We present an underapproximation for context-free languages by filtering out runs of the underlying pushdown automaton depending on how the stack height evolves over time. In particular, we assign to each run a number quantifying the oscillating behavior of the stack along the run. We study languages accepted by pushdown automata restricted to \( k \)-oscillating runs. We relate oscillation on pushdown automata with a counterpart restriction on context-free grammars. We also provide a way to filter all but the \( k \)-oscillating runs from a given PDA by annotating stack symbols with information about the oscillation. Finally, we study closure properties of the defined class of languages and the complexity of the \( k \)-emptiness problem asking, given a pushdown automaton \( P \) and \( k \geq 0 \), whether \( P \) has a \( k \)-oscillating run. We show that, when \( k \) is not part of the input, the \( k \)-emptiness problem is NLOGSPACE-complete.

1 Introduction

Since the inception of context-free languages (CFLs for short), researchers have studied their properties including how to define “well-behaved” subclasses. Typically, subclasses are obtained by posing restrictions excluding some behaviors of the underlying formalism (context-free grammar or pushdown automaton). For instance, visibly pushdown automata \([1]\) require input symbols to dictate push or pop operations on the stack. Another restriction is bounding the number of turns \([8]\)—switches from non-decreasing to non-increasing modes—of the stack over time.

In all those cases, restrictions are trying to achieve one or more of the following objectives: (i) capture a large subset of context-free languages; (ii) define a subclass with good closure properties (e.g. closure to boolean operations, to homomorphism or their inverse, \ldots) (iii) obtain more efficient algorithms (e.g. for parsing); (iv) obtain new decidability results (e.g. language equivalence).

In this paper, we define a new restriction that generalizes finite-turn pushdown automata \([8]\). Our restriction is based on the non-trivial yet natural notion of oscillation, a measure of how variable is the stack height over time. To get a glimpse of how our restriction generalizes finite-turn consider the language \( L = \{ (a^n b^n)^* \mid n \geq 0 \} \). A pushdown automaton (PDA for short) deciding \( L \) has to keep track—using its stack—of the number of symbols ‘\( a \)’: reading an ‘\( a \)’ results in a push while reading a ‘\( b \)’ results in a pop. By limiting the number of turns it thus seems difficult, if at all possible, to capture \( L \): e.g. one turn allows to capture precisely \( L \cap a^n b^n \), two turns \( L \cap a^n b^n a^n b^n \), \ldots However no finite number of turns captures \( L \).

On the other hand, restricting the runs of that PDA to those which have an oscillation of at most 1 is enough to capture \( L \) entirely.

The oscillation of PDA runs is defined using a hierarchy of so-called harmonics. Harmonics are prototypical sequence of stack moves: order 1 harmonic is \( \text{push pop push pop} \), order 2 harmonic is \( \text{push <order 1 harmonic> pop push <order 1 harmonic> pop} \). Hence, we say that a PDA run \( r \) is \( k \)-oscillating if the harmonic of order \( k \) is the greatest harmonic that can be “found” in \( r \).

Equipped with the restriction based on oscillation, we evaluate the aforementioned objectives. In particular,
• we study closure properties to boolean operations of the bounded-oscillation languages, we show they are not determinizable and that the problem whether a given context-free language is bounded-oscillation is undecidable.

• we study the \( k \)-emptiness problem which asks, given a PDA and a number \( k \), whether there exists a \( k \)-oscillating run. We show that, when \( k \) is not part of the input, the \( k \)-emptiness problem is NLOGSPACE-complete. A slight adaptation of the given algorithm solves the \( k \)-membership problem: given a PDA \( P \), \( k \), and a word \( w \), does there exist a \( k \)-oscillating run of \( P \) accepting input \( w \).

• we relate oscillation on PDA with a counterpart restriction on context-free grammars. This allows to reformulate some results and their proofs using PDAs instead of context-free grammars. Such reformulations are out of the scope of the paper but let us evoke some possibilities. For example, decidability and complexity results in computing procedure summaries for a class of procedural programs [7]. Also, the decidability of the reachability problem for a subclass of Petri nets extended with a stack [3]. The previously cited works (also [5]) sometimes include an unnecessary step translating from PDA to CFG and back. Thanks to the relation we prove, translations back and forth can be omitted thus obtaining more direct proofs.

