ABSTRACT

Background/Aims Prospective data on switching anti-vascular endothelial growth factors in patients with neovascular age-related macular degeneration (nAMD) who have previously shown no/partial response are limited. This prospective study assessed the effect of switching from aflibercept to ranibizumab on anatomical and functional outcomes in patients with persistent/recurrent disease activity.

Methods SAFARI (NCT02161575) was a 6-month, prospective, single-arm study conducted in the UK and Germany. Patients, meeting strict eligibility criteria for one of two subgroups (primary treatment failure or suboptimal treatment response), received 3 monthly intravitreal ranibizumab injections (0.5 mg). Thereafter, ranibizumab was administered pro re nata at monthly visits. The primary endpoint was change from baseline (CfB) to day 90 in central subfield retinal thickness (CSRT). Best-corrected visual acuity (BCVA) and retinal morphology parameters were assessed.

Results One hundred patients were enrolled (primary treatment failure, 1; suboptimal treatment response, 99). In the overall population, there was a significant CfB in median CSRT of −30.75 µm (95% CI −59.50,−20.50; p<0.0001) to day 90. Improvements were also observed in other quantitative and qualitative optical coherence tomography parameters. In Early Diabetic Retinopathy Study letters assessed by category, 55% and 59% of patients gained 0–≥15 letters versus baseline at day 90 and day 180, respectively. However, mean improvements in BCVA (CfB) to each time point were small (≤2 letters). No new safety signals were identified.

Conclusion Switching from aflibercept to ranibizumab led to a significant improvement in CSRT, with ~60% experiencing stabilised/improved BCVA. Therefore, patients with nAMD who have shown a suboptimal response to aflibercept may benefit from switching to ranibizumab.

INTRODUCTION

Age-related macular degeneration (AMD) is the leading cause of severe vision loss in people aged ≥50 years in the UK and other European countries.1-3 In both the developed and developing world, the burden of this disease is projected to increase due to ageing populations and rising life expectancies, respectively.1,4 The wet or neovascular form of AMD (nAMD) accounts for most cases associated with severe visual impairment.6

Intravitreal (IVT) vascular endothelial growth factor-A (VEGF-A) inhibitors (anti-VEGFs), such as ranibizumab and aflibercept, are now the standard of care.7-8 Ranibizumab has demonstrated clinically and statistically significant improvements in visual acuity (VA) and quality of life for patients with nAMD.9 Aflibercept was subsequently demonstrated to be clinically equivalent to ranibizumab with respect to improvement in VA at 52 weeks.10

Despite anti-VEGF therapy, a minority of patients still experience rapid, progressive deterioration in clinical status, with no demonstration of an adequate clinical response (primary treatment failure). This group contains patients who will not respond to continued therapy with the same anti-VEGF, termed ‘non-responders’.11 A further subgroup experience persistent or recurrent disease activity following an initial response to therapy (suboptimal treatment response).11,12 While anti-VEGF resistance is a well-established phenomenon, its causes remain poorly understood.13 An occasionally accompanying mechanism is tachyphylaxis, describing a reduction in response to a drug, often occurring following repeat administration.13-15

In the clinical setting, if an inadequate or diminishing response is observed, increasing dosing frequency to monthly injections until visual and anatomical stability is achieved, or switching to an alternative anti-VEGF may be considered. However, limited prospective data exist on retinal morphology and other potential benefits and risks associated with switching between anti-VEGFs in nAMD. Data on switching from aflibercept to ranibizumab are particularly sparse, with the majority being derived from ‘switch-back’ studies.16,17
This study determined whether switching treatment to ranibizumab reduces disease activity in patients with nAMD treated with aflibercept and in whom there was evidence of persistent or recurrent disease activity. Furthermore, this study evaluated retinal morphology to identify potential predictors of response to ranibizumab.

METHODS

Patients

Eligible patients were aged ≥50 years, with prior aflibercept treatment meeting strict criteria (Box 1) and with best-corrected visual acuity (BCVA) ≥23 Early Treatment Diabetic Retinopathy Study (ETDRS) letters in the study eye, at both screening and baseline. The patients had an active, angiographically documented, choroidal neovascularisation (CNV) lesion secondary to AMD in the study eye at screening, and evidence of active CNV in the centre of the study eye fovea at baseline. They also had a total area of fibrosis in the study eye comprising <50% of the lesion area, as assessed by all imaging data available, including fluorescein angiography, fundus photography and fundus autofluorescence.

In addition, all patients had to meet the criteria for one of two groups: primary treatment failure or suboptimal treatment response (Box 1; online supplementary table 1).

