Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Narrative Review

Post-acute COVID syndrome (long COVID): What should radiographers know and the potential impact for imaging services

Abstract

Objectives: The COVID-19 pandemic caused an unprecedented health crisis resulting in over 6 million deaths worldwide, a figure which continues to grow. In addition to the excess mortality, there are individuals who recovered from the acute stages, but suffered long-term changes in their health post COVID-19, commonly referred to as long COVID. It is estimated there are currently 1.8 million long COVID sufferers by May 2022 in the UK alone. The aim of this narrative literature review is to explore the signs, symptoms and diagnosis of long COVID and the potential impact on imaging services.

Key findings: Long COVID is estimated to occur in 9.5% of those with two doses of vaccination and 14.6% if those with a single dose or no vaccination. Long COVID is defined by ongoing symptoms lasting for 12 or more weeks post acute infection. Symptoms are associated with reductions in the quality of daily life and may involve multisystem manifestations or present as a single symptom.

Conclusion: The full impact of long COVID on imaging services is yet to be realised, but there is likely to be significant increased demand for imaging, particularly in CT for the assessment of lung disease. Educators will need to include aspects related to long COVID pathophysiology and imaging presentations in curricula, underpinned by the rapidly evolving evidence base.

Implications for practice: Symptoms relating to long COVID are likely to become a common reason for imaging, with a particular burden on Computed Tomography services. Planning, education and updating protocols in line with a rapidly emerging evidence base is going to be essential.

Introduction

Medical imaging played and continues to play an essential role during the COVID-19 pandemic for patient diagnostics and assessment. High-resolution chest computed tomography (CT) was established as the gold standard for identifying subtle changes within the lung fields caused in response to COVID-19 infection with 90% sensitivity and 91% specificity.1 In comparison, chest X-rays have a sensitivity and specificity estimated at 89% and 41%–66% due to their reliance on reader experience and ability.1 Magnetic resonance imaging (MRI), particularly ultrashort echo time MRI (UTE-MRI), is recommended as an alternative to CT to evaluate COVID-19.2 While some imaging increased during the initial waves of COVID-19, some non-urgent imaging was postponed, and some services, such as dual-energy X-ray absorptiometry (DXA) and the mammography screening programme,4–6 were closed in many hospitals, resulting in waiting list increases, which remain two years later.7,8

With each wave of COVID-19, significant pressure was put on the NHS and imaging services, not just from patient volume, but also increasingly due to staff sickness with COVID-19.9,10 Vaccination against SARS-CoV-2 limits the severity of symptoms, reduces the number of hospitalisations and is currently seen as the route out of the pandemic.11

As the acute phase of the pandemic recedes, however, there is a greater awareness, that many individuals who have recovered from the acute stages of the disease have reported prolonged changes in
their physical health and wellbeing post-COVID-19. The term “long COVID”, alongside the term “long haulers”, was first used by Dr. Elisa Perego on 20 May 2020 in a social media post describing the disease experience in Italy. In mid-March 2021, more than 50,000 mentions of long COVID were noted on social media, indicating an increase of 140%. Callard and Perego concluded that “long COVID has a strong claim to be considered the first illness to be collectively made by patients finding one another through Twitter and other social media.”

The UK National Health Service (NHS) continues to be severely challenged as it commences the recovery program to combat the built-up waiting lists for routine procedures and imaging at record levels. As such, the NHS must adapt to also diagnose and treat the long COVID patients with little insight and knowledge about known determinants. The World Health Organization has further refined this definition to a condition which “…occurs in individuals with a history of probable or confirmed SARS-CoV-2 infection, usually 3 months from the onset of COVID-19 with symptoms that last for at least 2 months and cannot be explained by an alternative diagnosis”. The Americans with Disability Act classified long COVID count as disability in July 2021, then at 1st of October 2021, the CDC and National Centre for Health Statistics (NCHS) developed a new code for post-COVID-19 conditions. The CDC and NICE have indicated that persistent symptoms of long COVID can be experienced even by non-hospitalised individuals, of any age group, with a history of confirmed acute COVID-19, even if that initial infection was asymptomatic.

Varying reports have noted the rates of developing long COVID with little insight and knowledge about known determinants. The Office for National Statistics (ONS) estimate that long COVID is 9.5% in people who self-reported two doses of vaccine and 14.6% for both single vaccinated and unvaccinated. Other studies estimate greater prevalence. Over the 6 months after their acute infection, a Norwegian study evaluated 312 patients who contracted COVID-19 during the first wave. Some of these cases were milder (247 home-isolated) whilst 65 were hospitalised due to their more severe disease. Rates of long-COVID in this population was 61%, much higher than the current ONS self-reporting estimates in the UK. Other data indicates that most patients requiring hospitalisation for COVID-19 still have persistent symptoms, even after a year. Care must be taken when interpreting these estimates as they vary depending in study methodologies. Currently, the ONS and The Solve ME/CFS Initiative (Solve ME) stated that about 3% of the UK and 7% of the U.S. population has reported experiencing long COVID symptoms.

