the higgsino component of a bino–like LSP vanishes as \( m_\chi \rightarrow \infty \), the matrix elements for \( \chi \chi \rightarrow VV \) and \( \chi \chi \rightarrow VH \) remain finite, where \( V = W, Z \) and \( H \) is a Higgs boson. This is because of the enhanced production of longitudinal gauge bosons; the same result can also be derived from the equivalence theorem.

In sec. 2c we briefly summarized the constraints imposed on the particle spectrum by the assumption of minimal supergravity (SUGRA). The relations between the masses of the gauginos and those of the superpartners of the light quarks and leptons are by now well known, and have been included in several previous analyses \([21, 22, 23, 24]\). However, SUGRA also implies relations between the mass of the top quark and the soft breaking parameters on the one hand, and the masses of the Higgs bosons as well as the supersymmetric Higgs(ino) mass parameter \( \mu \) on the other; these relations had previously only been included \([27, 25]\) for the case that the SUSY breaking gaugino mass \( M \) is much larger than the scalar mass \( m \) at the GUT scale. We saw in our numerical examples of sec. 3 that these relations can have large effects on the relic density. In particular, we found that the coupling of a bino–like LSP to gauge and Higgs bosons is usually suppressed for a heavy top quark and/or large \( m \), since increasing \( m_t \) or \( m \) tends to increase \( |\mu| \), which in turn reduces the higgsino component of \( \chi \). This strongly affects \( \Omega h^2 \) both in the pole region \( (m_\chi \simeq M_Z/2) \) and in the threshold region \( (m_\chi \simeq M_Z) \). Moreover, as already pointed out in ref.\([32]\), \( \Omega h^2 \) is greatly reduced if the ratio \( \tan \beta \) of the vevs of the two Higgs bosons is large, since this implies large \( b \) and \( \tau \) Yukawa couplings, and thus a light pseudoscalar Higgs boson \( P \) and reduced masses for the light \( \tilde{b} \) and \( \tilde{\tau} \) eigenstates.

The relations between particle masses and neutralino couplings imposed by SUGRA also imply that the region of parameter space where the LSP density can lead to a flat
universe \((0.25 \leq \Omega h^2 \leq 1)\), as predicted by inflationary models, has a very complicated shape, since the \(\chi \chi\) annihilation cross section depends on all input parameters; the same is true for the region where LSPs can at least provide the DM halo of galaxies \((\Omega h^2 \geq 0.025)\). Nevertheless it is clear from the results of sec. 3 that a cosmologically interesting relic density is obtained quite naturally, provided that \(\chi\) is gaugino–like and the SUSY breaking parameter \(m\) is not too small. If \(\chi\) is higgsino–like and \(m_\chi > M_W\), \(\chi \chi\) annihilation into pairs of gauge bosons is so strong that cosmologically interesting values of \(\Omega h^2\) only occur \([18,19]\) for \(m_\chi > 0.5\) TeV. Since in minimal SUGRA the gluino as well as most squarks are at least 6 times heavier than the LSP, requiring \(m_\chi > 0.5\) TeV leads to quite severe fine tuning \([35,16]\) and is thus unattractive. The \(\chi \chi\) annihilation cross section for higgsino–like \(\chi\) can be quite small below the \(WW\) threshold if the gaugino mass \(|M|\) is large; however, using results of ref.\([37]\) we estimated that in this case co–annihilation of \(\chi\) with the next–to–lightest neutralino \(\chi'\) will suppress \(\Omega h^2\) to a value well below 0.25, since the off–diagonal \(Z\chi\chi'\) coupling is large, and since co–annihilation can proceed from an \(s\)–wave initial state. We therefore conclude that the higgsino does not make a very attractive DM candidate in minimal SUGRA models.

Unfortunately we saw in sec. 4 that the complicated shape of the region of parameter space that yields \(\Omega h^2 \leq 1\) makes it difficult to derive interesting upper bounds on mass parameters from the requirement that relic neutralinos do not overclose the universe. In particular, \(m\) can be almost arbitrarily large, and thus all sfermions and most Higgs bosons can be very heavy, if \(m_\chi \simeq M_Z/2\) or \(m_\chi \simeq m_h/2\), where \(h\) denotes the light scalar Higgs boson. In this case the gluino, the lighter chargino and the next–to–lightest neutralino would still lie in the region accessible to the next generation of accelerators \((m_{\tilde{g}} \leq 500\) GeV, \(m_{\tilde{\chi}^\pm,\chi} \leq 150\) GeV). However, if \(|\tan\beta|\) is large, \(m_P\) can be greatly reduced so that \(m_\chi\) can be close to \(m_P/2\). Since \(P\) exchange mediates \(\chi \chi\) annihilation from an \(s\)–wave state, \(\Omega h^2\) is greatly suppressed in this case, allowing both \(m\) and \(|M|\) to be well beyond 1 TeV without getting in conflict with cosmology. If the top quark is not very heavy, \(m_t \leq 155\) GeV, cosmologically safe solutions with very large \(m\) and \(|M|\) also exist for small \(|\mu|\), so that the LSP is higgsino–like. In this case one would still have a “light”, almost degenerate \(SU(2)\) doublet of higgsinos, but all other particles would be very heavy. Since the mass splitting could be as small as \(O(1\) GeV\)), such light higgsinos would probably be very difficult to observe even at \(e^+e^-\) colliders \([60]\). This scenario is therefore very similar to the case of a very large \(m_\chi\) as far as collider experiments are concerned. We have to conclude that the requirement \(\Omega h^2 \leq 1\) does not strictly exclude the possibility that sparticle masses are well beyond the reach even of the planned supercolliders.

On the other hand, interesting upper bounds can be obtained for the “generic” case of a bino–like LSP away from poles. We found that in this case the total annihilation cross section is dominated by the \(l^+l^-\) final state produced via \(\tilde{l}_R\) exchange \((l = e, \mu, \tau)\). Contributions from \(\tilde{l}_L\) exchange and \(\tilde{q}\) exchange are suppressed by the larger masses and smaller hypercharges of these sfermions, while the contribution from \(Z\) exchange is suppressed by the small \(Z\chi\chi\) coupling. We mentioned earlier that the \(VV\) and \(Zh\) final states also contribute with full gauge strength if the LSP is sufficiently heavy, but the relevant hypercharge here is the one of the Higgs bosons, leading to a suppression factor of 1/16 compared to the \(\tilde{l}_R\) exchange contribution. This allowed us to derive the very simple and yet quite accurate expression \([31]\) for the total annihilation cross section, leading
to the analytically derived bounds (35) and (36). In particular, we find for this case an upper bound $m_\tilde{g} \leq 2$ TeV, which is only slightly less stringent than the bound derived from the requirement that fine tuning should occur at most at the 10% level; the corresponding bound on $m_\chi$ is considerable more stringent than the one that follows under similar assumptions [15] in a more general SUSY model. Our bound $m \leq 300$ GeV is potentially even more interesting, since this value is below the one derived from fine tuning arguments; together with the bound on $m_\tilde{g}$ it would virtually guarantee that at least the sleptons, the light chargino and the next-to-lightest neutralino should be observed at a TeV $e^+e^-$ supercollider. However, we have to remind the reader that there are several ways to evade these bounds.