As a collateral contribution, let us mention that our proofs propose a novel framework allowing to reason uniformly about parse trees and PDA runs through the use of well-parenthesized words. Doing so, we obtain objects which are simple, and intuitively easy to understand. Incidentally, proofs turn out to be elegantly simple.

Finally, we provide a syntactic characterization of bounded-oscillation pushdown automata in the following sense: given a PDA \( P \) and a number \( k \) we show that by modifying its stack alphabet and PDA actions, but by keeping unchanged its input alphabet, we obtain another PDA for the residual language of \( P \) where only the \( k \)-oscillating runs of \( P \) have been kept. Because the previous construction preserves the nature of PDA actions in the sense that a push remains a push and a pop remains a pop, applying it to visibly pushdown automata results into visibly pushdown automata with only \( k \)-oscillating runs.

Missing proofs are given in the appendix in the full version of this paper.

Related work. Nowotka and Srba [11] considered a subclass of PDA they call height-deterministic pushdown automata. Unlike their class, our class imposes restrictions on the evolution of the stack over time regardless of the input.

For context-free language specified by grammars, Esparza et al. [6, 4] relate two measures: the so-called dimension defined on parse trees and the index defined on derivations. Luttenberger and Schlund [10] made a step further and proved the dimension and path-width of parse trees are in linear relationship. Our work instates the notion of oscillation defined on PDA runs and establishes a linear relationship with the dimension of parse trees. In the process, we address the challenge of connecting notions formulated for equivalent yet different formalisms.

Wechsung [12] studies PDA runs by representing them in the 2-dimensional plane. Through a graphical notion of derivative applied on the representation of PDA runs, he formulates a notion of oscillation. Although Wechsung provides critical insights on oscillation, his definitions are ambiguous and lack proper formalization. We go further by proposing a clean, formal, and language based definition of oscillation.
2 Preliminaries

An alphabet $\Sigma$ is a nonempty finite set of symbols. A word $w$ is a finite sequence of symbols of $\Sigma$, i.e. $w \in \Sigma^*$. We denote by $|w|$ the length of $w$. Further define $(w)_i$ as the $i$-th symbol of $w$ if $1 \leq i \leq |w|$ and $\varepsilon$ otherwise. Hence, $w = (w)_1 \ldots (w)_{|w|}$. A language is a set of words.

A pushdown automaton (PDA) is a tuple $(Q, \Sigma, \Gamma, \delta, q_0, \gamma_0)$ where:

- $Q$ is a finite set of states including $q_0$, the start state;
- $\Sigma$ is an alphabet called input alphabet;
- $\Gamma$ is a finite set of stack symbols (pushdown alphabet) including $\gamma_0$, the start stack symbol;
- $\delta$ is a finite subset of $Q \times (\Sigma \cup \{\varepsilon\}) \times \Gamma \times Q \times \Gamma^*$.

We individually refer to each element of $\delta$ as an action and use the notation $(q, b, \gamma) \mapsto (p, \xi)$ for an action $(q, b, \gamma, p, \xi) \in \delta$.

An instantaneous descriptor (ID) of a PDA $P$ is a triple $(q, w, \xi)$ where $q$ is the state of the PDA, $w$ is the input word left to read, and $\xi$ is the stack content. Given an input word $w$, we define the initial ID of $P$ to be $(q_0, w, \gamma_0)$ and denote it $I_0(w)$. Given an ID $I = (q, w, \xi)$, define state($I$), tape($I$) and stack($I$) to be $q$, $w$ and $\xi$, respectively.