Long COVID subtypes

The acute phase of COVID-19, characterised based on symptoms severity as: asymptomatic, mild, moderate, severe, and critical has been well described [27]. The early-stage clinical examination or specific diagnostic criteria for post-COVID syndrome is still unclear and the persistence of symptoms fluctuates. Furthermore, the heterogeneity of long COVID makes it challenging to characterise specific subdivisions of the condition. Long COVID may be classified into four syndromes: post-intensive care syndrome, post-viral fatigue syndrome, permanent organ damage, and long-term COVID syndrome. Alternatively, Yong and Liu, based on the literature, suggested six post COVID syndrome subsets including: non-severe COVID-19 multiorgan sequelae (NSC-MOS), pulmonary fibrosis sequelae (PFS), myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS), postural orthostatic tachycardia syndrome (POTS), post intensive care syndrome (PICS), and medical or clinical sequelae (MCS) (Fig. 1). Furthermore, Becker developed five classifications of long COVID based on the initial symptoms, their period, inactivation duration, and onset (Fig. 2). Finally, Boix and Merino, from their practical perspective, sorted long COVID into five types: post-acute COVID body organ impairment sequelae, post-COVID derived from the hospitalisation itself (post-ICU syndrome), decompensation of previous chronic diseases, onset of a new disease triggered by COVID-19, and pharmacological toxicity from COVID-19 treatment.

Symptoms of long COVID

The duration of COVID-19 recovery is highly variable; some individuals will take only a couple of days, whereas others may take up to 12 weeks for a full recovery. Ongoing symptoms lasting over 12 weeks after positive COVID-19 testing is considered long COVID. In general, symptoms are associated with reductions in the quality of daily life and may involve multisystem manifestations or present as a single symptom. Many low-risk individuals with mild COVID-19 have been shown to present with diverse long-term symptoms with subsequent disruption of work, social, and home life. Therefore, patients understandably wish to adapt or treat any remaining symptoms that cause difficulty in daily life to eventually reach a stage of full recovery.

The pathological and mechanistic basis behind the persistence of long COVID symptoms has not yet been determined. However, proposed hypotheses include an ongoing healing process (the convalescent phase) after organ damage from the acute phase, an autoimmune response, ongoing infection, mini infection, or post-intensive care syndrome. It is suggested that COVID develops a cytotoxic memory immune T cell that affects the autoimmune response. Another cause of long COVID may be that the immune system does not attack the virus, in cases where COVID-19 is replicated in a protected anatomical location, such as the central nervous system (CNS) or the gut-associated lymphoid tissue (GALT). This was demonstrated by the remnants of SARS-CoV-2-RNA on the faecal samples post-acute phase, which resulted in long COVID effects. It is difficult to determine the pathophysiological mechanism behind long COVID without further cohort investigations.

Whilst there has been much focus on the symptoms of long COVID using different methods, evidence based on diagnostic imaging reports revealed biological changes in long COVID that could explain some of the symptoms experienced by patients. Therefore, it is important to explore symptoms of long COVID and the various imaging modalities involved in its management to plan strategies to address the demand.
Cardiovascular symptoms in long COVID

The formation of microclots and other cardiovascular conditions have been identified in people with long COVID. Pre-existing cardiovascular disease was highlighted early as a risk factor for having severe COVID-19 symptoms, with an increased risk of hospitalisation and mortality. COVID-19 infection may exacerbate cardiovascular disease, causing dysfunction, coagulopathies and...
thrombocytopenia, hypercoagulation, pulmonary intravascular coagulation, microangiopathy, venous thromboembolism or arterial thrombosis, myocardial injury, acute coronary syndromes (ACS), cardiomyopathy, acute cor pulmonale, arrhythmias, and cardiogenic shock. For those with no pre-existing disease, long COVID may be present with a cardiovascular disorder. The exact aetiology/pathogenesis is unknown, although the leading hypothesis includes this being a result of persistent SARS-CoV-2 infection in immune-privileged tissue triggering persistent inflammation and micro-emboli that block micro-capillary and prohibit oxygen exchange, eventually leading to tissue hypoxia. The immune system may aggressively respond to COVID-19 through the cardiopulmonary system both directly and indirectly. Vessel inflammation may lead to thromboembolism development, affecting vital organs function as it circulates through the bloodstream. One study investigating ongoing breathlessness symptoms using XeMRI for discharged patients with long COVID found that the symptoms were caused by alveolar-capillary thrombosis. They reported alveolar capillary diffusion limitation in all of the nine participants despite normal or relatively normal CT results. Further, a study using [18F] FDG-PET/CT on 13 adults with long COVID showed signs of brain hypometabolism. There was also poor metabolism in some areas related to long COVID symptoms, such as anosmia/ageusia, fatigue, and vascular uptake, and several participants still had lung abnormalities. FDG PET scans in three long COVID patients with brain fog showed an association with the brainstem, with hypometabolic conditions particularly at thepons.