As first pointed out in ref. [22] and also emphasized in refs. [23, 24], the LSP relic density can only lead to a flat universe with $0.5 \leq h \leq 1$ if $m$ is not too small. We quantified this in the simple relation (38), which shows that $\Omega h^2 \geq 0.25$ is only possible for $m \geq 40$ GeV. (In ref. [24] the more stringent bound $m \geq 100$ GeV has been found, but this is only valid for $m_\chi \leq M_W$.) Furthermore, requiring $\Omega h^2 \geq 0.25$ also implies a lower bound on the mass of $SU(2)$ singlet sleptons. The exact value of this bound depends on the top mass, as well as on the bounds on the masses of other sparticles and Higgs bosons, but it is always close to 100 GeV, see fig. 8. We thus see that requiring $0.25 \leq \Omega h^2 \leq 1$ determines $m_{\tilde{g}}$ to be within a factor of 2 of 200 GeV, if the LSP is gaugino–like and not near a pole. Unfortunately, in this case LEP200 will fail to discover a slepton. This has already been pointed out in ref. [22] for a light LSP, but at least within the framework of SUGRA models this conclusion also holds $m_\chi \geq M_W$. (Of course, we need $m_\chi \leq m_{\tilde{g}}$ always.) On the other hand, the gaugino mass parameter $M$ is only poorly determined by the requirement that $\Omega h^2$ lies in the cosmologically interesting range, since the annihilation cross section is almost independent of $M$ over a wide range, see figs. 1. In particular, the gluino, the squarks, the lighter chargino and at least one neutralino could all lurk “just around the corner”, but their masses could also lie in the range that can only be covered by supercolliders.

Our overall conclusion is that, while limits on the relic neutralino density allow to rule out large regions of parameter space, they do not allow to derive upper bounds on sparticle masses which are both interesting for experiments at existing or planned colliders and valid for all combinations of the other parameters. On the other hand, results for the perhaps most natural case of a gaugino–like LSP do indicate that sparticle masses should lie in the range to be covered by planned $e^+e^-$ and $pp$ supercolliders. Moreover, if the dark matter in our galaxy does indeed consist of neutralinos, one would expect their mass to lie within the range of sensitivity [11] of next–generation direct search experiments and [62] of experiments looking for neutralino annihilation in the sun, although a strict lower bound on the expected signal size is again difficult to derive. Cosmological arguments can therefore supplement and lend support to direct SUSY searches at collider experiments.

Acknowledgements

We thank K. Hikasa for sharing his expertise in the calculation of helicity amplitudes with us, as well as for many useful discussions. M.M.N. thanks the theory group at KEK, and M.D. the theory group at SLAC and the Institute of Particle Physics Phenomenology in
Appendix A: Matrix elements

Since we are interested in the nonrelativistic limit of the $\chi\chi$ annihilation cross section, we employ the partial wave formalism. In this formalism the helicity amplitude for the process

$$\chi(h) + \chi(\bar{h}) \rightarrow X(\lambda_X) + Y(\lambda_Y)$$  \hspace{1cm} (A.1)

($h, \bar{h}, \lambda_X$ and $\lambda_Y$ are the helicities of the corresponding particles) is expanded as follows:

$$T = \sum_{L=0}^{\infty} \sum_{S=0}^{L+1} \sum_{J=|L-S|}^{L+S} A^{(2S+1)L_J}(2S+1L_J)\mathcal{P}d^J_{\lambda_i,\lambda_f}. \hspace{1cm} (A.2)$$

Here the reduced partial wave amplitude $A$ describes annihilation from an initial state with definite spin $S$ and orbital angular momentum $L$, and thus also with definite $C$ and $P$ quantum numbers. The spin projectors $\mathcal{P}$ depend only on $h$ and $\bar{h}$, and the angular dependence is contained in the $d$ functions $d^J_{\lambda_i,\lambda_f}$. $\lambda_i = h - \bar{h}$ and $\lambda_f = \lambda_X - \lambda_Y$ are the differences of the helicities of the initial and final particles, respectively. Because our initial state consists of two identical Majorana fermions, we only need to consider initial states with $C = 1$. Furthermore, since we want to expand the total annihilation cross section only up to $O(v^2)$, only annihilation from $s$– and $p$–wave initial states has to be included. Altogether we thus find that we need to include only the contributions from the $1S_0$, $3P_0$, $3P_1$ and $3P_2$ initial states; explicit expressions for the relevant $\mathcal{P}$ can be found in ref.[63]. The annihilation cross section is then given by

$$\sigma(\chi\chi \rightarrow XY)v = \frac{1}{48\pi sS} \left\{ |A(1S_0)|^2 + \frac{1}{3} \left[ |A(3P_0)|^2 + |A(3P_1)|^2 + |A(3P_2)|^2 \right] \right\}. \hspace{1cm} (A.3)$$

Here $v$ is the the relative velocity of initial neutralinos and $s$ is the total energy. $S$ is a symmetry factor which is 2 when $X = Y$. The summation over the final helicities is implicit in this equation. Finally, the kinematical factor $\bar{\beta}_f$ is given by

$$\bar{\beta}_f = \sqrt{1 - \frac{2m_X^2 + m_Y^2}{s} + \left( \frac{m_X^2 - m_Y^2}{s^2} \right)^2}. \hspace{1cm} (A.4)$$

In this Appendix we list the helicity amplitudes $A^{(2S+1)L_J}$ for all two–body final states accessible to $\chi\chi$ annihilation in leading order in perturbation theory. We first list some couplings which appear in many matrix elements:

$$O_{0j}^L = - \frac{1}{\sqrt{2}} N_{04}V_{j2} + N_{02}V_{j1} \hspace{1cm} (A.5a)$$

$$O_{0j}^R = \frac{1}{\sqrt{2}} N_{03}U_{j2} + N_{02}U_{j1} \hspace{1cm} (A.5b)$$

$$Q_{0j}^L = N_{04}V_{j1} + \frac{1}{\sqrt{2}} (N_{0j} + N_{01}\tan \theta_W)V_{j2} \hspace{1cm} (A.5c)$$
\[ Q_{0j}^{SR} = N_{03}U_{j1} - \frac{1}{\sqrt{2}}(N_{02} + N_{01} \tan \theta_W)U_{j2} \quad \text{(A.5d)} \]
\[ O_{0j}^{\prime L} = -\frac{1}{2}N_{03}N_{j3} + \frac{1}{2}N_{04}N_{j4} \quad \text{(A.5e)} \]
\[ Q_{0j}^{\prime} = \frac{1}{2} \left[ N_{03}(N_{j2} - \tan \theta_W N_{j1}) + (0 \leftrightarrow j) \right] \quad \text{(A.5f)} \]
\[ S_{0j}^{\prime} = \frac{1}{2} \left[ N_{04}(N_{j2} - \tan \theta_W N_{j1}) + (0 \leftrightarrow j) \right] \quad \text{(A.5g)} \]

The expressions for \( O_L \), \( O_R \) and \( O''_L \) are the same as in ref. [6]; our definitions for \( Q_L^{\prime} \), \( Q_R^{\prime} \), \( Q^{\prime} \) and \( S^{\prime} \) differ slightly from those of ref. [42]. \( U \) and \( V \) are the matrices that diagonalize the chargino mass matrix \( \mathcal{M}^\pm \), which is given by:
\[ \mathcal{M}^\pm = \begin{pmatrix} M_2 & M_W \sqrt{2} \sin \beta \\ M_W \sqrt{2} \cos \beta & \mu \end{pmatrix}. \quad \text{(A.6)} \]

The matrices \( U \) and \( V \) can be chosen to be real:
\[ U = \begin{pmatrix} \cos \phi_- & \sin \phi_- \\ -\sin \phi_- & \cos \phi_- \end{pmatrix}, \quad V = \begin{pmatrix} \cos \phi_+ & \sin \phi_+ \\ -\sin \phi_+ & \sin \phi_+ \end{pmatrix}. \quad \text{(A.7)} \]

In the limit where either \( |M_2| \) or \( |\mu| \) is much larger than \( M_W^2 \), the chargino mass eigenstates are almost identical to the current states. The (small) mixing angles then become:
\[ \phi_- = \frac{\sqrt{2}M_W}{M_2^2 - \mu^2} (M_2 \cos \beta + \mu \sin \beta); \quad \text{(A.8a)} \]
\[ \phi_+ = \frac{\sqrt{2}M_W}{M_2^2 - \mu^2} (M_2 \sin \beta + \mu \cos \beta). \quad \text{(A.8b)} \]

The \( N_{ij} \) in eqs. (A.3) are elements of the matrix that diagonalize the neutralino mass matrix, eq.(4); as already discussed in sec. 2b, it also becomes almost diagonal if \( |M_2| \) or \( |\mu| \) is very large, see eqs.(6). Unlike refs.[1] and [12], we do not require the chargino and neutralino masses to be positive; \( N_{ij} \) can therefore also chosen to be real. We have checked by explicit calculation that this still preserves all relative signs in our amplitudes, provided we keep the sign of the fermion masses everywhere. Finally, the suffix zero in eqs.(A.5) refers to the lightest neutralino, \( \chi \).

