Abstract: Accounting the increasing commercial need of rational strategies for passive icing and anti-microbial protection, the development of simple, time-efficient and scalable laboratory micropatterning techniques is highly desirable. Whilst the laser irradiation is an acknowledged technology for rapidly tuning the properties of any carbon allotropes, including soot aerosols, very barely is known about the impact of the laser beam on the physicochemical profile of the soot if it appears as a functional coating. In this pioneering research, the prolonged laser treatment of a super-nonwettable soot coating actuates morpho-chemical transformations in the material, depending on the laser power and irradiation time, without interfering its anti-wetting capability and optical transmittance. Our observations could be used as a foundation for facilitating the launch of soot coatings with customized anti-icing and anti-microbial performance.

Keywords: laser irradiation; physicochemical properties; soot

Despite being considered as one of the major anthropogenic contributors to the global warming [1], the carbon soot nanoparticles steadily become popular as a useful tool for the fabrication of liquid-repellent interfaces with potential applicability in cryobiology, medicine, shipbuilding, oil industry, civil and environmental engineering [2–6]. Finding suitable approaches for regulating the physicochemical profile of the as-prepared soot-based nanostructures is critical for their subsequent flexibility and functionality in a variety of practical settings (e.g., for passive icing and anti-microbial protection of civil and industrial facilities).

Currently, the laser irradiation of different carbon allotropes such as diamond, graphite and carbon nanotubes is recognized as a powerful and facile technology for appropriately modulating the relevant surface properties [7–9]. It is demonstrated that the structure of graphite and diamond composite films can be varied by adjusting the laser power fluence, wavelength and pulse duration, affecting the degree of graphitization and hindering the laser energy conduction from the surface to the interior of the material [7,8]. Furthermore, the laser pulses can stimulate the formation of new carbon phases such as amorphous carbon and nanocages, next to the original carbon nanotube matrix [9].

Interestingly, the scientific literature published in the last two decades provides also undisputed evidences for the opportunity of triggering laser-induced changes in the structure, morphology, chemical composition and optical properties of soot aerosols [10–17], allowing accurate control of the size and concentration of the incipient soot particles [11], synthesis of fluorescent carbon quantum dots [16], creation of smart optically-reconfigurable surfaces [15] and even subtle manipulation of the sooting propensity of laminar diffusion flames [12]. However, and regardless of the tremendous progress of laser diagnostics in combustion, the impact of laser irradiation on the physicochemical properties of the soot is still far from well-understood at a molecular level [17], but it is of substantial importance...
for improving the nanoparticle production techniques [11]. Moreover, to the best of our knowledge, there is a profound lack of literature data concerning the laser-soot interactions when the latter occur in a pristine (chemically non-modified) surface coating rather than in an aerosol.

Within the present short communication, we describe the one-of-a-kind research related to laser irradiation of super-nonwettable carbon soot coatings. We demonstrate experimentally that the continuous laser radiation triggers morphological and chemical alterations in the soot, but surprisingly without amending its optical transmittance and wettability, thus, raising many meaningful questions of fundamental significance and opening a space for future systematic studies.

The fabrication of carbon soot coatings maintaining weak contact with a wide range of polar and non-polar liquids [2–4] was performed via controlled combustion of rape-seed oil at atmospheric pressure [18]. Shortly, soot with quasisquare particle/aggregate morphology, surface roughness of ~110 nm, thickness of ~25 µm and inherent robustness under watery liquids was generated by setting the rate of the air flow reaching a steel conical chimney, used as a combustion chamber, to 0.0035 m³/min by means of a flow meter/controller (Fisher Scientific 11998014, Sindelfingen, Germany) [18]. Inside the chimney was placed an inflamed paper wick soaked in rapeseed oil, whose vaporization in an oxygen deficient environment triggered desublimation of the nascent polyaromatic hydrocarbons into soot, uniformly deposited for ~20 s on a 25 × 25 mm glass slide.

Surface characterization of the as-prepared soot was executed through scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS) and wetting analysis. Top-view SEM images, revealing the soot morphology prior to and after the laser irradiation, were obtained using a JEOL JSM-5510 scanning electron microscope (JEOL, Akishima, Tokyo, Japan) at magnifications up to 10 k. The chemical composition of the unaffected and laser-affected surface areas was studied with an energy dispersive spectrometer Bruker at 126 keV and an EDAX detector of 1.3 mm² active area. Static contact angle and contact angle hysteresis measurements of 10 µL water droplets were carried out inside and outside the irradiated soot regions using OCA 15EC analytical instrument (DataPhysics, Filderstadt, Germany).

