Abstract

Epithelial repair following acute kidney injury (AKI) requires epithelial-mesenchyme-epithelial cycling associated with transient re-expression of genes normally expressed during kidney development as well as activation of growth factors and cytokine-induced signaling. In normal kidney, the Hnf-1β transcription factor drives neprogenesis, tubulogenesis and epithelial homeostasis through the regulation of epithelial planar cell polarity and expression of developmental or tubular segment-specific genes. In a mouse model of ischemic AKI induced by a 2-hours hemorrhagic shock, we show that expression of this factor is tightly regulated in the early phase of renal repair with a biphasic expression profile (early down-regulation followed by transient over-expression). These changes are associated to tubular epithelial differentiation as assessed by KSP-cadherin and megalin-cubulin endocytic complex expression analysis. In addition, early decrease in Hnf1b expression is associated with the transient over-expression of one of its main target genes, the suppressor of cytokine signaling Socs3, which has been shown essential for renal repair. In vitro, hypoxia induced early up-regulation of Hnf-1β from 1 to 24 hours, independently of the hypoxia-inducible factor Hif-1α. When prolonged, hypoxia induced Hnf-1β down-regulation while normoxia led to Hnf-1β normalization. Last, Hnf-1β down-regulation using RNA interference in HK-2 cells led to phenotype switch from an epithelial to a mesenchyme state. Taken together, we showed that Hnf-1β may drive recovery from ischemic AKI by regulating both the expression of genes important for homeostasis control during organ repair and the state of epithelial cell differentiation.

Introduction

In the general population, acute renal failure (ARF) is noted in 1% of all hospital admissions. Hospital-acquired ARF occurs in up to 7% of all hospitalizations. Ischemic acute kidney injury (AKI) is the major cause of ARF and is associated with increased mortality in hospitalized populations [1]. Renal pathological changes of ischemic AKI are characterized by changes in proximal tubule epithelium. Disruption of the cytoskeleton and the loss of cell polarity result in the loss of the proximal tubule brush border, patchy loss of tubule cells, focal areas of proximal tubular dilatation and distal tubular casts, and areas of cellular regeneration characterized by cell proliferation [2]. Following AKI, replacement of lethally injured tubular cells is achieved by a complex reparative process leading to cell proliferation. Epithelial-mesenchyme-epithelial cycling allows almost complete recovery of renal architecture and renal function in most of the cases [3]. Tight regulation of this complex process involves cell cycle control [4], transient re-expression of genes normally expressed during kidney development, including Pax2, Notch-2, Wnt4 and Ets-1 [5,6,7,8], and transient activation of growth factors- or cytokine-induced signaling, including the hepatocyte and epidermal growth factor (HGF/EGF) and the interleukine-6 receptor pathways [9,10].

During early kidney development, hepatocyte nuclear factor-1β (Hnf-1β) drives neprogenesis, tubulogenesis and epithelial maturation through the regulation of epithelial planar cell polarity and expression of developmental or tubular segment-specific genes [11,12,13]. Hnf1b is expressed during early mouse embryogenesis, especially in the Wolffian duct, the ureteric bud and the metanephric kidney [14]. During later stages of kidney development, Hnf1b is expressed in all segments of the nephron, from the proximal tubule (PT) to the collecting duct. Hnf-1β is a transcription factor that controls the expression of a number of genes including Pkh1, Uimod and Soc3 [15,16]. Hnf-1β acts as a homo- or heterodimer with the closely related transcription factor

* E-mail: faguer.s@chu-toulouse.fr
Hnf-1α. The latter is mostly expressed in PT cells where it drives cells differentiation [17]. Antenatal kidney-specific conditional inactivation of Hnf1b in mice induces polycystic kidney disease with lethal renal failure around three weeks after birth [15,18]. Some recent studies suggested that Hnf-1β may have a role in epithelial kidney and liver repair [19,20].

Data concerning the role of Hnf-1β in renal repair following AKI are scarce. Interestingly, invalidation of epithelial kidney and liver repair [19,20].