Given an action $(q, b, \gamma) \mapsto (p, \xi')$ and an ID $(q, bw, \gamma \xi)$ of $P$ define a move to be $(q, bw, \gamma \xi') \rightarrow_p (p, w, \xi' \xi)$. We often omit the subscript $P$ when it is clear from the context. A move sequence of $P$ is finite sequence $I_0, I_1, \ldots, I_m$ where $m \geq 0$ of IDs such that $I_i \rightarrow_p I_{i+1}$ for all $i$. We respectively call $I_0$ and $I_m$ the first and last ID of the move sequence and write $I_0 \rightarrow^*_P I_m$ to denote a move sequence from $I_0$ to $I_m$ whose intermediate IDs are not important. A quasi-run of $P$ is a move sequence $I \rightarrow^*_P I'$ such that tape($I$) is $\varepsilon$ and stack($I'$) is $\varepsilon$. A run $r$ of $P$ on input $w \in \Sigma^*$ is a quasi-run $r \rightarrow^*_P I'$ where $I = I_s(w)$ and tape($I'$) is $\varepsilon$. Intuitively, a run is a quasi-run that starts from ID $I_s(w)$ and reads all of $w$. We say that a word $w \in \Sigma^*$ is accepted by $P$ if there exists a run on input $w$. The language of $P$, denoted $L(P)$, is the set of words for which $P$ has a run. Formally, $L(P) = \{w \in \Sigma^* \mid I_s(w) \rightarrow^*_P I \text{ and } \text{tape}(I) = \text{stack}(I) = \varepsilon\}$.

A context-free grammar (CFG or grammar for short) is a tuple $G = (V, \Sigma, S, R)$ where $V$ is a finite set of variables (or non-terminals) including the start variable $S$; $\Sigma$ is an alphabet (or set of terminals), $R \subseteq V \times (\Sigma \cup V)^*$ is a finite set of rules. We often write $X \rightarrow w$ for a rule $(X, w) \in R$. We define a step as the binary relation $\Rightarrow_G$ on $(V \cup \Sigma)^*$ given by $u \Rightarrow_G v$ if there exists a rule $X \rightarrow w$ of $G$, $(u)_i = X$ and $v = (u)_1 \ldots (u)_{i-1}w(u)_{i+1} \ldots (u)_{|u|}$. We call $i$ as the position selected by the step. Define $u \Rightarrow^*_G v$ if there exists a step sequence $u_0 \Rightarrow_G u_1 \Rightarrow_G \ldots \Rightarrow_G u_n$ such that $u_0 = u$ and $u_n = v$. A step sequence $u \Rightarrow^*_G w$ is called a derivation whenever $u = S$ and $w \in \Sigma^*$. A step sequence $u_0 \Rightarrow_G u_1 \Rightarrow_G \ldots \Rightarrow_G u_n$ is said to be leftmost if for each step $u_i \Rightarrow_G u_{i+1}$, the position $p_i$ selected is such that $(u)_j \in V$ for no $j < p_i$. Define $L(G) = \{w \in \Sigma^* \mid S \Rightarrow^*_G w\}$ and call it the language generated by $G$.

Given a grammar $(V, \Sigma, S, R)$ and $Z \in V \cup \Sigma \cup \{\varepsilon\}$, define a quasi parse tree (or quasi-tree for short), denoted $t_Z$, to be a tree satisfying:

- $Z$ labels the root of $t$; and
- Each interior node is labelled by a variable; and
- Each leaf is labelled by either a terminal $b \in \Sigma$ or $\varepsilon$. If the leaf is labelled $\varepsilon$, then it must be the only child of its parent (if any); and
- If an interior node is labelled by $X$, and its $k$ children are labelled $X_1$ to $X_k$, in that order, then $X \rightarrow X_1X_2 \ldots X_k$ is a rule in $R$.

Next we define a parse tree to be a quasi-tree with root $S$—the start variable of $G$. Observe that all parse trees have at least two nodes while quasi-trees have at least one. Also when the root of a quasi-tree is labelled with $a \in \Sigma$ or $\varepsilon$ then it contains no other nodes. Given a quasi-tree $t$ define its yield, denoted $\mathcal{Y}(t)$, to be the word over $\Sigma$ obtained by concatenating the labels of the leaves of $t$ from left to right.