STUDY DESIGN

SAFARI (NCT02161573) was a 6-month, phase IV, prospective, single-arm, multicentre study. Ranibizumab (0.5 mg) was administered by monthly IVT injection on day 1 (baseline), day 30 (±7 days) and day 60 (±7 days) (figure 1A). Thereafter, patients received IVT ranibizumab (0.5 mg) on a pro re nata (PRN) basis, at the investigators’ discretion, at monthly study visits (±7 days): day 90, day 120 and day 150. An end-of-study (EOS) visit was scheduled for day 180 (±7 days).

The study was conducted from August 2014 to September 2017 at 22 study sites in the UK and 6 sites in Germany.

Efficacy and safety assessments

The primary efficacy variable was change from baseline (ΔB) to day 90 in central subfield retinal thickness (CSRT), defined as the average retinal thickness (μm) of the circular area within 1 mm diameter around the foveal centre. The spectral domain-optical coherence tomography (SD-OCT) instruments that were permitted are described in the online supplementary materials.

The secondary efficacy variables are presented in figure 1A. BCVA was assessed with refraction on ETDRS charts. Colour fundus photography, fluorescein angiography and fundus autofluorescence imaging were conducted at screening and at the EOS. SD-OCT was acquired at each visit, including at screening. Indocyanine green angiography was performed at screening only. All imaging data were independently reviewed by a central reading centre (CRC; GRADE Reading Centre, Bonn, Germany) to ensure standardised evaluation.

The safety assessments included adverse events (AEs), ophthalmic examinations and vital signs. AEs were coded using MedDRA, V.20.1.

Exploratory analysis

The exploratory variables presented include ΔB in subfoveal choroidal (SFC) thickness to day 180, ΔB in area of macular CNV lesion, change in area of leakage from screening to day 180, presence of dry retina and the correlation between change over time in CSRT or BCVA and baseline parameters, as well as prior patient treatment history. The regression analysis methodology for assessing the effects of baseline parameters on change in CSRT and BCVA is presented in the online supplementary materials.

Statistical analysis

Sample size and power analyses, summary statistics and analysis set definitions are outlined in the online supplementary materials.

Primary efficacy assessment

Due to the non-normal distribution of the observed data for the primary efficacy variable (CSRT), the prespecified, Wilcoxon signed-rank test was used. A sensitivity analysis verified the use of the Wilcoxon signed-rank test; a transformation of ln(−1°CSRT

Figure 1  Safari study design, patient disposition and analysis sets. Percentages=n/(patients treated at any visit)×100. A total of 10 patients were excluded from the PPS (overall) based on protocol deviations. The PRN regimen permitted retreatment with ranibizumab if, in the opinion of the investigator, persistent or worsening visual symptoms were attributable to nAMD, and/or if there was evidence of worsening visual acuity determined by ETDRS BCVA (>1 letter decline since last study visit), and/or the presence of persistent or worsening disease activity on OCT (eg, presence of subretinal fluid, persistent or increased number, size, or total volume of IRC, or increased central retinal or foveal thickness). BCVA, best-corrected visual acuity; CF, change from baseline; CSRT, central subfield retinal thickness; EOS, end of study; ETDRS, Early Treatment Diabetic Retinopathy Study; FAS, full analysis set; FCP, foveal centre point; IRC, intraretinal cyst; IRF, intraretinal fluid; nAMD, neovascular age-related macular degeneration; PED, pigment epithelial detachment; PPS, per protocol set; OCT, optical coherence tomography; PRN, as required (pro re nata); SCN, screening; SF, subretinal fluid; SS, safety set.

Secondary and exploratory efficacy assessments
There was no replacement of missing data for the secondary or exploratory variables. For summary statistics presenting percentages, the denominator is the overall N value (ie, for full analysis set (FAS), N=100) and not the number of patients at each time point.

RESULTS

Patients
Despite two extensions to the recruitment period due to slow enrolment, recruitment was halted before the planned sample size of 124 patients had been reached. Nevertheless, a sample size of 102 had 83% power to detect a change of 30 µm in CSRT to day 90 (primary efficacy variable).

A total of 103 patients received at least one dose of study drug; of these, 92 (89.3%) completed the study, and 11 (10.7%) discontinued prematurely (figure 1B). The number of patients included in each analysis set is summarised in figure 1B. The mean (SD) age of the 100 patients in the FAS was 77.0 (6.5) years (table 1). The patients were predominantly Caucasian (99%; Asian, 1%) with a similar proportion of males and females (45% and 55%, respectively).

The patients’ treatment history prior to the switch is presented in table 1.

A median of 6.0 ranibizumab injections (range 1–6; N=100 (safety set)) were administered in the study eye. The decision

*Duration=day of last aflibercept injection−day of first aflibercept injection+1
†Retreatment interval=(day of last aflibercept injection−day of first aflibercept injection) / (total number of aflibercept injections−1), defined only for patients with >1 aflibercept injections. The retreatment interval for the monthly and bimonthly data were collected together.