The optical experiments were implemented via a semiconductor laser model LSR-PS-II (Lasever Inc., Glendora, CA, USA), shown in Figure 1, equipped with an optical camera T-560C1/3” having spectral response range of 190–1100 nm, a scanning system supporting CCIR interface and a laser source operating at wavelength \( \lambda = 405 \) nm. The laser beam was focused by a lens with a focal length of 150 mm, chosen to obtain an optimal ratio between the lens’focal length towards the sample and the optimal cross-section of the spot. The lens-to-substrate distance was set to 165 mm in order to ensure the highest possible photon density for modification of the soot at maximum width of the spot, facilitating the subsequent wetting state analysis. The soot coated glass substrate was irradiated in four distinct surface locations with a laser power of \( p = 114 \) mW and \( p = 171 \) mW, and irradiation time \( t_{ir} = 350–450 \) s, while during the assays, the laser spot was characterized with asymmetric Gaussian distribution and dimensions \( x:y = 0.89:0.64 \) mm, depicted in Figure 2. Although the Gaussian beam profile would not allow uniform heating of the surface, it is appropriate to warrant high homogeneity in the center of the spot.
Figure 1. Scheme of the experimental setup.

Finally, the light transmission coefficient of the soot coating in the irradiated and non-irradiated domains was measured via LAMBDA 1050 UV/Vis/NIR spectrophotometer (Perkin Elmer, Waltham, MA, USA) furnished with double monochromator generating a light beam in the range of 320–2500 nm at minimized noise levels within 0.01%–0.1% [18].

Figures 3 and 4 demonstrate the morphological and structural features of the soot coating before and after the laser processing. The surface areas in Figures 3b–d and 4b–d correspond to a spot formed by a Gaussian beam with intensity of 6.8 and 9.12 W/cm², accordingly. Notably, the original fractal-like structure is preserved, but extensive morphological transformations in the material occur, similarly to the results reported for soot aerosols [10,17]. For instance, the pristine coating is composed of numerous quasisquare-shaped carbonaceous aggregates with dimensions between ~200–2000 nm (see Figures 3a–c and 4a–c) [18], while in the laser irradiated areas, the number of these agglomerates (qualitatively defined by “naked eye”) reduces due to their confluence into much bigger clusters with size up to 6000 nm (see Figure 4b). Moreover, the process of aggregates fusion seems to be controlled by the laser treatment conditions and the most pronounced morphological modifications are induced at $p = 171$ mW and $t_{ir} = 350$ s, in contrast to the negligible changes observed at $p = 114$ mW and $t_{ir} = 350$ s (juxtapose Figures 3b and 4b).
Furthermore, the laser beam oxidizes the soot nanostructures and the oxygen content increases by 7 at.%, according to the data in Table 1, but unexpectedly, the morpho-chemical rearrangements do not cause even slight variations in the optical transmittance and non-wettability of the sample.

Figure 3. Morphology and structure of the soot coating (a,c) in the unaffected areas and (b,d) after laser irradiation with $p = 114$ mW for 350 and 450 s, respectively.

Figure 4. Morphology and structure of the soot coating (a,c) in the unaffected areas and (b,d) after laser irradiation with $p = 171$ mW for 350 and 450 s, respectively.
Furthermore, the laser beam oxidizes the soot nanostructures and the oxygen content increases by 7 at.%, according to the data in Table 1, but unexpectedly, the morpho-chemical rearrangements do not cause even slight variations in the optical transmittance and non-wettability of the sample.

**Table 1.** Chemical composition of each group soot coatings defined by EDS with an experimental uncertainty within ±0.1 at.%. The elements Na, Mg, Si and Ca are associated with the chemical composition of the glass substrate itself.

| Soot Area  | Irradiation Conditions | Chemical Element (at.%) |
|------------|------------------------|-------------------------|
| non-irradiated | n/a  | 79 | 15.6 | 0.7 | 0.3 | 3.8 | 0.6 |
| irradiated  | $p = 171$ mW; $t_{ir} \sim 350$ s | 72 | 21.5 | 0.9 | 0.3 | 4.6 | 0.7 |

As seen in Figure 5, the graphite-like nature of the soot [4] leads to nearly full and similar light absorption in both the unaffected and affected surface areas, whereas the static contact angle and contact angle hysteresis values of 152–156° and 1.2–2.2°, respectively, confirm the preserved extreme water repellency of the soot (see the insets in Figure 5). Therefore, it can be concluded that the as-performed laser processing does not change the thickness and hybridization ($sp^2/sp^3$ ratio) of the coating, since these are the main two parameters governing the light transmission through the soot [18].