The coupling of the neutral Higgs bosons to neutralinos can be expressed in terms of \( Q'' \) and \( S'' \) [12]:
\[ T_{P0j} = -\sin \beta Q_{0j}^{''} + \cos \beta S_{0j}^{''}; \quad \text{(A.9a)} \]
\[ T_{10j} = -\cos \alpha Q_{0j}^{''} + \sin \alpha S_{0j}^{''}; \quad \text{(A.9b)} \]
\[ T_{20j} = \sin \alpha Q_{0j}^{''} + \cos \alpha S_{0j}^{''}; \quad \text{(A.9c)} \]
\[ T_{20j} = \sin \alpha Q_{0j}^{''} + \cos \alpha S_{0j}^{''}; \quad \text{(A.9d)} \]

Here the labels \( P \), 1, and 2 refer to the pseudoscalar, and the heavier and lighter neutral scalar; \( \alpha \) in eqs.(A.9) is the mixing angle of the neutral scalar Higgs bosons as defined in ref.[12], including leading one-loop radiative corrections.
Finally, we define some kinematical quantities and propagators:

\[
\Delta^2 = \frac{m_X^2 + m_Y^2}{2m_\chi}; \quad (A.10a)
\]

\[
P_I = 1 + R_I^2 - \frac{R_X^2 + R_Y^2}{2}; \quad (A.10b)
\]

\[
R_X = m_X/m_\chi, \quad R_Y = m_Y/m_\chi, \quad R_I = m_I/m_\chi. \quad (A.10c)
\]

Here, \(m_I\) is the mass of an exchanged particle, and \(P_I\) the \(v \to 0\) limit of the inverse of the corresponding \(t\) or \(u\) channel propagator.

We are now ready to list the partial wave amplitudes of the contributing processes. As mentioned above, we only need the nonrelativistic limit of the annihilation cross section, i.e. its expansion in powers of \(v\) up to and including terms of \(O(v^2)\). However, this expansion breaks down \([37]\) in the vicinity of poles and thresholds, since there the “higher order” terms can actually diverge. In our expressions below we therefore only include those terms of order \(v^2\) that result from the expansion of well-behaved functions of \(v\). Specifically, we include terms that result from the expansion of \(t\)– and \(u\)–channel propagators, as well as terms that result from the calculation of spinors or bosonic wave functions. On the other hand, we do not expand the kinematical function \(\beta_f\), nor \(s\)–channel propagators.

Of course, far away from the threshold or pole, these terms can be expanded safely. This can be incorporated into our matrix elements by the following substitutions:

\[
\bar{\beta}_f \to \bar{\beta}_f(v = 0) + \frac{v^2}{8\beta_f(v = 0)} \left[ \Delta^2 - \frac{(m_X^2 - m_Y^2)^2}{8m_\chi^4} \right]; \quad (A.11a)
\]

\[
\frac{1}{4 - R_I^2} \to \frac{1}{4 - R_I^2} \left( 1 - \frac{v^2}{4 - R_I^2} \right). \quad (A.11b)
\]

Clearly, these substitutions should only be used in the \(O(v^0)\) terms of the \(^1S_0\) amplitudes. Because of the suppression factor \(3/x_F\) in the expression \([3]\) for \(\Omega h^2\), as well as the smallness of the the numerical factors in eq.\((A.11a)\), the numerical effect of these substitutions is only sizable in cases where the expansion itself can no longer be trusted; in this case only the much more complicated methods described in ref.\([41]\) give reliable results. Since a more careful treatment of poles and thresholds will not change our conclusions, we do not pursue this avenue here. It should be noted that the \(O(v)\) terms that result from the expansion of \(t\)– and \(u\)–channel propagators can, e.g., change the annihilation cross section into \(f\bar{f}\) final states by a factor of two; fortunately the \(O(v)\) terms are always regular.

We list contributions with different final state helicities separately; all these contributions have to be added incoherently, as shown in eq.\((A.3)\).

1) \(\chi\chi \to W^-(\lambda)W^+(\bar{\lambda})\)

This final state receives contributions from the exchange of the two chargino eigenstates (labelled by \(j\)) in the \(t\)– or \(u\)–channel, as well as from the exchange of the two neutral

*Far away from the pole, the propagator can be taken to be real.
scalar Higgs bosons (labelled by $i$) as well as the $Z$ boson in the $s$–channel. In the following expressions, summation over subscripts ($i, j, \ldots$) that appear more than once is always understood.

\[ A(^1S_0) : \lambda_f = 0, \lambda = \pm 1 \]

\[
2\sqrt{2} \beta_f g^2 \frac{O_{ij}^L + O_{ij}^R}{P_j} + \sqrt{2} v^2 \beta_f g^2 \left\{ \frac{2 R_i^+}{3 P_j^2} O_{ij}^L O_{ij}^R + 2 \left[ \frac{1}{4} - \frac{4}{3 P_j} + \frac{2 \beta_f^3}{3 P_j^2} \right] \right\}
\]

\[ A(^3P_0) : \lambda_f = 0, \lambda = 0 \]

\[
\frac{\sqrt{6} v^2}{R_W^2} \left\{ -4 \frac{O_{ij}^L + O_{ij}^R}{P_j} + 4 \frac{O_{ij}^L O_{ij}^R R_i^+}{P_j} \left[ 1 - \frac{2}{3 P_j} \right] \right\}
\]

\[ \lambda_f = 0, \lambda = \pm 1 \]

\[
\frac{\sqrt{6} v^2}{R_W^2} \left\{ \frac{O_{ij}^L + O_{ij}^R}{P_j} \left[ \frac{1}{3} - \frac{2 \beta_f}{3 P_j} \right] - \frac{2 O_{ij}^L O_{ij}^R R_i^+}{P_j} \left[ 1 - \frac{4}{3 P_j} \right] \right\} + \frac{\sqrt{6} v^2 R_W F_i}{4 - R_H^2 + i G_H}
\]

\[ A(^3P_1) : |\lambda_f| = 1, \]

\[
\frac{2 \beta_f^2}{R_W} \left\{ \frac{O_{ij}^L + O_{ij}^R}{P_j} \left[ 1 - \frac{1}{P_j} \right] - \frac{2 O_{ij}^L O_{ij}^R R_i^+}{P_j^2} \right\}
\]

\[ \lambda_f = 0, \lambda = 0 \]

\[
\frac{2 v^2}{R_W P_j^2} (3 - \beta_f^2) g^2 (O_{ij}^L - O_{ij}^R) - \frac{4 v^2 \beta_f g^2 O_{ij}^L}{(4 - R^2) R_W} (3 - \beta_f^2)
\]

\[ \lambda_f = 0, \lambda = \pm 1 \]

\[
\frac{2 v^2}{P_j^2} g^2 (O_{ij}^L - O_{ij}^R) - \frac{4 v^2 \beta_f g^2 O_{ij}^L}{4 - R^2} \]

\[ A(^3P_2) : |\lambda_f| = 2 \]

\[
- \frac{2 \sqrt{2} v}{P_j^2} g^2 (O_{ij}^L + O_{ij}^R)
\]