Renal Expression of Hnf-1β and Some of its Target Genes after Ischemic AKI in Mouse

In this mouse model of hemorrhagic shock-induced AKI, we now show a significant ~50% decrease in the expression of Hnf1b within the first 10 hours post-shock followed by a transient over expression at 24 hours (Fig. 2a). The kinetics of Hnf-1β expression was confirmed at protein level (Fig. 2b).

Renal expression of Cdh16 (KSP-cadherin), Pkd1l (Polyductin) and Socs3, three genes directly regulated by Hnf-1β, were also assessed. Cdh16 and Pkd1l are known to be positively regulated, while Socs3 is negatively regulated by Hnf-1β [15,16]. A significant decrease of Cdh16 and Pkd1l expression was observed 10 hours after the hemorrhagic shock followed by progressive normalization until day 21 (Fig. 3a-b). Conversely, the expression of Socs3 (a gene negatively regulated by Hnf-1β) displayed a mirror expression profile with Hnf-1β in this model (Fig. 3c). These results suggest that the expression of Hnf-1β and three of its target genes is tightly regulated during the regeneration phase following ischemic AKI in mouse.

Renal Expression of Hnf1a and Proximal Tubule Markers after Ischemic AKI in Mouse

Hnf-1α is involved in epithelial repair in the liver [28]. In addition, Hnf-1α is required for proper differentiation of renal proximal tubule [17] and acts in homo- or heterodimers with Hnf-1β, but respective target genes of Hnf-1β - Hnf-1β and Hnf-1α dimers have not been fully characterized. We have therefore studied Hnf1a renal expression after ischemic AKI in parallel with Hnf1b. A significant ~50% decrease in the expression of Hnf1a was observed at 10 hours followed by a transient rebound at 48 hours (Fig. 4a). Thus, temporally changes in Hnf1a expression occur later than the change in Hnf1b expression. We also studied the renal expression of proximal tubule markers Lyp2 and Cdb1, which encode for the endocytosis complex megalin-cubulin, in this ischemic AKI mouse model. Expression of both genes was significantly decreased from 3 up to 24 hours after hemorrhagic shock. Expression of Cdb1 normalized at 48 hours while Lyp2 remained down regulated until 21 days after the insult (Fig. 4b-c). Persistent down-regulation of Lyp2 at day 21 suggested permanent proximal tubule dysfunction escaping clinical and pathological detection.

In vitro studies of Hnf1b and Hif-1α Expression Under Hypoxic Conditions

To decipher the molecular mechanisms that controls Hnf1b expression in kidney during and after ischemic injury, we assessed the consequences of hypoxia on Hnf-1β in vitro. HK-2 cells (a cell line issued from human proximal tubule) were grown under normoxia (21% oxygen) or hypoxic (1% oxygen) conditions, and Hnf-1β levels were measured at various time of hypoxia. Western blot analyses showed a significant increase of Hnf-1β expression as early as one hour after hypoxia and up to 24 hours (Fig. 5a and Fig. S1), followed by a progressive decline reaching control values after 48 hours hypoxia and a down regulation at 72 hours. Restoring normoxia after 2 hours of hypoxia leads to the normalization of Hnf-1β expression at 24 hours (Fig. 5c). Contrasting with changes of Hnf-1β protein, Hnf1b mRNA was significantly decreased during hypoxia (Fig. 5b). Hence, these data suggest that Hnf-1β amount in epithelial cells submitted to hypoxia is controlled at both protein (early effect) and mRNA (late effect) level.