To each node $n$ in a tree $t$ we assign a dimension $\dim(n)$ as follows:
• If \( n \) is a leaf, then \( \dim(n) = 0 \).
• If \( n \) has children \( n_1, n_2, \ldots, n_k \) with \( k \geq 1 \) then

\[
\dim(n) = \begin{cases} 
\max_{i \in \{1, \ldots, k\}} \dim(n_i) & \text{if there is a unique maximum} \\
\max_{i \in \{1, \ldots, k\}} \dim(n_i) + 1 & \text{otherwise}
\end{cases}
\]

We define the dimension of a tree \( t \) with root \( n \), denoted \( \dim(t) \), as \( \dim(n) \).

**Example 2.1.**

![Parse tree diagram]

Let \( G_D = (\{S\}, \{\bar{a}, a\}, S, \{S \to \bar{a}aS, S \to \varepsilon\}) \). We denote \( L(G_D) \) by \( L_D \), the Dyck language over \( \{\bar{a}, a\} \). A parse tree \( t \) for the word \( \bar{a}a\bar{a}aa \) such that \( \dim(t) = 1 \) is given left.

### 3 Oscillation For Trees: a Dyck Word Based Approach

In this section, we match trees with Dyck words and define a measure based on a partial ordering on Dyck words and special Dyck words we call harmonics. We start by recalling that \( G_D \) is unambiguous.

**Proposition 1.** The CFG \( G_D = (\{S\}, \{\bar{a}, a\}, S, \{S \to \bar{a}aS, S \to \varepsilon\}) \) is unambiguous.

Let \( w \in L_D \) and let \( t \) be its unique corresponding parse tree. Unambiguity of \( G_D \) enables us to elegantly define matching pairs inside a word \( w \in L_D \). Two positions \( i < j \) form a matching pair \( (i, j) \) if \( (w)_i = \bar{a} \), \( (w)_j = a \) and the two leaves corresponding to \( (w)_i \) and \( (w)_j \) in \( t \) have the same parent.

**Example 3.1.** Consider the parse tree \( t \) of Example 2.1 and the word \( w = \bar{a}a\bar{a}aa \) it defines. The matching pairs of \( w \) are given by \( \{(1, 2), (3, 6), (4, 5)\} \). We prefer to use the more intuitive representation where the endpoints of the arrows are the matching pairs:

\[
\bar{a} \rightarrow a \quad \bar{a} \rightarrow a \quad a \rightarrow \bar{a} \quad a \rightarrow \bar{a}
\]

Thus, we can determine following properties of matching pairs:

• Arrows can only go forward: each matching pair \( (i, j) \) is such that \( i < j \).
• For each word \( w \in L_D \) and each position \( p \) in \( w \), if \( (w)_p = \bar{a} \) then there is exactly one arrow leaving from \( p \); else \( (w)_p = a \) there is exactly one arrow ending in \( p \).
• Arrows cannot cross: no two matching pairs \( (i_1, j_1) \) and \( (i_2, j_2) \) are such that \( i_1 < i_2 < j_1 < j_2 \).

Graphically, the following is forbidden:

\[
\bar{a} \ldots \bar{a} \ldots a \ldots a
\]

Given two words \( w_a \) and \( w_b \) of \( L_D \), define the ordering \( w_a \succeq w_b \) to hold whenever \( w_a \) results from \( w_b \) by deleting 0 or more matching pairs.

**Example 3.2.** For \( w_a = \bar{a}a\bar{a}a \) and \( w_b = \bar{a}a\bar{a}a\bar{a}a \); \( w_a, w_b \in L_D \) the ordering \( w_a \succeq w_b \) holds since \( w_a \) results from deleting the three matching pairs in \( w_b \) depicted by thicker arrows:

\[
w_b = \bar{a} \ldots \bar{a} \ldots a \ldots a
\]

**Lemma 1.** \((L_D, \succeq)\) is a partial order: a reflexive, transitive and anti-symmetric relation.
Definition 1 (harmonics and rank). Define \((h_i)_{i\in\mathbb{N}_0}\), a sequence of words of \(L_D\) given by:

\[ h_0 = \varepsilon \quad h_{i+1} = \hat{a} h_i a \quad \text{for } i \geq 0 \]

We call \(h_i\) the \(i\)-th order harmonic and collectively refer to them as harmonics. Letting \(\hat{h}_i = \hat{a} h_i a\) we obtain the following alternative definition of \((i+1)\)-st order harmonic: \(h_{i+1} = \hat{h}_i h_i\). Given \(w \in L_D\), define its rank, denoted as \(\text{rank}(w)\), as the greatest harmonic order embedded in \(w\), that is the greatest \(q \geq 0\) such that \(h_q \preceq w\). Note that the rank is well-defined because \(h_0 = \varepsilon\) and \(\varepsilon \preceq w\) for all \(w \in L_D\).