$|\lambda_f| = 1$
\[ \frac{2v g^2}{R_W} \left\{ -R_j^+ P_j^2 (O_{0j}^L + O_{0j}^R) + 2O_{0j}^L O_{0j}^R R_j^+ \beta_j^2 + \lambda_f \beta_j^3 (O_{0j}^L - O_{0j}^R) \right\} \]  
(A.12h)

\[ \lambda_f = 0, \lambda = \pm 1 \]

\[ \frac{2v g^2}{\sqrt{3}} (O_{0j}^L + O_{0j}^R) \frac{1 - R_j^2 - R_j^2}{P_j^2} \]  
(A.12i)

\[ |\lambda_f| = 0, \lambda = 0 \]

\[ \frac{4v g^2}{\sqrt{3}R_W} \left\{ -O_{0j}^L + O_{0j}^R \left[ 1 - \beta_j^2 \frac{R_W^2}{P_j^2} \right] + 4\beta_j^2 O_{0j}^L O_{0j}^R R_j^+ \right\} \]  
(A.12j)

Here, the \( R \) are the rescaled masses of exchanged or final state particles, see eq.A.10c), and we have introduced the rescaled widths

\[ G_{H_i} = \frac{\Gamma_{H_i m_{H_i}}}{m^2_\chi}. \]  
(A.13)

The definition of the \( P_j \) is as in eq.(A.10b), and the \( F_i \) are given by [42]:

\[ F_1 = \cos(\beta - \alpha)T_{100}, \quad F_2 = \sin(\beta - \alpha)T_{200} \]  
(A.14)

2) \( \chi\chi \rightarrow Z(\lambda)Z(\bar{\lambda}) \)

Here the contributing diagrams are very similar to those of the \( W^+W^- \) final state, except that the \( Z \) exchange contribution is absent. Moreover, the subscript \( j \) now labels the 4 neutralino eigenstates. The nonvanishing partial wave amplitudes can be written as:

\[ A(^1S_0) : \quad \lambda_f = 0, \lambda = \pm 1 \]

\[ \frac{4\sqrt{2}\beta_j g^2 O_{0j}^L}{P_j^2} + 2\sqrt{2}v^2 \beta_j g^2 O^L_{0j} \left\{ -\frac{R_j}{3P_j^2} \right\} \]

\[ + \frac{1}{P_j^2} \left[ \frac{1}{4} - \frac{4}{3P_j^2} + \frac{2\beta_j^2}{3P_j^2} \right] \]  
(A.15a)

\[ A(^3P_0) : \quad \lambda_f = 0, \lambda = 0 \]

\[ \frac{4\sqrt{6}v g^2}{R_W} O^L_{0j} \left\{ -\frac{2}{3P_j^2} - \frac{R_j}{P_j^2} \left[ 1 - \frac{2}{3P_j^2} \right] \right\} \]

\[ + 2\sqrt{6}v g^2 O^L_{0j} \left\{ \frac{1}{P_j^2} \left[ 1 - \frac{2\beta_j^2}{3P_j^2} \right] + \frac{R_j}{P_j^2} \left[ 1 - \frac{4}{3P_j^2} \right] \right\} \]

\[ - \frac{\sqrt{6}v g^2 (1 + \beta_j^2) F_i}{(4 - R_{H_i}^2 + iG_{H_i})R_W} \]  
(A.15b)

\[ \lambda_f = 0, \lambda = \pm 1 \]

\[ 2\sqrt{6} v g^2 O^L_{0j} \left\{ \frac{1}{P_j^2} \left[ \frac{1}{3} - \frac{2\beta_j^2}{3P_j^2} \right] + \frac{R_j}{P_j^2} \right\} + \frac{\sqrt{6} v g^2 R_W F_i}{4 - R_{H_i}^2 + iG_{H_i}} \]  
(A.15c)
\[ A^{(3P_1)} : |\lambda_f| = 1, \quad 4v\beta_f^2 \lambda_f g_Z^2 O_{0j}^{\prime l^2} \left\{ \frac{1}{P_j} \left[ 1 - \frac{1}{P_j} \right] + R_j \right\} \] (A.15d)

\[ A^{(3P_2)} : |\lambda_f| = 2, \quad -\frac{4\sqrt{2}v g_Z^2}{P_j} O_{0j}^{\prime l^2} \] (A.15e)

\[ |\lambda_f| = 1, \quad -\frac{4v g_Z^2}{R_Z} O_{0j}^{\prime l^2} \left\{ \frac{R_j^2}{P_j^2} + \frac{R_j \beta_f^2}{P_j} \right\} \] (A.15f)

\[ |\lambda_f| = 0, \lambda = \pm 1, \quad \frac{4v g_Z^2}{\sqrt{3} R_Z} O_{0j}^{\prime l^2} \left\{ \frac{1}{2} \left( R_j - 5 \right) - \frac{2(R_j - 1)}{P_j} \right\} + \frac{2R_j \beta_f^2}{P_j^2} \] (A.15g)

\[ |\lambda_f| = 0, \lambda = 0, \quad -\frac{8v g_Z^2}{\sqrt{3} R_Z} O_{0j}^{\prime l^2} \left\{ \frac{1}{P_j} \left[ 1 - \frac{R_j \beta_f^2}{P_j} \right] + \frac{2R_j \beta_f^2}{P_j^2} \right\} \] (A.15h)

In eqs. (A.15) we have used the usual notation

\[ g_z = \frac{g}{\cos \theta_W}. \] (A.16)

3) \( \chi \chi \rightarrow Z(\lambda)H_a \)

This final state receives contributions from the exchange of the four neutralinos (labelled by \( j \)) in the \( t- \) or \( u- \) channel, as well as from the \( s- \) channel exchange of the \( Z \) boson as well as of the pseudoscalar Higgs bosons \( P \). The result is:

\[ A^{(1S_0)} : \lambda = 0 \]

\[ -\frac{2\sqrt{2}\beta_f}{R_Z} g g_Z \left\{ \frac{2J_j(R_j - 1)}{P_j} + O_{R_Z \cos \theta_W} - \frac{4L}{4 - R_Z^2 + iG_P} \right\} \]

\[ -v^2 \frac{\sqrt{2}\beta_f}{R_Z} g g_Z \left\{ \frac{J_j}{P_j} \left\{ \frac{1}{2} (R_j - 5) - \frac{2(R_j - 1)}{P_j} \right\} + \frac{4(R_j - 1) \beta_f^2}{3P_j^2} \right\} \]

\[ + (2 - \Delta^2) \frac{2}{3P_j} \] (A.17a)

\[ A^{(3P_1)} : \lambda = \pm 1 \]

\[ -4v g g_Z \frac{\beta_f}{P_j^2} \left\{ \frac{R_j^2 - \delta^4}{4} \right\} - 4v g g_Z \frac{J_j R_j}{P_j} + 2v g_Z^2 O_{Z - O} \] (A.17b)

\[ \lambda = 0 \]

\[ -2v \frac{R_Z}{\sqrt{2}} \left( 1 + \frac{\delta^2}{2} \right) g g_Z \left\{ \frac{2(1 + R_j)}{P_j} - \frac{R_Z}{\cos \theta_W (4 - R_Z^2)} \right\} \] (A.17c)

\[ A^{(3P_2)} : \lambda = \pm 1 \quad -4\lambda v \beta_f^2 g g_Z \frac{J_j}{P_j^2} \] (A.17d)
In addition to $\Delta$, which has already been defined in eq.(A.10a), we have introduced the following quantities:

$$G_P = \frac{\Gamma_P m_P}{m_X} ; \quad (A.18a)$$

$$\delta^2 = \frac{R_Z^2 - R_H^2}{2} ; \quad (A.18b)$$

$$J_j = - O''_{0j} T_{a0j} \quad \text{for } H_a ; \quad (A.18c)$$

$$L = \frac{1}{2} \sin(\alpha - \beta) T_{P0j} \quad \text{for } H_1 ; \quad (A.18d)$$

$$\frac{1}{2} \cos(\alpha - \beta) T_{P0j} \quad \text{for } H_2 ; \quad (A.18e)$$

$$O = O''_{0j} \sin(\alpha - \beta) \quad \text{for } H_1 ; \quad (A.18f)$$

$$O''_{0j} \cos(\alpha - \beta) \quad \text{for } H_2 . \quad (A.18g)$$

4) $\chi\chi \rightarrow Z(\lambda)P$

The contributing diagrams are very similar to those of the $ZH$ final state, except that the single $P$ exchange diagram has to be replaced by $H_1, H_2$ exchange diagrams; notice that these scalar Higgs bosons cannot be on-shell, so that we need not introduce complex propagators here.