The transcriptome adaptive response to hypoxia has been shown to be primarily controlled by hypoxia-inducible factor Hif-1α [29]. To determine whether Hnf1b expression is dependant of Hif-1α we analyzed its expression in HK-2 cells submitted to hypoxia (see raw data of western blot in supplementary material online). As shown in figure 5d, Hif-1α was early and significantly up-regulated when HK-2 cells were submitted to 1%-hypoxia reaching a maximal value after 2 hours of hypoxia. This increase was transient since persistent hypoxia lead to down-regulation of
Figure 1. Renal functional, histological and mRNA expression changes after a 2 hours-hemorrhagic shock in mouse. A. doi:10.1371/journal.pone.0063585.g001
Hif-1α after 24 hours of hypoxia. This down regulation became highly significant at 72 hours of hypoxia. As Hnf-1β and Hif-1α expression followed a similar but not overlapping expression profile with time in hypoxic HK-2 cells, we hypothesized that the increase in Hnf-1β could be related to Hif-1α overexpression. To test it, we cultivated HK-2 cells in normoxic conditions and added to the culture medium an inhibitor of Hif-1α specific prolylhydroxylases (PHD) to inhibit Hif-1α degradation. As expected, PHD inhibition was accompanied by a significant over-expression of Hif-1α (Fig. 6a and Fig. S2), while Hnf-1β expression was not modified (Fig. 6b), a finding consistent with a differentially targeted regulation for each of the transcription factor under hypoxia. In line with this result, we failed to find HIF-1α binding region ([A/G]CGTG motif; i.e. hypoxia responsive element), conserved in at least four species [30] (Homo Sapiens, Mus Musculus, Bos Taurus and Equus Caballus), in the 4000 pb upstream of the transcription start site of Hnf1b.

Role of Hnf-1β in Epithelial Cells Submitted to Hypoxia

To assess the role of Hnf-1β during hypoxia, HK-2 cells were efficiently transfected with specific small interference RNA (siRNA)-targeting HNF1B (Figure 7A) and then grown under normoxic or hypoxic conditions for 24 hours. Using Fluorescence-activated cell sorting (FACS) approach, we observed that viability was slightly but significantly higher in HK-2 cells with previous HNF1B down-regulation (Figure 7B). Moreover, transfection with HNF1B-specific siRNA was followed by dramatic phenotypic changes of HK-2 cells, in both normoxic and hypoxic conditions, with significant down-regulation of epithelial markers E-Cadherin.
KSP-Cadherin and ZO-1, and a trend in up-regulation of the mesenchyme marker Vimentin (Figure 7C).

Discussion

Hnf-1β is a transcription factor that controls planar cell polarity, tubulogenesis and tubular segment differentiation [11,12,13,15], which are all events required for proper renal repair. To date, the
role of Hnf-1β in epithelial regeneration remains highly elusive. The main finding in this study is that Hnf1b mRNA and protein expression is tightly regulated during epithelial repair following ischemic AKI induced by a 120-minutes hemorrhagic shock-related hypotension. The biphasic kinetics suggests that Hnf1b may control expression of molecular actors required for proper epithelial repair (e.g. Socs3). However, injury of tubules in ischemic AKI happens in both ischemic and reperfusion periods. In our model of hemorrhagic shock, tubular injuries were identified up to 6 days after the insult. Hence, further studies will have to decipher the respective roles of Hnf-1β in injury and regeneration.

Verdeguer et al. showed that ischemic AKI in mice with conditional renal-specific inactivation of Hnf1b in adulthood induces a severe tubular disorder characterized by the loss of planar cell polarity and abnormal epithelial cell proliferation with subsequent cystic dilatation [31]. Hnf-1β may drive the tubular regeneration by controlling the network of epithelial genes that have to be early re-expressed after mitosis. This finding was identified in vitro with conditions mimicking physiological process of cell renewal. The consequences of (ischemic) AKI on Hnf1b expression and role were not reported in this article. In a rat model of cell renewal. The consequences of (ischemic) AKI on renal repair following ischemic insult. Hence, further studies will have to decipher the respective roles of Hnf-1β in injury and regeneration.