From now on, unless stated otherwise we assume grammars to be in Chomsky normal form. A grammar \(G = (V, \Sigma, S, R)\) is in Chomsky normal form if each production rule \(p\) of \(R\) is such that \(p = X \rightarrow Y Z\) or \(p = X \rightarrow b\) where \(X, Y\) and \(Z\) are variables and \(b\) is a terminal.

A parse tree of a grammar in Chomsky normal form has the following property: all interior nodes have one or two children where the nodes with one child correspond to a rule of the form \(X \rightarrow b\) and every other interior node has two children such that the three nodes correspond to a rule of the form \(X \rightarrow Y Z\).

Next, we give a mapping of quasi-trees onto Dyck words based on the pre-order traversal of a tree. Given a quasi-tree \(t\), we define its footprint, denoted \(\alpha(t)\), inductively as follows:

- If \(n\) is a leaf then \(\alpha(n) = a\).
- If \(n\) has \(k\) children \(n_1\) to \(n_k\) (in that order) then \(\alpha(n) = a \hat{a} a \ldots \hat{a} \alpha(n_1) \alpha(n_2) \ldots \alpha(n_k)\).

Finally, if, in addition, \(n\) is the root of \(t\) then we define \(\alpha(t) = \hat{a} \alpha(n)\).

Using harmonics we can also formulate an equivalent, alternative definition of dimension. For space reasons, that definition is given in the appendix.

Lemma 2. Let \(t\) be a quasi-tree.

1. For every node \(n\) of \(t\), we have \((\alpha(n))_\preceq \in L_D\). In particular, when \(n\) has \(k\) children \(n_1\) to \(n_k\) we have

\[(\alpha(n))_\preceq = \hat{a} \ldots \hat{a} (\alpha(n_1))_\preceq (\alpha(n_1))_\preceq \ldots (\alpha(n_k))_\preceq.\]

Following the definition of the footprint, for \(t\) rooted at \(n\) we have \(\alpha(t) = \hat{a} \alpha(n)\), hence \(\alpha(t) \in L_D\).

2. Let \(t_1\) be a subtree of \(t\): \(\alpha(t_1) \preceq \alpha(t)\), hence \(\text{rank}(\alpha(t_1)) \leq \text{rank}(\alpha(t))\).

Since Lemma 2 shows that the footprint \(\alpha(t)\) belongs to \(L_D\), we can define the rank of the footprint of the tree. We call this rank the oscillation of the tree: \(\text{osc}(t) = \text{rank}(\alpha(t))\).

Using harmonics we can also formulate an equivalent, alternative definition of dimension. For space reasons, that definition is given in the appendix.

4 Relating Dimension and Oscillation on Trees

In this section, we establish the following relationship between the dimension and the oscillation of a tree.

Theorem 1. Let a grammar \(G = (V, \Sigma, S, R)\) be in Chomsky normal form and let \(t\) be a parse tree of \(G\). We have that \(\text{osc}(t) - 1 \leq \text{dim}(t) \leq 2\text{osc}(t)\).

Proof. The proof of both inequalities is an induction on the dimension of \(t\).

First, we prove if \(\text{dim}(t) = d\), then \(\text{osc}(t) \leq d + 1\).
**Basis.** Let $\text{dim}(t) = 0$. Being in Chomsky normal form, the grammar $G$ generates only one tree $t$ such that $\text{dim}(t) = 0$: it consists of two nodes, the root is labelled with the start variable and the leaf with some $b \in \Sigma$ following a rule $S \rightarrow b$. The footprint of $t$ is given by $\alpha(t) = \overrightarrow{a a a a}$ from which we see that $\text{osc}(t) = 1$. Therefore, the inequality holds for the base case.