$$A(3P_0) : \lambda = 0 \quad 4\sqrt{6} v^3 f ggZ \left\{ \left[ 1 + \frac{\delta^2}{2} \right] \frac{K_j R_j}{J_j^2} - \left[ \frac{2}{3} + R_j^2 - \frac{2\Delta^2}{3} + \frac{\delta^2}{6} \right] \frac{K_j}{J_j^2} \right\} \quad (A.19a)$$

$$A(3P_1) : \lambda = \pm 1 \quad - 4v^3 f ggZ \left[ \left[ -R_j + \frac{\delta^2}{2} \right] \frac{K_j}{J_j^2} \right] \quad (A.19b)$$

$$A(3P_2) : \lambda = \pm 1 \quad 4v^3 f ggZ \left[ \left[ -R_j + \frac{\delta^2}{2} \right] \frac{K_j}{J_j^2} \right] \quad (A.19c)$$

$$\lambda = 0 \quad - \frac{8}{\sqrt{3}} v^3 f ggZ \frac{K_j}{J_j^2} \left\{ 1 + R_j - \Delta^2 + \frac{\delta^2}{2} (R_j - 1) \right\} \quad (A.19d)$$

In eqs.(A.19) we have defined:

$$\delta^2 = \frac{1}{2} (R_Z^2 - R_P^2) \quad (A.20a)$$

$$L_1 = \frac{1}{2} \sin(\alpha - \beta) T_{100}, \quad L_2 = \frac{1}{2} \cos(\alpha - \beta) T_{200} \quad (A.20b)$$

$$K_j = O''_{0j} T_{P0j} \quad (A.20c)$$
5) $\chi \chi \rightarrow W^-(\lambda)H^+$

In this case one has contributions from the exchange of the two charginos, which are again labelled by the suffix $j$, as well as from the exchange of all three neutral Higgs bosons. Notice also that there are equal contributions from $W^+H^-$ and $W^-H^+$ production, leading to an overall factor of 2 in the final cross section in this case. The contributing partial wave amplitudes are:

$$A^{(1S_0)} : \lambda = 0$$

$$A^{(3P_0)} : \lambda = 0$$

$$A^{(3P_1)} : \lambda = \pm 1$$

$$A^{(3P_2)} : \lambda = \pm 1$$

In eqs[A.21] we have introduced:

$$\delta^2 = \frac{1}{2}(R^2_W - R^2_{H^+})$$

(A.22a)
\[ F'_j = -\frac{1}{4}(O'^R_{0j} - O'^L_{0j})(Q'^R_{0j} \sin \beta + Q'^L_{0j} \cos \beta) \] (A.22b)

\[ F''_j = -\frac{1}{4}(O'^R_{0j} + O'^L_{0j})(Q'^R_{0j} \sin \beta - Q'^L_{0j} \cos \beta) \] (A.22c)

\[ K'_j = -\frac{1}{4}(O'^R_{0j} - O'^L_{0j})(Q'^R_{0j} \sin \beta - Q'^L_{0j} \cos \beta) \] (A.22d)

\[ K''_j = -\frac{1}{4}(O'^R_{0j} + O'^L_{0j})(Q'^R_{0j} \sin \beta + Q'^L_{0j} \cos \beta) \] (A.22e)

6) \( \chi \chi \rightarrow H_a H_b \) or PP

Both the \( H_a H_b \) \((a, b = 1, 2)\) and the PP final state can be produced by the exchange of one of the four neutralinos (labelled by \( j \)) in the \( t- \) or \( u- \)channel, as well as by scalar Higgs exchange in the \( s- \)channel. The contributing amplitudes for the \( H_a H_b \) final state can be written as:

\[
A(3P_0) : \sqrt{6} v^2 \frac{R_Z}{4 - R^2_{H_i} + iG_{H_i}} - 2T_{a0j}T_{b0j} \frac{1 + R_j}{P_j} + \frac{4}{3} T_{a0j}T_{b0j} \frac{\bar{\beta}_f^2}{P_j^2}
\] (A.23a)

\[
A(3P_2) : -\frac{8}{\sqrt{3}} \bar{\beta}_f^2 g^2 T_{a0j}T_{b0j} \frac{1}{P_j^2}
\] (A.23b)

The corresponding PP amplitudes can simply be obtained by replacing \( a, b \) by \( PP \) and \( R_j \) by \(-R_j\). The rescaled width \( G_{H_i} = \Gamma_{H_i}, m_{H_i}/m_\chi \) as before, and the trilinear Higgs couplings are [42]:

\[
g_{111} = -\frac{3}{2\cos \theta_W} \cos 2\alpha \cos (\alpha + \beta) \] (A.24a)

\[
g_{222} = -\frac{3}{2\cos \theta_W} \cos 2\alpha \sin (\alpha + \beta) \] (A.24b)

\[
g_{112} = g_{121} = \frac{1}{2\cos \theta_W} [2\sin 2\alpha \cos (\alpha + \beta) + \sin (\alpha + \beta) \cos 2\alpha] \] (A.24c)

\[
g_{122} = g_{221} = -\frac{1}{2\cos \theta_W} [2\sin 2\alpha \sin (\alpha + \beta) - \cos (\alpha + \beta) \cos 2\alpha] \] (A.24d)

\[
g_{PP1} = g_{1PP} = \frac{\cos (\alpha + \beta)}{2\cos \theta_W} \cos 2\beta \] (A.24e)

\[
g_{PP2} = g_{2PP} = -\frac{\sin (\alpha + \beta)}{2\cos \theta_W} \cos 2\beta \] (A.24f)

Recall that the suffix 1 (2) refers to the heavier (lighter) Higgs scalar.

7) \( \chi \chi \rightarrow H_a P \)

This process receives contributions from diagrams where one of the four neutralinos (labelled by \( j \)) is exchanged in the \( t- \) or \( u- \)channel, as well as from \( s- \)channel exchange of
or $P$ bosons. The result is:

$$A(1S_0) : 2\sqrt{2}g^2 g_{aPP} T_{P00} \frac{R_Z}{4 - R_P^2} \left(1 + \frac{v^2}{8}\right) + \sqrt{2}g^2 g_{aPZ} \frac{R_P^2 - R_a^2}{R_Z^2}(1 - \frac{v^2}{8})$$

$$- 4\sqrt{2}g^2 T_{a0j} T_{P0j} \frac{R_i}{P_j} \left\{1 + v^2 \left[\frac{1}{8} - \frac{1}{2P_j} + \frac{\beta_j^2}{3P_j^2}\right]\right\}$$

$$- \sqrt{2}(R_P^2 - R_a^2) g^2 T_{a0j} T_{P0j} \left\{1 + v^2 \left[-\frac{1}{8} - \frac{1}{2P_j} + \frac{\beta_j^2}{3P_j^2}\right]\right\}$$

(A.25a)

$$A(3P_1) : -4v\bar{\beta}_f g^2 g_{aPZ} \frac{4 - R_Z^2 + i G_Z}{4 - R_Z^2} - 4v\bar{\beta}_f g^2 T_{a0i} T_{P0i} \frac{P_j}{P_j}$$

(A.25b)