In our study, we identified a more complex role of Hnf1b after ischemic AKI. First, during the early steps of epithelial repair, its expression is significantly decreased which is consistent with the concomitant dramatic up-regulation of Socs3, a gene negatively regulated by Hnf-1β [16]. Socs3 acts as an inhibitor of signaling pathways downstream of the interleukin-6-receptor and the EGF/HGF receptors, two pathways actively involved in renal repair [10,33,34,35]. Thus, one of the roles of Hnf-1β during renal epithelial repair could be to control a number of cytokines or growth factor signaling pathways by allowing the transient up-regulation of Socs3. Second, the subsequent transient over-expression of Hnf1b was accompanied by the progressive normalization of the expression of its target genes Cdh16 and Phdl1. Hence, together with the report from Verdeguer et al [31], our findings also confirm the role of Hnf-1β in the epithelial renal repair following ischemic AKI through the tight regulation of a number of cystic disease-associated genes that control renal tubular morphogenesis.

The molecular mechanisms that underlie the kinetics of Hnf-1β expression after AKI remain unknown. The sharp decrease suggests a direct post-transcriptional effect involving an as yet unknown pathway. We hypothesized that hypoxia, inflammatory response or growth factors may trigger the expression of Hnf1b in vivo. Relevant to the first possibility, we assessed the expression of Hnf-1β in a proximal tubule cell line (HK-2 cells) grown in various conditions of hypoxia. In vitro, hypoxia was followed by an early up-regulation of Hnf-1β (one hour), while Hnf-1β down-regulation was observed only if hypoxia was maintained for 48 to 72 hours. This effect of hypoxia was reversible as Hnf-1β expression returned to a basal value after 24 hours of normoxia. Interestingly, we demonstrated that Hnf-1β is controlled at both mRNA and protein level by hypoxia. The timing of Hnf-1β up-regulation was similar to that of Hif-1α over-expression. Hif-1α is a hypoxia-inducible transcription factor dramatically up-regulated during cell hypoxia (as soon as 0.5 to 1 hour after the start of hypoxia). Under normoxic condition, hydroxylation of Hif-1α by specific prolylhydroxylase 1–3 (PHD) leads to its degradation through the proteasomal pathway. Hypoxia inhibits Hif-1α specific PHD and abolishes the degradation of Hif-1α which is thus translocated to the nucleus where it acts as a transcription factor. During hypoxia, Hif-1α directly regulates the expression of specific target genes, like the vascular endothelial growth factor (VEGF) [36], and induces a dedifferentiation of epithelial cells with loss of epithelial markers like E-cadherin [37]. Herein, we showed that up-regulation of Hnf-1β is a very early event during hypoxia but is not dependent on Hif-1α expression. Further studies will have to better delineate the molecular pathways that regulate Hnf1b expression during epithelial hypoxia.

Interestingly, our in vivo study showed that epithelial repair is accompanied by modulation of Hnf1b expression potentially allowing specific transcriptional changes like transient Socs3 over-expression. However, contrasting with in vitro data, first Hnf-1β change observed after ischemic insult was a dramatic fall despite the concomitant low intra-renal oxygen partial pressure observed.
in this model, as demonstrated by pimonidazole staining [38]. These conflicting results suggest that the expression of Hnf-1β during epithelial regeneration is dependent of various pathways and that hypoxia is not the main regulator of Hnf-1β in this context. Moreover, we showed that lack of Hnf-1β expression during hypoxia in vitro is associated with partial loss of epithelial phenotype of HK-2 cells and a trend in better survival to hypoxic stress (Figure 7). Hence, we concluded that, in vivo, alternative pathways favor transient Hnf-1β down-regulation in order to allow surviving epithelial tubular cells to enter in an epithelial-mesenchyme-epithelial cycle, the later being required for proper epithelial reparation [3].