**Induction.** Let $\text{dim}(t) = d + 1$ and call $n_e$ the root node of $t$. Since the dimension of $t$ is $d + 1$, the definitions of dimension and Chomsky normal form show that there is a node $n$ of $t$ also of dimension $d + 1$ that has two children $n_1$ and $n_2$ of dimension $d$. We first show the oscillation of the tree $t_n$ rooted at $n$ is bounded by $d + 2$. We know that $\text{osc}(t_n) = \text{rank}(\overrightarrow{a a a a}) \alpha(n_1) \leq (\alpha(n_1)) \leq (\alpha(n_2)) \leq (\alpha(n_2))$. Moreover, it follows from the induction hypothesis that $h_{d+2} \not\leq (\alpha(n_i))$ for $i = 1, 2$. Therefore, since

$$\alpha(n) = a \overrightarrow{a a a a} (\alpha(n_1))_1 (\alpha(n_1))_2 (\alpha(n_2))_2 \leq (\alpha(n_2))$$

following Lemma 2, we find that $h_{d+3} \not\leq a \alpha(n)$, hence that $\text{rank}(a \alpha(n)) \leq d + 2$ and finally that $\text{osc}(t_n) \leq d + 2$.

**Basis.** In base case, the node $n$ is the root of $t$ and we are done.

**Induction.** Now let us assume that the depth of node $n$ is $h$. Since $t$ is a tree there is a unique path from $n$ to the root of $t$ following the parent. The parent $m$ of $n$ is such that $\text{dim}(m) = d + 1$ since $\text{dim}(t) = d + 1$ and $\text{dim}(n) = d + 1$. Moreover, since $t$ is the parse tree of a grammar in Chomsky normal form we have that $m$ has two children: $n$ and a sibling we call $n'$. It follows from the definition of dimension that $\text{dim}(n') < d + 1$. Thus we find that $\alpha(m) = a \overrightarrow{a a a a} (\alpha(n))_1 (\alpha(n))_2 (\alpha(n'))_2$ or with $n$ and $n'$ in inverted order. By induction hypothesis, we have that $h_{d+3} \not\leq (\alpha(n))_2$ and $h_{d+2} \not\leq (\alpha(n'))_2$, hence we conclude that $h_{d+3} \not\leq (\alpha(m))_2$ and finally that $\text{rank}(\alpha(m)) \leq d + 2$. Since $m$ is at depth $h - 1$ we can apply the induction hypothesis to conclude that $\text{osc}(t) \leq d + 2$. The other case with $n$ and $n'$ inverted is treated similarly.

To complete the proof of the theorem, we prove: if $\text{dim}(t) = d$, then $\text{osc}(t) \geq [d/2]$. This part of the proof is done by the induction on dimension of the parse tree, using the 2-induction principle.

**Basis.** In base case we show the inequality holds for dimensions 0 and 1. Let $\text{dim}(t) = 0$. In that case the grammar $G$, being in Chomsky normal form, generates only one possible parse tree: it consists of two nodes, the root is labelled with the start variable $S$ and the leaf with some $b \in \Sigma$ following a rule $S \rightarrow b$. This parse tree has the footprint $\alpha(t) = \overrightarrow{a a a a}$ and $\text{osc}(t) = 1$, what satisfies the inequality we want to prove. Now let $\text{dim}(t) = 1$. The parse tree of dimension 1 that we can construct with the minimal possible number of nodes is the following: the root $n_2$ is labelled with the start variable $S$, $S$ has two children $n_1$ and $n_2$ following the rule $S \rightarrow BC$, and $B$ and $C$ have one child each following the rules $B \rightarrow b$ and $C \rightarrow c$ for some $b, c \in \Sigma$. The footprint of this tree is $\alpha(t) = \overrightarrow{a a a a} \overrightarrow{a a a a}$ and $\text{osc}(t) = 1 \geq [1/2]$. Since any parse tree of $G$ of dimension 1 will have the tree with this structure as its subtree and from the fact that $G$ is in Chomsky normal form, from Lemma 2 it follows that the oscillation of the parse trees of dimension 1 will be at least 1, and therefore always greater than $1/2$. Hence, the inequality $\text{dim}(t) \leq 2\text{osc}(t)$ holds in the base case.