Here, $G_Z = M_Z \Gamma_Z / m_\chi^2$ as usual, and we have introduced the combinations of couplings

$$g_{1PZ} = -\frac{\sin(\alpha - \beta)}{2 \cos^2 \theta_W} O^L_{00} \text{ (A.26a)}$$

$$g_{2PZ} = -\frac{\cos(\alpha - \beta)}{2 \cos^2 \theta_W} O^L_{00} \text{ (A.26b)}$$

8) $\chi \chi \rightarrow H^+ H^-$

This final state gets contributions from exchange of the two chargino states, labelled by $j$, as well as from the exchange of the $Z$ boson and the two scalar Higgs bosons, labelled by $i$. The nonvanishing amplitudes are:

$$A(3P_0) : -\sqrt{3}v^2 g^2 \left\{(Q_{0j}^{L2} + Q_{0j}^{R2}) \left[\frac{1}{P_j} - \frac{2\bar{\beta}_j^2}{3P_j^2}\right] + 2Q_{0j}^{L} Q_{0j}^{R} \frac{R_j^+}{P_j}\right\}$$

$$+ \sqrt{3}v^2 g^2 R_W \frac{g_{4-i}}{4 - R_W^2}$$

(A.27a)

$$A(3P_1) : 2v\bar{\beta}_f g^2 (Q_{0j}^{L2} - Q_{0j}^{R2}) \frac{1}{P_j} + 4v\bar{\beta}_f \cos \theta_W \frac{2g^2 \cos \frac{\theta_W}{2}}{4 - R_Z^2} O_{00}^{L}$$

(A.27b)

$$A(3P_2) : \frac{4}{\sqrt{3}}v^2 \bar{\beta}_f g^2 (Q_{0j}^{L2} + Q_{0j}^{R2}) \frac{1}{P_j^2}$$

(A.27c)

In eqs.(A.27) we have introduced the quantities

$$g_{4-1} = -T_{100} \left[\cos(\beta - \alpha) - \frac{\cos(\alpha + \beta)}{2 \cos^2 \theta_W} \cos 2\beta\right] \text{ (A.28a)}$$

$$g_{4-2} = -T_{200} \left[\sin(\beta - \alpha) + \frac{\sin(\alpha + \beta)}{2 \cos^2 \theta_W} \cos 2\beta\right] \text{ (A.28b)}$$

42
9) $\chi \chi \rightarrow f_a(h) \bar{f}_a(h)$

Here we use the suffixes $a, b$ to label the up and down components of weak isodoublets, with $T_{3a} = \pm 1/2$. This allows us to use the same notation for quarks and leptons. Of course, in the final cross section a color factor of 3 has to be included in case of quarks.

This final state can be produced by the exchange of the two sfermion eigenstates in the $t-$ and $u-$channel, as well as by $s-$channel exchange of the $Z$ boson or of one of the three neutral Higgs bosons. Since the final state particles can be massless, we have to include finite widths for all $s-$channel propagators. We remind the reader that we do not expand $s-$channel propagators with respect to $v$, while we do expand $t-$ and $u-$channel propagators. The contributing partial wave amplitudes can be written as:

$$A^{(1S_0)} : \lambda_f = 0$$

$$\sqrt{2}(-1)^{h+\frac{1}{2}}(X_{a0}^2 + W_{a0}^2) \left\{ 1 + v^2 \left[ -\frac{1}{2P_1} + \frac{\beta^2_f}{3P_1^2} \right] \right\} \frac{R_f}{P_1}$$

$$+ 2\sqrt{2}(-1)^{h+\frac{1}{2}}X_{a0}W_{a0} \frac{1}{P_1} \left\{ 1 + v^2 \left[ -\frac{1}{4P_1} - \frac{1}{2P_1} - \frac{\beta^2_f}{6P_1} + \frac{\beta^2_f}{3P_1^2} \right] \right\}$$

$$+ (X_{a0} \leftrightarrow Z_{a0}, W_{a0} \leftrightarrow Y_{a0}, P_1 \leftrightarrow P_2)$$

$$+ (-1)^{h+\frac{1}{2}} \frac{2\sqrt{2}g^2}{\cos^2\theta_W} O_{00}^{\nu} T_{3a} \frac{R_f}{R_Z}$$

$$+ 4\sqrt{2}(-1)^{h+\frac{1}{2}}g h_{PA} T_{P00} \frac{1}{4 - R_P^2 + iG_P} \left( 1 + \frac{v^2}{4} \right)$$

(A.29a)

$$A^{(3P_0)} : \lambda_f = 0$$

$$\sqrt{6}v \beta_f (X_{a0}^2 \leftrightarrow W_{a0}^2) \left\{ \frac{1}{P_1} - \frac{2}{3P_1^2} \right\} + \sqrt{6}v \beta_f (X_{a0}^2 + W_{a0}^2) \frac{R_f}{P_1^2}$$

$$+ (X_{a0} \leftrightarrow Z_{a0}, W_{a0} \leftrightarrow Y_{a0}, P_1 \leftrightarrow P_2)$$

$$- 2\sqrt{6}v \beta_f g \frac{h_{T_{a0}}}{4 - R_{H_t}^2 + iG_{H_t}}$$

(A.29b)

$$A^{(3P_1)} : \lambda_f = 0$$

$$\frac{vR_f}{P_1} (X_{a0}^2 \leftrightarrow W_{a0}^2) + (X_{a0} \leftrightarrow Z_{a0}, W_{a0} \leftrightarrow Y_{a0}, P_1 \leftrightarrow P_2)$$

$$- 2g^2 O_{00}^{\nu} \left\{ T_{3a} - 2e_{fa} \sin^2\theta_W \right\} \frac{R_f}{4 - R_Z^2 + iG_Z}$$

(A.29c)

$$\lambda_f = \pm 1$$

$$\sqrt{2}v \left\{ \lambda_f \beta_f (X_{a0}^2 + W_{a0}^2) \left[ -\frac{1}{P_1} + \frac{1}{P_1^2} \right] \right\}$$

$$+ (X_{a0}^2 - W_{a0}^2) \left[ \frac{1}{P_1} - \frac{\beta^2_f}{P_1^2} \right] + 2\beta_f \lambda_f (X_{a0}^2 W_{a0}) \frac{R_f}{P_1^2}$$

43
\[ \frac{1}{4 - R_Z^2 + iG_Z} \] (A.29d)

\[ A^3 P_2 : \lambda_f = 0 \]
\[ -\frac{2}{\sqrt{3}} \nu \bar{\beta}_f \] \[ \frac{1}{P_1} \left\{ R_f(X_{a0}^2 + W_{a0}^2) + 2X_{a0}W_{a0} \right\} \]
\[ + (X'_{a0} \leftrightarrow Z'_{a0}, W'_{a0} \leftrightarrow Y'_{a0}, P_1 \leftrightarrow P_2) \] (A.29e)

\[ \lambda_f = \pm 1 \]
\[ \sqrt{2} \nu \bar{\beta}_f \frac{1}{P_1} \left\{ -(X_{a0}^2 + W_{a0}^2) + \bar{\beta}_f \lambda_f (X_{a0}^2 - W_{a0}^2) - 2R_f X_{a0}W_{a0} \right\} \]
\[ + (X'_{a0} \leftrightarrow Z'_{a0}, W'_{a0} \leftrightarrow Y'_{a0}, P_1 \leftrightarrow P_2) \] (A.29f)