AMD, age-related macular degeneration; BCVA, best-corrected visual acuity; CNV, choroidal neovascularisation; CSRT, central subfield retinal thickness; PCV, polypoidal choroidal vasculopathy; RAP, retinal angiomatous proliferation; RPE, retinal pigment epithelium.

to initiate treatment during the PRN phase was predominantly based on anatomical (OCT) data.

**Primary efficacy variable**

There was a statistically significant median decrease in CSRT of −30.75 μm (95% CI −58.50,−20.50; p<0.0001) from baseline to day 90 (figure 2A–B; online supplementary table 2). Further analysis using the per protocol set demonstrated a statistically significant median decrease of −29.25 μm (95% CI −58.50,−19.00; p<0.0001).

**Secondary efficacy variables**

Decreases in median (or mean) CSRT and foveal centre point (FCP) thickness were observed throughout the monthly and PRN treatment periods (figure 2A–B; online supplementary table 2). The maximum median CiB achieved in CSRT and FCP thickness occurred at day 30 and were −35.00 μm and −38.00 μm, respectively. Maximum pigment epithelial detachment (PED) and intraretinal cyst (IRC) height were also reduced with treatment; the maximum median CiB, −24.25 μm and −33.50 μm for maximum PED and IRC height, respectively, were recorded at day 60 (online supplementary table 3). Improvements in qualitative OCT parameters (intraretinal fluid, subretinal fluid, IRCs and PEDs) are illustrated in figure 2C–F.

Mean gains in BCVA in the study eye from baseline to each time point were generally small (≤2 letters) (online supplementary table 4). No change in BCVA was observed in the study eye from day 90 to day 180 (online supplementary table 4).

There was some evidence of improvement in ETDRS letters, when assessed by category. At day 90, 29%, 14%, 7% and 5% of patients had gained 0–<5, 5–<10, 10–<15 and ≥15 letters versus baseline, respectively. At day 180, 25%, 17%, 6% and 11% had gained 0–<5, 5–<10, 10–<15 and ≥15 letters compared with baseline, respectively (figure 3 and online supplementary file 1).

**Safety variables**

Overall, 11 patients (11.0%) experienced an ocular treatment-emergent AE (TEAE) that was suspected to be related to study drug treatment by the investigator (online supplementary table 5). Most of these events were mild, and all resolved; none were severe. TEAEs leading to study discontinuation were reported by two patients (2.0%); these were the treatment-emergent serious adverse events (SAEs) of transient ischaemic attack (TIA) and retinal haemorrhage. The case of TIA, which occurred on day 150 and was mild, was the only SAE considered to be related to the study drug treatment by the investigator. Concomitant medication/therapy was administered, and the event resolved on the same day. No patients had a TEAE leading to death.

**Exploratory efficacy variables**

Overall, no marked CiB to day 180 was observed in SFC thickness, or from screening to day 180 in area of leakage. Small numerical changes were documented from screening to day 180 in the exploratory variables of area of total lesion and macular CNV (online supplementary table 6). No patients had dry retina during the study.

Regression analyses demonstrated that greater baseline area of leakage and FCP thickness were associated with reduced CSRT to day 90, whereas higher maximum PED diameter and baseline BCVA were significantly associated with an increase in CSRT to day 90, after adjusting for baseline risk factors (online supplementary results).

**DISCUSSION**

The SAFARI study assessed the anatomical and visual outcomes of switching from aflibercept to ranibizumab following persistent or recurrent disease activity in patients with nAMD. The primary endpoint showed a statistically significant median CiB of −30.75 μm in CSRT to 3 months, following monthly IVT injections with ranibizumab. There was also evidence of improvement after switching in both quantitative and qualitative OCT parameters, and ETDRS letters assessed by category. While the changes observed after relatively small, the results demonstrated OCT stability following the switch to ranibizumab, with stabilised or improved BCVA for −60% of this challenging-to-treat patient population. No new safety findings were identified.18

Collectively, anti-VEGF switching studies have suggested clinical benefit following switching for poor responders with nAMD, typically reporting a small gain in ETDRS letters.17 19 However, these findings are largely derived from retrospective and uncontrolled studies with heterogeneous criteria for ‘poor respondents’. The SAFARI study is the first prospective study...
to have examined the potential benefits and risks associated with anti-VEGF switching in patients with nAMD with a poor response to aflibercept treatment meeting strict criteria.

The putative mechanisms underlying anti-VEGF resistance and considerations regarding classification of ‘responder status’ have been discussed elsewhere.\textsuperscript{13–15,17} There is no consensus on the classification of ‘non-responders’ or ‘poor responders’, and the defining criteria employed in the literature vary.\textsuperscript{13} In this study, patients were eligible for inclusion in the suboptimal response group if they had worsened disease activity at screening (increasing retinal or subretinal fluid, or new or increasing in size PED in the study eye compared with prior visits).