Altogether, these results suggest that (1) hypoxia may have short and long term effect on Hnf-1β expression, (2) molecular mechanisms underlying Hnf-1β changes observed during epithelial renal repair are more complex than a sole response to hypoxia/normoxia condition and (3) Hnf1β may drive an adaptative response to epithelial injury by regulating growth factors/cytokine signaling (Socs3 expression) and epithelial differentiation (Cdh16, Pkd1, Cdh1 and Zo-1 expression). Whether these findings may be

Figure 7. Molecular consequences of Hnf-1β inhibition in epithelial cells submitted to hypoxia. extended to other cause of acute kidney injury (i.e. septic or toxic insult) and to other ischemic epithelial insults (i.e. liver or gut injury) needs to be addressed.

Materials and Methods

Hemorrhagic Shock Protocol

Validation of this model of ischemic AKI was recently reported [38]. Animal experimentations were performed according to national and institutional animal care and ethical guidelines, and were approved by local board (Comités régionaux d’éthique en matière d’expérimentation animale, INSERM, Toulouse, France). Briefly, a 2 hours-hypotension (35 mmHg mean arterial blood pressure) induced by temporary blood removal was applied to C57/B6 female mice (Harlan France, Gannat, France), further called shocked mice. Anesthesia was based on ketamine and xylazine (250 mg/kg and 10 mg/kg, respectively). Mice were intubated and left jugular vein and femoral artery were catheterized. Mechanical ventilation through intratracheal cannula was realized with a specific ventilator Minivent 845® (Hugo Sachs Electronic, Germany). At the end of that period, shed blood and lactated Ringer’s solution (twice the shed blood volume) were infused in order to provide adequate fluid resuscitation. Sham-operated mice (further called sham mice) underwent the same anesthetic and surgical procedures, but neither hemorrhage nor fluid resuscitation were performed. Shocked (n = 5–6) and sham mice (n = 4) were sacrificed at different times: 3 hours, 10 hours, 24 hours, 2 days, 6 days and 21 days after the beginning of the blood removal.

Renal Function and Histological Analyses

Glomerular filtration rate was assessed at day 2, day 6 and day 21 by measuring the inulin clearance. Kidney samples, preserved in 10% buffered formalin, were dehydrated and embedded in paraffin. Four-micrometer sections were stained with periodic acid-Schiff. Histological changes consistent with acute tubular injury (cell necrosis, loss of brush border, cast formation and tubule dilatation) were recorded.

Molecular Analyses

The left kidney of mice was excised, washed with 1X PBS and subsequently used for molecular studies.

Total RNA was collected with the help of the RNaseasy® Mini Kit (Qiagen, Courtaboeuf, France) and 1 μg of total RNA was engaged in a reaction of RT-PCR (Superscript II Rnase H Reverse Transcription® (Invitrogen, Villebon sur Yvette, France)). cDNA were subsequently quantified using the LightCycler Mix (Roche, Meylan, France) or a LightCycler® 480 sequence detection system. The primers were designed using Primer3 and GeneQant softwares. The efficiency of each set of primers was assessed by dilution curves and only set with efficiency higher than 95% were used. Ct differences between the reference (Gadph and 18S) and target genes were calculated for each sample.

The formula used to quantify the relative changes in target over references mRNAs between the two groups is derived from the 2−ΔΔCt formula [2]. Primers used for quantitative PCR in mouse tissue were the following: Cdh1 (D) CCAGGCGTTTGACATCGCA (R) GGATGGTTGCAAGCGAGATG; Hnf1b (D) GCGGTGAGCTCAGCTAGAA (R) CACCATGGA-GATGGGAAC; Pkd1 (D) AAGTCAGGCAGCAGTCCAT; Cubilin (D) CCCTTTGGACCAGCTGTCATGGCA (R) ACAGGTTCA-TACCTCAGCAGTTGA. For protein extraction, kidney samples were homogenized in lysis buffer (10 mM Tris pH 7.5, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA and 0.1% SDS) with a protease inhibitor cocktail (Complete Mini kit (Roche, Meylan, France)) and separated on non-denaturing electrophoresis (10% gel) and visualized by staining with Coomassie Blue. The relative expression levels of kidney-specific Hif-1α was obtained with the use of specific anti-Hif-1α antibody (R&D Systems, Minneapolis, MN, USA) and quantified using ImageJ public open source software and results are expressed as Hif-1α/Beta-actin ratio.

