Abstract

It is commonly believed that the transition line separating a liquid and a solid cannot be interrupted by a critical point. This opinion is based on the traditional symmetry argument that an isotropic liquid cannot be continuously transformed into a crystal with a discrete rotational and translational symmetry. We present here a molecular-dynamics simulation of a simple monatomic system that demonstrates a liquid-solid spinodal terminating at a critical point. We show that, in the critical region, the isotropic liquid continuously transforms into a phase with a mesoscopic order similar to that of the smectic liquid crystals. We argue that the existence of both the spinodal and the critical point can be explained by the close structural proximity between the mesophase and the crystal. This indicates a possibility of finding a similar thermodynamic behaviour in gelating colloids, liquid crystals and polymers.
1 Introduction

In many systems, a domain of spinodal instability can be observed where a liquid phase coexists in equilibrium with a gas phase. The spinodal terminates at a critical point\(^1\) which manifests a possibility of a continuous transformation between the two phases. Whether a single-component system can exhibit a spinodal where a liquid and a crystalline solid phase coexist in equilibrium, and a respective critical point, still remains an unanswered question of a significant conceptual interest. A liquid-solid critical point has never been observed hitherto, and its existence is commonly regarded impossible based on the argument that a continuous transformation from an isotropic liquid to a crystal with a discrete symmetry is inconceivable.\(^1\)

Here, we report a molecular dynamics simulation of a simple monatomic system that demonstrates under cooling a first-order transition from a liquid phase into a spinodal domain where the liquid coexists in equilibrium with a crystalline phase. Within the spinodal, the relative volume occupied by the crystalline phase shrinks with density reduction, vanishing in the low-density limit where the spinodal is terminated by a critical point. It is demonstrated that, upon cooling to the vicinity of the critical point, the isotropic liquid continuously transforms into a low-density phase with a mesoscopic order similar to that of smectic liquid crystals.\(^2\) Furthermore, we observed a close structural proximity between the mesophase and the crystal which extends much beyond the local order of nearest neighbours. We argue that this structural peculiarity of the mesophase can account for the existence of both the spinodal and the critical point. It also makes it possible to conjecture that a liquid-solid critical point like the
one we observe here might exist in liquid crystals, polymers and in gelating colloidal systems.

The following crystallization scenario suggested by the classical nucleation theory is commonly accepted. In a metastable supercooled liquid, nuclei of the lower free energy crystalline phase are being spontaneously created by virtue of thermal fluctuations. Because the two phases are symmetry-unrelated, appearance of a nucleus involves creation of an interface. The free-energy cost of the interface blocks the growth of the nucleus unless the latter exceeds a critical size. In this scenario, the entire volume of a metastable supercooled liquid rapidly crystallizes as soon as a critical nucleus has been created. The existence of a spinodal instability domain where no single phase can be in a stable or metastable equilibrium implies that the interfacial free-energy barrier vanishes.

In general, there are two independent order parameters involved in a first-order phase transition: density and the local structural symmetry. The former controls fluid-fluid phase transitions where a spinodal instability domain is commonly observed, whereas the latter plays the key role in crystallization of dense liquids. However, it was pointed out that density fluctuations seen in the vicinity of a metastable liquid-liquid spinodal with a critical point may cause a dramatic increase of the nucleation rate, indicating a reduction of the interfacial barrier for crystallization. The possibility of a liquid-solid spinodal was also inferred from the crystallization anomalies in simple liquids under deep supercooling and phase transformations in atomic clusters. It was also predicted, based on analytic arguments, that a fluid-solid spinodal region may appear in the system of hard spheres in higher dimensions.
A possible microscopic mechanism for the density-driven spinodal domain in the liquid-solid transition of a simple single-component system was conjectured by Debenedetti et al.\textsuperscript{14} based on a lattice model. A pair potential, attractive at the nearest-neighbour distance and repulsive at the second-nearest neighbour distance, was shown to induce low-density open structures, associated with the liquid phase, which collapse into a dense solid phase under pressure. Due to a significant difference in density, the two phases can coexist within a spinodal domain of infinite compressibility.

2 Simulation details

In the present simulation study, we explore the type of the pair potential suggested in the above conjecture in a molecular dynamics simulation of a single-component system. The pair potential we exploit\textsuperscript{15} (denoted as Z2 in that reference) has been found to induce a pronounced icosahedral local ordering of the nearest neighbours due to the design of its short-range attraction, while the repulsion incorporated in its longer-range part inhibits bulk packing of icosahedra. In this simulation, we used a system of 3456 identical particles in the NVT ensemble. All results here are presented in reduced simulation units following from the definition of the pair potential.\textsuperscript{15}

3 Results

The phase behaviour of the simulated system was explored within a wide range of densities by cooling it at constant density $\rho$ from the high-temperature isotropic liquid state. The cooling was performed stepwise, with comprehensive equilibration at each
temperature point. The isochoric variation of enthalpy $H$ as a function of temperature $T$ is shown in Fig. 1a. For each isochore where $\rho > 0.32$ we observe a discontinuity in $H(T)$ indicating a first-order freezing transition into a low-temperature state. The first-order character of this transition is confirmed by distinct hysteresis loops in the $H(T)$ isochores that are observed when the system is heated from the low-temperature state towards the high-temperature liquid.