![Figure 5. Light transmission spectra of the non-irradiated and laser-irradiated soot sample. The insets display the water contact angle before and after the laser treatment at $p = 171$ mW; $t_{ir} \sim 350$ s.](image)

Two primary physical mechanisms are considered responsible for the observed physico-chemical alterations in the soot, namely thermal annealing and heat-induced oxidation [17]. Upon laser irradiation of the coating, the increased temperatures (~450 °C, defined by performing laser-triggered paper ignition experiments) overcome the energy barrier of the solid-state interatomic forces (in the case of soot, covalent carbon-carbon and carbon-oxygen bonds) and boost the soot particle reorientation and realignment [10]. In turn, energetically more favorable morphological configuration is formed, where the numerous soot aggregates merge into larger clusters composed of smaller individual particles (see Figures 3 and 4), differently from the effects described for soot aerosols [17]. On the other hand, the increased surface oxidation (see Table 1) is attributed likely to the abundance of point defects [4], acting as active sites that accelerate the oxidative processes.
in the ambient environment due to the laser heating, in agreement with the outcome announced for carbon nanotube films, for example [19]. However, the unaltered light transmission coefficient of our soot coating implies that there is no loss of solid matter, since if the laser inflicts irreversible particle vaporization, the overall film thickness and the optical extinction will decrease [14,17] i.e., the coating will be able to transmit higher % of the incident light beam [18].

Herein, the irradiation of a liquid-repellent soot coating with a continuous laser beam was successfully accomplished for the first time. The laser energy melted the multiple quasisquare-shaped carbon aggregates and merged them into sizeable “soot clumps” with dimensions of a few microns, whereas the protracted heating promoted additional oxidation of the freshly nascent soot agglomerates. Unlike previous studies, it seems there was no loss of material from the nanoparticles, which paves the route for facile single-step modeling of soot-based non-wettable materials with a given morphology, porosity and surface chemistry; features that greatly influence the icephobicity and anti-bioadhesiveness of the interface [4,20]. For that purpose, further experiments encompassing the use of different types of lasers, laser wavelengths, optical lenses and/or soot nanostructures (e.g., those with quasispherical or mixed initial morphology [18]) are mandatory to gain novel insights into the laser-soot interaction mechanisms. These important tasks cannot be solved within the present communication, which focuses on a particular aspect of the problem (i.e., laser irradiation of soot in the form of a thin carbon film) and discloses novel findings that will potentially have significant impact (e.g., for designing optimized passive icephobic and anti-microbial surfaces). Lastly, our coatings must be subjected to transmission electron microscopy, Raman spectroscopy and selected area electron diffraction analyses for elucidating the probability of soot crystallization and graphitization upon laser irradiation, which regrettably is a forthcoming work due to the “COVID-19 pandemic” and the almost complete blocking of the scientific infrastructure (worldwide).

Author Contributions: K.D.E. provided the soot sample, planned and supervised the experiments, processed and interpreted the data, contrived the scientific concept of this short communication and wrote its first and final versions. Y.I.F., along with K.A.T., conceived the research idea for laser irradiation of soot coatings. Y.I.F. organized also the surface characterization analysis, drew some of the figures, found a few of the relevant references and assisted during the data acquisition. G.P.Y. designed the experimental setup, performed the laser irradiation of the soot and calculated the intensity of the Gaussian beam profile. K.A.T. constructively reviewed the first draft of the manuscript. All authors approved the scientific content of this communication prior to submission. All authors have read and agreed to the published version of the manuscript.

Funding: This research received no external funding.

Data Availability Statement: All the required data is available in the short communication.

Acknowledgments: The contact angle measurement system OCA 15EC was purchased thanks to the financial support of Bulgarian National Science Fund under grant №KP-06-H37/7/06.12.2019. The authors wish to gratefully acknowledge Stoyan Russev (Department of Solid State Physics and Microelectronics at Sofia University), Daniela Karashanova (Head of Electron Microscopy Laboratory at IOMT-BAS) and Ilko Miloushev (Optics and Spectroscopy Laboratory at ISSP-BAS) for helping with the EDS, SEM and optical analyses.

Conflicts of Interest: The authors declare no conflict of interest.