Cell Culture

The human proximal tubule epithelial cell-line HK-2 was purchased from ATCC® (Molsheim, France) and were grown in DMEM/F12+ Glutamax® (1/1) medium supplemented with 50 U/mL, Penicillin, 50 mg/mL Streptomycin, 400 μg/mL of hydrocortisone, 10 μg/mL of EGF, 1.4 μg/mL of triiodothyrin, 5 mg/mL of insulin and 10% fetal calf serum. The cells were grown in 6-wells plates. All experiments were conducted with confluent cultures. For hypoxic culture, cells were placed in a hypoxic (1% O2, 5% CO2, 37°C) incubator (Sanyo 02/C02 incubator, Ontario) for 0, 5, 1, 2, 24, 48 or 72 h. Control cells were incubated for equivalent periods under normoxic conditions (21% O2, 5% CO2, 37°C). Last, normoxic up-regulation of Hif-1α was obtained with the use of specific prolylhydroxylase inhibitor (Calbiochem-Merck®, Fontenay-sous-Bois, France) (Figure 6) or Dimethylallyl Glycine (DMOG, Cayman Chemical company, Ann Arbor, Michigan, USA) (Supplementary Material).

RNA Interference

100 pmol of HIF1B-specific Ambion™ siRNA (siRNA IS 31871, Life Technologies SAS, Saint Aubin, France) or a negative control siRNA (Silencer Select negative control n°1, Life Technologies SAS, Saint Aubin, France) were transfected into HK-2 cells with DharmaFECT Duo transfection reagent (ThermoScientific, Courtaboeuf, France). After 48 hours of transfection, cells were placed in 1%hypoxic or normoxic incubator for another 24 hours. Total RNA was collected, reverse transcribed and quantified (see ammun). Primers used for quantitative PCR in human cells were the following : HIF1B (D) GAACCTCAGCCACAGAGGAG (R) GATGTTGTGCTGCTGCAAGT; Hnf1b (D) GCGGTGAGCTCAGCTAGAA (R) CACCATGGA-GATGGGAAC; Cdh1 (D) AAGTCAGGCAGCCTCCAT; Cubilin (D) CCCTTTGGACCAGCTGTCATGGCA (R) ACAGGTTCA-TACCTCAGCAGTTGA. For protein extraction, kidney samples were homogenized in lysis buffer (10 mM Tris pH 7.5, 150 mM NaCl, 1 mM EDTA, 1 mM EGTA and 0.1% SDS) with a protease inhibitor cocktail (Complete Mini kit (Roche, Meylan, France)) and separated on non-denaturing electrophoresis (10% gel) and visualized by staining with Coomassie Blue. The relative expression levels of kidney-specific Hif-1α was obtained with the use of specific anti-Hif-1α antibody (R&D Systems, Minneapolis, MN, USA) and quantified using ImageJ public open source software and results are expressed as Hif-1α/Beta-actin ratio.
GAGGGAGTGAATCCAGA (R) AGATGGCCCTTGACATT-GAG.

Flow Cytometry Analysis

LIVE/DEAD® Fixable Dead Cell Stain Kit (Invitrogen Corporation, Carlsbad, CA USA) were used to evaluate HK-2 cell viability by flow cytometry. After treatment (siRNA transfection and/or hypoxia), cells were incubated with LIVE/DEAD reagent for 20 min. Then, cells were analyzed by BD Fortessa flow cytometry (Becton Dickinson, San Jose, CA), as recommended by the manufacturer.

Statistical Analysis

Quantitative parameters are reported as median and limits, and qualitative parameters as numbers and percentage. Continuous variables were compared using one-way ANOVA test followed by unpaired t-test or Bonferroni correction, as appropriated. A P-value <0.05 was considered as statistically significant. Analyses were performed using GraphPad Prism 4 (Graphpad software Inc, San Diego, USA).