Both the freezing and melting temperatures derived from the isochoric enthalpy variations are shown in the $\rho - T$ phase diagram, Fig. 1b. A distinctive anomaly of the observed phase transition is that the melting line and the freezing line confining the metastability domain converge at $\rho = 0.33$ and $T = 0.31$. The first-order phase transition apparently disappears at densities below $\rho = 0.33$. This is confirmed in Fig. 1c that shows the density dependence of the latent heat $\Delta H$ of this transition. That quantity reduces in an apparently linear manner with the reduction of density, eventually vanishing at the indicated density point. Indeed, no trace of discontinuity or hysteresis can be discerned in the isochoric variation of enthalpy within the relevant temperature interval at $\rho = 0.32$ presented in Fig. 1a. These observations lead to the conclusion that at $\rho = 0.33$ and $T = 0.31$ we observe a critical point which terminates the first-order transition line.

Another interesting anomaly of this phase transition can be observed in the behaviour of the isothermal compressibility $\chi_T$. It is related to the low-$Q$ limit of the structure factor $S(Q)$ as $\chi_T = \rho T S(0)$. The structure factor is defined as $S(Q) = \langle \rho(Q)\rho(-Q) \rangle$, where $Q = |Q|$ and $\rho(Q)$ is the Fourier transform of the system’s den-
\[ \rho(Q) = \frac{1}{N} \sum_{k=1}^{N} \exp(-iQr_k) \]  

\( N \) being the number of particles and \( r_k \) the real space location of particle \( k \). Fig. 1d shows the density dependence of \( S(0) \) in the low-temperature state along the freezing line. Within the density interval above the estimated critical density \( S(0) \) evidently demonstrates a pronounced tendency for divergence. The observed behaviour of the isothermal compressibility indicates the system’s large-scale decomposition into domains of different density, a characteristic signature of spinodal instability. We stress that this result was obtained after a thorough equilibration of the low-temperature state and, therefore, cannot be regarded as a transient effect of the phase transition.

In order to gain an insight into the microscopic mechanism of these thermodynamic anomalies, we now analyse the structural aspects of the observed phase transformation by directly inspecting the atomic configurations of the low-temperature state. We note that, to get rid of the thermal noise, all the configurations investigated here were subjected to steepest-descent minimization of potential energy.

Fig. 2 depicts a set of configurations representing the system’s states equilibrated at \( T \) immediately below the freezing transition, at different densities. At \( \rho = 0.5 \), the transition evidently produces a structure characterised by a well-defined global periodic order. This is a low-density crystalline phase with a local order apparently dominated by tetrahedral close packing. The central element of its unit cell is a cubically-symmetric configuration composed of eight icosahedra which are kept apart by low-dimensional arrangements of tetrahedra. In a similar manner, low-dimensional tetrahedral bridges link the described cubes into a periodic structure. To the best of our knowledge, this
crystalline structure has not been reported so far. A detailed crystallographic description of this phase will be reported elsewhere.

Other atomic configurations shown in Fig. 2 b-d represent the density domain of diverging isothermal compressibility that we identified as spinodal. Within each of these configurations, we are able to discern a distinct compact domain of the same crystalline structure as the one observed at $\rho = 0.5$. These crystalline domains are marked by red in the plots. The rest of the volume of the MD simulation cell outside the crystalline domains is occupied by an apparently different structure that is visibly less dense and doesn’t exhibit any immediately detectable global order. Its local order, however, appears to be quite similar to that of the crystalline structure, being dominated by the same kind of tetrahedral close packing with a high number of icosahedra linked in a low-dimensional manner. The plots in Fig. 2 also demonstrate that the relative volume occupied by the crystalline phase shrinks approximately linearly with reduction of density, eventually vanishing at the critical point. This observation is evidently consistent with the respective variation of the latent heat shown in Fig. 1c. It demonstrates that the liquid phase can be continuously transformed into a crystal via the critical point.

We now analyse the transformation of the liquid phase under cooling. First, we consider the isochore $\rho = 0.32$, i.e. below the critical density. Temperature variations of the specific heat $C_V$ at that density, shown in Fig. 3a, displays a pronounced maximum at $T_m = 0.45$. The density dependence of $T_m$ is shown in the phase diagram, Fig. 1b. The line of $C_V$ maximum extends to higher densities until it eventually encounters the freezing transition line. The appearance of excess specific heat under cooling is
an indicator of the development of bonded structures, and a common precursor of percolation.\textsuperscript{16,17} Indeed, a steep increase in the number of icosahedra can be observed below $T_m$, Fig. 3b. This leads to the development of extended clusters and a rapid growth of the correlation length, as it is demonstrated by the temperature-dependence of the maximum cluster size, Fig. 3b. These clusters are extended low-dimensional structures composed of interconnected icosahedra and face sharing tetrahedra, like the one exemplified in Fig. 3c. Upon further cooling, the maximum cluster size diverges, and at $T = 0.28$, a continuous tetrahedrally packed network is formed that includes approximately 90\% of all the atoms. An example of that network is shown in Fig. 2e. Another interesting structural feature developed in this liquid state under cooling is a low-$Q$ pre-peak of $S(Q)$, Fig. 3d. This anomaly, as well as the maximum of $C_V$, are commonly observed in the context of gelation in colloidal systems.\textsuperscript{18}