In eqs.(A.29), we have defined \( R_f = m_{f_a}/m_{\chi} \) as in eq.(A.10c). These expressions fully include mixing between \( SU(2) \) doublet and singlet sfermions. The sfermion mass eigenstates, labelled by 1 and 2 in eqs.(A.29), are defined by

\[ \tilde{f}_1 = \tilde{f}_L \cos \theta_f + \tilde{f}_R \sin \theta_f, \quad (A.30a) \]
\[ \tilde{f}_2 = -\tilde{f}_L \sin \theta_f + \tilde{f}_R \cos \theta_f; \quad (A.30b) \]

the corresponding rescaled masses determine the inverse propagators \( P_1 \) and \( P_2 \) as shown in eq.(A.10b). Sfermion mixing also affects their couplings to neutralinos:

\[ X'_{a0} = X_{a0} \cos \theta_f + Z_{a0} \sin \theta_f, \quad W'_{a0} = Z_{a0} \cos \theta_f + Y_{a0} \sin \theta_f, \]
\[ Z'_{a0} = -X_{a0} \sin \theta_f + Z_{a0} \cos \theta_f, \quad Y'_{a0} = -Z_{a0} \sin \theta_f + Y_{a0} \cos \theta_f. \] (A.31)

The couplings of the unmixed sfermions in eq.(A.31) can be found in ref.[42]:

\[ X_{a0} = -\sqrt{2} g [T_{3a}N_{02} - \tan \theta_W (T_{3a} - e_{f_a}) N_{01}] \] (A.32a)
\[ Y_{a0} = \sqrt{2} g \tan \theta_W e_{f_a} N_{01} \] (A.32b)
\[ Z_{u0} = -\frac{g m_u}{\sqrt{2} \sin \beta M_W} N_{03} \] (A.32c)
\[ Z_{d0} = -\frac{g m_d}{\sqrt{2} \cos \beta M_W} N_{04} \]

Finally, the couplings between Higgs bosons and SM fermions are [42]:

\[ h_{P_u} = -\frac{g m_u \cot \beta}{2 M_W}, \quad h_{P_d} = -\frac{g m_d \tan \beta}{2 M_W} \] (A.33a)

\[
^1\text{Notice that the last term in the relevant eq.(5.5) of that reference has a wrong sign; H. Haber, private communication.}
\]
\[ h_{1u} = -\frac{g m_u \sin \alpha}{2M_W \sin \beta}, \quad h_{1d} = -\frac{g m_d \cos \alpha}{2M_W \cos \beta} \quad (A.33b) \]
\[ h_{2u} = -\frac{g m_u \cos \alpha}{2M_W \sin \beta}, \quad h_{2d} = \frac{g m_d \sin \alpha}{2M_W \cos \beta} \quad (A.33c) \]

**Appendix B: Application of the Equivalence Theorem**

As already discussed in sec. 2b, the high–energy limit of the amplitudes for the production of longitudinal gauge bosons can be understood from the equivalence theorem \[50\]. This also provides a useful check of these amplitudes. As an example, we discuss in this Appendix the production of two longitudinal \( Z \) bosons. We see from eqs.(A.15) that only two amplitudes contribute to the \( \lambda = \bar{\lambda} = 0 \) final state; in the limit \(|m_\chi| \gg M_Z\) they become
\[
A(3P_0) = -\frac{4\sqrt{6} g_Z v}{R_Z^2 P_j} O_{0j}^{\nu L^2} \left[ \frac{2}{3} + R_j \left( 1 - \frac{2}{3P_j} \right) \right] + \frac{2\sqrt{6} v g_2 F_i \left( 4 - R_{H_0} \right) R_W}{(4 - R_{H_0})^2 R_W}; \quad (A.34a)
\]
\[
A(3P_2) = -\frac{8 v g_Z}{\sqrt{3} R_Z^2 P_j} O_{0j}^{\nu L^2} \left( 1 + \frac{2R_j}{P_j} \right), \quad (A.34b)
\]
where we have already made use of the fact that \( O_{0j}^{\nu L^2} \propto R_Z^2 \), so that only contributions with an explicit factor \( 1/R_Z^2 \) survive in the high–energy limit. More specifically, we see from eqs.(6) that only the contributions from the higgsino–like neutralinos \( j = 3, 4 \) will survive in this limit:
\[
R_3 = -R_4 = \frac{\mu}{M_1}; \quad (A.35a)
\]
\[
P_3 = P_4 = 1 + \frac{\mu^2}{M_1^2}; \quad (A.35b)
\]
\[
O_{03}^{\nu L^2} + O_{04}^{\nu L^2} = \frac{1}{4} \left( \frac{M_Z \sin \theta_W}{M_1^2 - \mu^2} \right)^2 \left( M_1^2 + \mu^2 + 2M_1\mu \sin 2\beta \right); \quad (A.35c)
\]
\[
O_{03}^{\nu L^2} - O_{04}^{\nu L^2} = -\frac{1}{4} \left( \frac{M_Z \sin \theta_W}{M_1^2 - \mu^2} \right)^2 \left[ \left( M_1^2 + \mu^2 \right) \sin 2\beta + 2M_1\mu \right]. \quad (A.35d)
\]
In SUGRA, \( m_\chi^2 \gg M_Z^2 \) almost always implies \( m_P^2 \gg M_Z^2 \). In that case \( F_1 \) becomes very small, so that the contribution from the heavy Higgs scalar can be neglected; moreover, one has \( R_{H_2}^2 \ll 1 \) in this limit, and \( \alpha = \beta + \pi/2 \). This gives:
\[
F_2 = T_{200} = \frac{M_Z \sin^2 \theta_W}{\cos \theta_W \left( \mu^2 - M_1^2 \right)} \left( M_1 + \mu \sin 2\beta \right), \quad (A.36)
\]
where we have used eq.(6a). Inserting eqs.(A.35) and (A.36) into (A.34) finally yields:
\[
A(3P_0) = \sqrt{6} v g_Z^2 \frac{M_1^2}{\mu^2 + M_1^2} \left( \frac{1}{3} M_1 \left( M_1^2 + \mu^2 + 2M_1\mu \sin 2\beta \right) \right)
\]
45
\[-M_1 \mu \left(1 - \frac{2}{3} \frac{M_1^2}{M_1^2 + \mu^2}\right) \left[\left(M_1^2 + \mu^2\right) \sin 2\beta + 2M_1 \mu\right]\]

\[+ \frac{\sqrt{6}}{2} g' v \frac{M_1}{\mu^2 - M_1^2} (M_1 + \mu \sin 2\beta); \quad (A.37a)\]

\[A^{(3)P_2} = -\frac{2}{\sqrt{3}} v g' \frac{1}{M_1^2 + \mu^2} \left(\frac{M_1^2}{M_1^2 - \mu^2}\right)^2 \left\{M_1^2 + \mu^2 + 2M_1 \mu \sin 2\beta\right\} - \frac{2\mu M_1}{M_1^2 + \mu^2} \left[\left(M_1^2 + \mu^2\right) \sin 2\beta + 2M_1 \mu\right]\]. \quad (A.37b)

The last term in eq. (A.37a) comes from Higgs exchange. One recognizes the form of our “symbolic” expression (13) of sec. 2b.

On the other hand, since the neutral Goldstone boson \(G\) is a pseudoscalar, the amplitudes for the production of a \(GG\) pair can be directly read off from our results for \(PP\) production, eqs. (A.23). Retaining only those terms that remain finite as \(m_2^*/M_2^* \to \infty\), one has

\[A^{(3)P_0} = -\frac{2\sqrt{6} v g^2}{P_j} T_{G0j}^2 \left(1 - R_j - \frac{2}{3P_j}\right); \quad (A.38a)\]

\[A^{(3)P_2} = -\frac{8}{\sqrt{3}} v g^2 T_{G0} \frac{1}{P_j^2}. \quad (A.38b)\]

The couplings \(T_{G0j}\) can be obtained from eq. (A.9a) by the substitution \(\sin \beta \to -\cos \beta, \cos \beta \to \sin \beta\). We see that again only the contributions from the exchange of the higgsino–like neutralinos \((j = 3, 4)\) survive:

\[T_{G03}^2 + T_{G04}^2 = \frac{1}{4} \tan^2 \theta_W; \quad (A.39a)\]

\[T_{G03}^2 - T_{G04}^2 = -\frac{1}{4} \tan^2 \theta_W \sin 2\beta. \quad (A.39b)\]

Inserting this into eqs. (A.38) gives:

\[A^{(3)P_0} = -\frac{\sqrt{6}}{2} v g^2 \frac{M_1^2}{M_1^2 + \mu^2} \left(1 - \frac{2}{3} \frac{M_1^2}{M_1^2 + \mu^2} + \frac{\mu}{M_1^2} \sin 2\beta\right); \quad (A.40a)\]

\[A^{(3)P_2} = -\frac{2}{\sqrt{3}} v g^2 \left(\frac{M_1^2}{M_1^2 + \mu^2}\right)^2. \quad (A.40b)\]

While perhaps not immediately obvious, it can be shown that eqs. (A.40) are indeed identical to eqs. (A.37).