In this 6-month study, 59\% of patients switching to ranibizumab following a suboptimal response with aflibercept experienced stabilised or improved BCVA to day 180, although this was counterbalanced by a large minority (38\%) who lost ≥1 letter. The lack of a substantial improvement in mean VA requires further investigation, but it may be due, in part, to the relatively long duration of disease activity prior to the switch (mean±SD total duration of prior aflibercept treatment: 325.5 days±160 (min: 63; max: 933 days)), which could have resulted in some of the structural changes becoming permanent. Switching early on may be helpful in elucidating the most appropriate drug and regimen for individual patients to preserve vision in the long term. However, this study did not ultimately assess the impact of switching early, as only one patient was recruited to the primary treatment failure group, and further research on this is required.

The largest improvements in clinical outcomes in the SAFARI study were observed during the initial monthly treatment period.

---

**Figure 2** Changes in quantitative retinal morphology and qualitative OCT parameters with ranibizumab treatment up to 6 months (N=100). Full analysis set. *The primary efficacy endpoint was CFB in CSRT to day 90; ***p<0.0001. Data presented in A and B represent median±min/max (as not normally distributed) and mean±SD, respectively. Baseline was defined as the last available non-missing value collected just prior to the start of treatment in the study eye. Visit days represent day ±7 days. BL, baseline; CFB, change from baseline; CSRT, central subfield retinal thickness; FCP, foveal centre point; NA, not accessible; OCT, optical coherence tomography.

---

**Figure 3** Change from baseline in best-corrected visual acuity (letters) (N=100). Full analysis set. *Data for 1 patient are missing at day 30. Visit days represent day ±7 days.
This finding was anticipated given that these patients were experiencing persistent or recurrent disease activity with aflibercept before being switched to a monthly treatment regimen with ranibizumab. In the PRN phase, there was some evidence of the CSRT response diminishing; however, the difference between the median CfB at day 90 and day 180 was only 1.25 µm, which is likely to be of minimal clinical significance. While the clinical significance of this statistically significant reduction in CSRT to day 90 is unclear, it is supported by a trend towards improved BCVA. Regression analyses demonstrated that baseline parameters such as greater area of leakage and FCP thickness, and higher maximum PED diameter and BCVA, were associated with reduced or increased CSRT to day 90, respectively. The value of these parameters as potential predictors of response to ranibizumab merits further investigation.

In addition to switching anti-VEGFs, the importance of regular dosing cannot be understated. The lack of a tightly controlled monthly treatment regimen is thought to account for the poor translatability of VA gains associated with clinical trials in the real-world setting. It is also possible for patients to experience similar clinical improvements to those achieved by switching anti-VEGF by simply reverting to fixed dosing with their current anti-VEGF treatment. In line with this, in patients with nAMD who required monthly treatment following a 2-year trial, no significant difference in clinical outcomes was reported between continuing on ranibizumab and switching to aflibercept. This is also reflected in clinical practice, where the treatment response achieved is inadequate or diminishes, the strategy is often to increase the dosing frequency of the current anti-VEGF regimen. Thus, prior underdosing with the first anti-VEGF therapy, by transitioning from a ‘real life’ paradigm to a prospective study protocol, can be a confounding factor. However, a key strength of the SAFARI study was that patients had to meet strict inclusion criteria with respect to prior aflibercept treatment, including the number and timeframe of injections.

At the time of study in the UK, licensed treatment with aflibercept in year 1 consisted of 3 monthly IVT injections followed by one injection every 2 months. The results of this study suggest that switching to ranibizumab for patients who do not achieve a dry retina while on aflibercept therapy may be beneficial. The use of a fixed monthly regimen rather than PRN, even after switching anti-VEGFs, or a treat and extend regimen, could also be considered. Further studies are warranted to evaluate longer term anti-VEGF switching outcomes.

Study limitations
As only one patient was recruited to the primary treatment failure group, the findings of the SAFARI study largely represent patients who achieved a suboptimal treatment response with aflibercept; comparison across subgroups was not possible. Furthermore, it is difficult to discern if the effect of the switch was solely due to the drug or also the posology. Due to the relatively small number of patients included, the findings of the secondary efficacy and exploratory analyses should be interpreted with caution.

Main conclusion
The SAFARI study demonstrated that switching to ranibizumab following an inadequate response or loss of efficacy with aflibercept led to a significant improvement in the primary efficacy endpoint of CSRT with ~60% achieving stabilised or improved VA. No new safety signals were identified. Therefore, patients with nAMD who have shown a suboptimal response to aflibercept may benefit from switching to ranibizumab.