Fig. 3e presents the ratio of the number of icosahedra in the high temperature state to the respective number in the low temperature state within the metastability domain, as a function of density. It indicates that, as the density is reduced, the difference in the local order between the two states shrinks, vanishing at the critical point. A considerable degree of local structural similarity between the liquid in the critical-point region and the crystal is exemplified by the ring-like arrangement of icosahedra depicted in Fig. 2e. A trend for the formation of similar structural arrangement, although in a more defective rudimentary form, can be detected in the higher-temperature cluster, Fig. 3c. Moreover, the liquid exhibits an instantaneous mesoscopic-scale periodicity consistent with that of the crystal. Fig. 4a shows the intensity pattern of the liquid’s $S(Q)$ on a sphere in the $Q$-space, with a radius equal to $Q_{pp}$, the position of the low-$Q$
pre-peak of $S(Q)$; Fig. 4b shows the respective pattern exhibited by the crystal on the $Q$-sphere of the same radius. The liquid diffraction pattern shows a sizable degree of periodicity along two perpendicular axis, consistent with the respective periodicity pattern in the crystal. The observed periodic order in the liquid is however limited in both time and space. Its dissipation in time is demonstrated in Fig. 4c where we present the decay of the respective component of the density-density correlator $F(Q_{pp}, t) = \langle \rho(Q_{pp}, 0) \rho(-Q_{pp}, t) \rangle$, for a set of temperatures. The density-correlation pattern manifested by the pre-peak of $S(Q)$ evidently dissipates. The relaxation time exhibits a strong temperature-dependence, and exceeds the timescales accessible in our simulation for temperatures below $T = 0.28$.

4 Discussion

The liquid phase formed by cooling from the high-temperature liquid at $\rho = 0.32$ can be classified as a mesophase similar to the smectic phases observed in polymeric liquids. We also mention that a liquid-crystal smectic phase interposed between the isotropic liquid and the crystalline solid was discussed as a possible scenario for the bond ordering in the supercooled liquid state. Both melting of such a phase and its transformation to a crystal were conjectured to be continuous. The present result supports that conjecture. Another possible candidate for the observation of a liquid-solid critical point may be polymers where a liquid-solid spinodal was recently observed.

Based on these observations, we can understand the existence of a spinodal domain where the mesophase coexists with the crystal, and the critical point considering two
factors. First, there is a significant difference in density between the two coexisting phases. The characteristic low-density open structure of the mesophase is induced by the pair potential which enforces a strong tendency for icosahedral ordering of the nearest neighbours while keeping the icosahedra apart due to the repulsion incorporated in its long-range part. Second, the structural proximity between the mesophase and the crystal that extends well beyond the nearest-neighbours’ configurations can be expected to greatly reduce the free-energy cost for the interface separating the two structural domains. These two factors render the system unstable with respect to density fluctuations of a large spatial scale, making possible both an equilibrium coexistence of the two phases within the spinodal domain and the existence of the critical point at its low-density limit. In this way, the present observation can be compared with the coexistence of structurally similar liquid phases discriminated by density, and a respective critical point observed in a simulation of a one-component system using a pair potential with a long-range repulsion.21

The structural similarity between the mesoscopic liquid state formed by the present system under cooling at sub-critical density and gel-forming colloidal systems that we have already mentioned deserves an additional comment. It was found22 that the appearance of spanning clusters involved in gelation in low-density systems of colloidal particles with short-range interaction can be interpreted in terms of density fluctuations caused by the existence of a liquid-gas spinodal instability. A possible relation between that instability and the higher-density liquid-solid critical point we report here looks quite intriguing, and deserves to be investigated in future studies. In particular, a question of significant interest is whether the tetrahedrally-packed colloidal clusters
demonstrating gelation at low densities\textsuperscript{17,18} would at higher densities display coexistence between a disordered phase and a crystal, and a respective liquid-solid critical point like the one we report here.

5 Conclusions

In summary, the molecular dynamics simulation presented here demonstrates a novel kind of phase behaviour in a simple one-component system. Its phase diagram is found to include a spinodal domain separating a stable liquid phase and a crystalline solid phase where the two phases coexist in equilibrium. Moreover, it is demonstrated that the spinodal terminates at a critical point. The existence of a liquid-solid critical point implies that an isotropic liquid can be transformed into a crystal without crossing the line of first-order phase transition. We argue that the existence of both the spinodal and the critical point can be explained by the structural transformation of the liquid phase. Upon cooling towards the critical point, the liquid is found to develop a mesoscopic order, reminiscent of that in smectic liquid crystals, which demonstrates a strong structural similarity with the crystalline phase. We conjecture that the observed phase behaviour can be expected in other systems possessing a similar kind of mesoscopic order, including liquid crystals, polymers and gelating colloidal systems.