The fact that the Goldstone amplitudes (A.40) automatically yield more compact expressions shows that they can not only be used to check some amplitudes of Appendix A, but they also allow to derive the high–energy limit of the amplitudes for the production

\[\text{Up to an overall sign between the } 3^P_n \text{ amplitudes; however, as shown in the Appendix of ref. [3], the signs of noninterfering amplitudes are ambiguous when Majorana spinors are involved.}\]
of longitudinal gauge bosons more quickly. We saw already that the amplitudes for the production of transverse gauge bosons vanish with some power of $M_Z/m_\chi$ in the limit of large $|m_\chi|$ if $X$ is bino–like; the longitudinal helicity states therefore dominate the total production of gauge bosons in this important special case. (This is not true for higgsino–like or mixed LSP, however.) Most amplitudes for the production of Goldstone bosons can be read off directly from our results for the production of pseudoscalar and charged Higgs bosons, replacing $\sin \beta \to -\cos \beta$, $\cos \beta \to \sin \beta$ in the corresponding couplings of Higgs bosons to neutralinos and charginos. The only exception is $H^+G^-$ production, which gives the high–energy limit of $H^+W^-_L$ production. We list the nonvanishing partial wave amplitudes for completeness:

\begin{align}
1S_0 & : 2\sqrt{2}g^2Q'_{0j}^LQ'_{0j}^R \frac{R_j^+}{1+R_j^+} \left\{ 1 + v^2 \left[ \frac{1}{8} - \frac{1}{2(1+R_j^+)^2} + \frac{1}{3(1+R_j^+)^2} \right] \right\} \quad (A.41a) \\
3P_0 & : -\frac{\sqrt{6}}{2} v \sin 2\beta g^2(Q'_{0j}^L - Q'_{0j}^R) \left\{ \frac{1}{1+R_j^+} - \frac{2}{3(1+R_j^+)^2} \right\} \\
& \quad + \sqrt{6} v g^2 Q'_{0j}^L Q'_{0j}^R \cos 2\beta \frac{R_j^+}{1+R_j^+} \quad (A.41b) \\
3P_1 & : v \sin 2\beta g^2(Q'_{ij}^L + Q'_{ij}^R) \frac{1}{1+R_j^+} \quad (A.41c) \\
3P_2 & : -\frac{2}{\sqrt{3}} v \sin 2\beta g^2 \frac{Q'_{0j}^L - Q'_{0j}^R}{(1+R_j^+)^2} \quad (A.41d) 
\end{align}

In eqs. (A.41), we have again only kept terms that remain finite at high energies.

Fig. 1 The rescaled LSP relic density $\Omega h^2$ as a function of the LSP mass $m_\chi$ for scalar SUSY breaking mass parameter $m = 300$ GeV and four combinations of the ratio $\tan\beta$ of Higgs vevs and the mass $m_t$ of the top quark. The solid (dashed) curves are for positive (negative) gaugino mass parameter $M$. Notice that $M$, the trilinear soft breaking parameter $A$ and the supersymmetric Higgs(ino) mass parameter $\mu$ all vary along the curves, due to the relations between model parameters implied by radiative gauge symmetry breaking; in particular, the locations of the pole and thresholds caused by the light scalar Higgs boson are different in each case.

Fig. 2 An enlargement of the threshold region of the solid curves in figs. 1a,b. For $m_t = 130$ GeV (solid curve) the $hh$ and $Z\chi$ final states are accessible for $m_\chi > 75$ and 84 GeV, respectively, while for $m_t = 160$ GeV (dashed), they are only accessible for $m_\chi > 95$ and 93 GeV, respectively.

Fig. 3 The rescaled LSP density as a function of the LSP mass for two examples of higgsino–like LSPs. $M$, $m$ and $m_t$ are fixed for each curve, while $\mu$, $A$ and $\tan\beta$ vary. For $M = -1$ TeV (dashed curve) the LSP becomes bino–like at $m_\chi \simeq 430$ GeV, which explains the rapid rise of this curve at large $m_\chi$. Only $\chi\chi$ annihilation has been included in the calculation; this substantially overestimates $\Omega h^2$ for $m_\chi \leq M_W$, as argued in the text.

Fig. 4 Demonstration of the importance of the SUGRA imposed relations between particle masses. The solid curve shows the full SUGRA prediction for $\Omega h^2$ as a function of $\tan\beta$; eq.(23) implies that $m_\chi = m_P/2$ at $\tan\beta=35.3$, where $P$ denotes the pseudoscalar Higgs boson. The long dashed curve has been obtained by keeping $m_P$ constant at the value SUGRA predicts for $\tan\beta=2$, i.e. $m_P = 783$ GeV, but the $\tilde{\tau}$ and $\tilde{b}$ masses are still allowed to vary with $\tan\beta$. For the short dashed curve all effects of the $b$ and $\tau$ Yukawa couplings have been switched off.

Fig. 5 Contours of constant $\Omega h^2$ in the plane spanned by $M$ and $\tan\beta$, for fixed $m = 250$ GeV and $m_t = 140$ GeV; results for all 4 combinations of signs of $M$ and $\tan\beta$ are shown. The solid and long dashed lines are contours where $\Omega h^2=1$ and 0.25, respectively. The short dashed lines in (a) are contours where $\Omega h^2=0.025$; since these contours are very close to the $Z$, $h$ or $P$ poles, in (b) - (d) we have merely indicated the location of these poles by the short dashed lines. The region outside of the dotted curves is excluded by various experimental and theoretical constraints, as described in the text. A flat universe requires $0.25 \leq \Omega h^2 \leq 1$, while LSPs can build up the dark matter halo of galaxies if $\Omega h^2 \geq 0.025$. 
Fig. 6 Contours of constant $\Omega h^2$ in the plane spanned by $M$ and $\tan\beta$, for the quadrant $M > 0$, $\tan\beta > 0$, and four different combinations of $m$ and $m_t$ as indicated. The notation is as in figs. 5 (b)–(d).

Fig. 7 The upper bound on $|M|$ which follows from the requirement that LSPs do not overclose the universe, $\Omega h^2 \leq 1$. The long dashed, solid, and short dashed curves are valid for $m_t = 110, 140$ and $170$ GeV, respectively, and show the absolute upper bound over the entire experimentally and theoretically allowed parameter space. The dotted curves emerge when one restricts the parameter space to $|\tan\beta| \leq 15$; the upper (lower) dotted curve is for $m_t = 140$ ($170$) GeV. In all cases the maximal $|M|$ is found in the quadrant $M < 0$, $\tan\beta < 0$.

Fig. 8 Upper bounds on $\Omega h^2$ as a function of the mass $m_{l_R}$ of the $SU(2)$ singlet sleptons. The long dashed, solid, and short dashed curves are for $m_t = 110, 140$ and $170$ GeV, respectively, and present experimental bounds on sparticle masses; the long-short dashed curve is valid if the lower bounds on the masses of charged sparticles and gluinos are raised to 80 and 200 GeV, respectively, for $m_t = 140$ GeV. The dotted curve is based on a simple analytical approximation that assumes that the LSP is a pure bino, as described in the text.