**Respiratory symptoms in long COVID**

The epithelium in the respiratory tract is the front-line of the COVID-19 infection following inhalation of the virus. Respiratory symptoms and severity following a COVID-19 infection are broad with mild upper respiratory tract symptoms such as a sore throat and cough regularly reported. However, patients can develop symptoms and severity following a COVID-19 infection are broad despite normal or relatively normal CT results. Further, a study investigating ongoing breathlessness using XeMRI for discharged patients with long COVID found that the symptoms were caused by alveolar-capillary thrombosis. They reported alveolar capillary diffusion limitation in all of the nine participants despite normal or relatively normal CT results. Further, a study using [18F] FDG-PET/CT on 13 adults with long COVID showed signs of brain hypometabolism. There was also poor metabolism in some areas related to long COVID symptoms, such as anosmia/ageusia, fatigue, and vascular uptake, and several participants still had lung abnormalities. FDG PET scans in three long COVID patients with brain fog showed an association with the brainstem, with hypometabolic conditions particularly at the pons.

**Musculoskeletal (MSK) symptoms in long COVID**

Though studies have identified MSK-related conditions associated with long COVID, this aspect remains unclear. An early paper identified “profound fatigue” as a common symptom in many patients with long COVID and fatigue is the most common self-reported symptom of long COVID. Furthermore, studies of MSK-related long COVID symptoms have reported fatigue as one of the main manifestations, followed by myalgia and arthralgia, which are as ambiguous as other long COVID symptoms. These symptoms may result from inflammatory, neuro-physiological, and psychological factors, or from the negative impact of extended lockdown associated with the COVID-19 pandemic.

Other infrequent MSK related signs and symptoms of long COVID include bone density reduction and muscle weakness. These may be in part caused by the sedentary condition and limited mobility imposed by quarantine measures. The long lockdown period that the COVID pandemic forced into countries led to people staying indoors with functional limitations and reduced exposure to sunlight. Similar to astronauts, who suffer from a reduction in bone mass on the weight-bearing bones, certain at-risk individuals may have experienced similar conditions during the COVID pandemic, leading to bone turnover system disruptions and systemic osteoporosis. Indeed, many investigations have studied the effect of physical activity reduction on the function of bone and muscle, and in patients with total knee replacement may affect the balance of bone density, and resulting in bone loss and an increased chance of fracture. Likewise, myalgia or joint pain have been recorded with other MSK symptoms. A study found that almost two in every five long COVID patients report extensive spreading pain in joints and muscles, likely induced by the acute COVID phase, in which it has been reported that 15% of patients experience arthralgia, and 19% experience myalgia. However, 45% of post-hospitalised patients with long COVID will experience generalised muscle pain, frequently at the lower extremity. Some studies have reported MSK-related biological changes, which could explain some of the symptoms. A recent review showed one study found an association between MSK related COVID-19 symptoms and imaging hematoma, nerves injuries, thickening, and compression, muscle oedema and myositis, multi-joint rheumatoid arthritis, synovitis and other findings, which may be linked with the post COVID syndrome theme. Furthermore, CT findings on COVID patients at 24 h and 20
days following ICU admission show a loss of lean body mass,\textsuperscript{97} which has been linked with fatigue and reduced neuromuscular function.\textsuperscript{98} In addition, utilising dual-energy X-ray (DXA) may provide further information regarding bone mineral density in long COVID,\textsuperscript{99} and MSK ultrasound can determine abnormal articular changes in long COVID.\textsuperscript{100}

**Current diagnosis of long COVID and the impact on imaging services**

The current understanding of long COVID is still developing. The health sector is supposed to be in a post-pandemic recovery period following the COVID-19 overload, as elective medical procedures were postponed during the pandemic. Additionally, the number of long COVID patients is increasing, and they require reliable clinical, imaging and laboratory biomarkers to diagnose and monitor their disease and any future treatments. The multidisciplinary community needs more studies to help better understand the mechanisms underlying multi-organ persistent symptoms of COVID-19. The Health-Related Quality of Life (HRQOL) EQ-5D-5L questionnaire with visual analogue scale\textsuperscript{91,92} and the Newcastle post-COVID syndrome follow-up screening questionnaire,\textsuperscript{93} have been utilised in some studies. Significantly, the COVID-19 Yorkshire Rehabilitation Scale C19-YRS was developed to assess the severity of long COVID-19 symptoms during screening, aligning with The International Classification of Functioning of the WHO,\textsuperscript{94} and recommended by the NHS Clinical Guidance.\textsuperscript{95} These techniques were used to help triage suspected long COVID patients, were key tools in initial studies investigating ongoing COVID symptoms and are trusted as part of the initial clinical examination for long COVID.

The NHS has already committed £145 million, establishing more than 80 long COVID assessment clinics around the nation,\textsuperscript{100} however, this still equates to less than £100 per person. These clinics primarily act as an investigation hub (to exclude alternative diagnoses) and then signpost people to existing services.\textsuperscript{96}

Several protocols and guidelines have been proposed throughout the literature. One suggested diagnostic algorithm indicates that there should be three successive primary care visits to cover long COVID, which encompasses both ongoing and post-COVID syndrome, starting from COVID-19 diagnosis. The purpose of the initial visit aims to gather patient medical history, COVID-19 screening, complete physical examination, lab tests and complementary tests. After the initial assessment, when alternative diagnoses are considered, it is recommended to schedule the second visit between 8 and 10 weeks. Finally, to determine any further symptom development, the third appointment is recommended between weeks 12–14.\textsuperscript{101} In cases of post-hospitalisation COVID-19 survival with lung complications, a 4-week post-discharge phone call check is recommended, followed by a 12-week clinic appointment assessment accompanied by a number of standardised tests. If any of the results were abnormal, more advanced tests would be performed, such as a chest X-ray, chest CT or CT angiography.\textsuperscript{102} NICE guidelines recommend a holistic assessment that focuses on the overall health of the patient, requesting tests deemed necessary for physical, psychological, social and spiritual wellbeing.\textsuperscript{103} In cases of long COVID, a chest X-ray may be required with another medical test\textsuperscript{104} especially with 12-week post-positive COVID-19 pneumonia, or ongoing respiratory symptoms.\textsuperscript{105,106} Specific medical imaging scans are also recommended for dealing with long COVID patients based on symptoms, body system or sequelae (Table 1).\textsuperscript{97,102}

| Imaging modality | Imaging test | Evaluation | System/symptoms/sequelae |
|------------------|-------------|------------|--------------------------|
| X-ray            | Chest X-ray | Lung parenchyma evaluation | Pulmonary |
| CT               | Chest high resolution CT or angio-CT | Shortness of breath | Pulmonary |
|                  | CT Abdomen  | Unexplained cardiovascular symptoms | Cardiac |
|                  | CT Brain    | Gastrointestinal complications | Abdominal |
| MRI              | Cardiac MRI/CMR | Unexplained neurological symptoms | Neurological |
|                  | Brain MRI   | Unexplained cardiovascular symptoms | Pulmonary |
| Ultrasound       | Hepatic/Pancreatic MRI | Persistent or new unexplained chest pain | Cardiac |
|                  | Joint ultrasound | Shortness of breath | |
|                  | Abdominal ultrasound | Frequent palpitations | |
|                  | Duplex ultrasound | Postural lightheadedness | |
|                  | Lung ultrasound | Unexplained neurological symptoms | Neurological |
|                  | Chest ultrasound | Intra-abdominal inflammation | Abdominal |
|                  | Echocardiography | Unexplained cardiovascular symptoms | Cardiac |

During the pandemic, unprecedented delays in patients attending routine screening appointments have been seen. An additional estimated 2 million people suffer from long COVID, a number likely to grow with further infections and repeat infections. Radiology departments will face a significant amount of catching-up; they will need to account for this increased workload in their plans. In addition, there will be potential for trials tackling the need for imaging to help clinical differential diagnoses and follow-up patients. Strengthen research training by the field experts and increase research radiographer roles within the departments, which is more weight than adding to a sort of managers trying to get those signing rolls to facilitate. Likewise, it is important for radiography educators to include long COVID in their curricula to know the presentation and justification of imaging in patients presenting with long COVID. As the evidence base evolves, protocols for imaging and monitoring will need to be developed and as therapeutics enter the market, imaging is likely to play an integral part in evaluating the efficacy and longer term effectiveness of these treatments. It is also possible that imaging may play a role in identifying candidates for appropriate therapeutic intervention in the future.
The COVID-19 pandemic has significantly affected the world over the past 2 years, but its impact will be felt for longer in patients with long COVID. Healthcare communities and governments have gained support for research on long COVID. Therefore, there is an opportunity to investigate the causes of these persistent symptoms and methods to cure or avert them. The percentage of people suffering from long COVID is growing, and action is needed. The full impact of long COVID on imaging services is yet to be realised, but its impact will be felt for longer in patients with long COVID. Healthcare communities and governments have over the past 2 years, but its impact will be felt for longer in patients with long COVID.