**Induction.** Let $\text{dim}(t) = d + 2$, and assume the right inequality of the theorem is true for the trees of dimension $d$ and $d + 1$. If the dimension of the tree is $d + 2$, then from the definition of di-
mension it follows there is a node \( n \) in \( t \) with dimension \( d + 2 \) that has two children \( n_1 \) and \( n_2 \) of dimension \( d + 1 \), and each one of those nodes has two successors with dimension \( d \) that are also siblings. Set \( n_{11} \) and \( n_{12} \) to be those successors of the node \( n_1 \), and \( n_{21} \) and \( n_{22} \) the successors of the node \( n_2 \). We thus find that: \[
\alpha(n) = a \xrightarrow{\alpha} a \xrightarrow{\alpha} a \xrightarrow{\alpha(n_1)} \xrightarrow{\alpha} a \xrightarrow{\alpha(n_2)} .
\] It also holds \[
\bar{a} \xrightarrow{\alpha} a \xrightarrow{\alpha(n_1)} \xrightarrow{\alpha} a \xrightarrow{\alpha(n_2)} \leq (\alpha(n_1))_{k_l} \text{ for } i = 1, 2.\]

We show that the oscillation of the tree \( t_n \) rooted at the node \( n \) is bounded from below by \( \frac{d + 2}{2} \). From induction hypothesis it follows that \( h_{i/2} \leq \bar{a} \xrightarrow{\alpha(n_i)} (\alpha(n_i))_{<,} \) for \( i, j \in \{1, 2\} \). Thus, due to transitivity of \( (L_D, \leq) \) we find \( \bar{a} h_{i/2} a \xrightarrow{\alpha} (\alpha(n_i))_{<,} \), for \( i = 1, 2 \). Hence it follows that \( h_{i/2 + 1} \leq \alpha(n) \), and for the tree \( t_n \) it holds that \( osc(t_n) \geq \lceil \frac{d}{2} \rceil + 1 \).

Since \( t_n \) is a subtree of \( t \), it follows that \( osc(t) \geq osc(t_n) \) from Lemma 2 and thus \( dim(t) \leq 2 osc(t) \).

These bounds are tight up to \( \pm 1 \). For the right inequality, define \( \Pi_h \) to be the perfect binary tree of height \( h \). We have \( dim(\Pi_h) = h \) for all \( h \). However, by induction on \( h \) we find that \( osc(\Pi_{2h-1}) = osc(\Pi_{2h}) = h \) for all \( h \), hence \( osc(\Pi_{2h-1}) = osc(\Pi_{2h}) = dim(\Pi_h) \). Therefore, the upper bound is off by 1 for perfect binary trees of odd height.

For the lower bound we consider the following structure of trees. We define \( P_0 \) as the tree consisting of a root and one child. The tree \( P_n \) is defined inductively as depicted on the right. We call \( n_1 \) and \( n_2 \) the roots of the first and second \( P_{n-1} \) subtree, respectively. It is easy to see by induction on \( n \) that the dimension of the tree \( P_n \) is \( n \).

We show, also by induction on \( n \), that the oscillation of the tree \( P_n \) grows with dimension. After constructing the footprint of \( P_0 \), we have \( \alpha(P_0) = \bar{a} a \bar{a} a \), hence that \( osc(P_0) = 1 \). For \( P_n \) we have \( \alpha(P_n) = a \xrightarrow{\alpha} a \xrightarrow{\alpha} a \xrightarrow{\alpha(n_1)} \xrightarrow{\alpha} a \xrightarrow{\alpha(n_2)} a \). From there and from the inductive hypothesis, if follows that \( h_{n+1} \leq \alpha(P_n) \) and \( h_{n+2} \notin \alpha(P_n) \), hence \( dim(P_n) = osc(P_n) - 1 = n \).

5 Oscillation: from Trees to Runs

In what follows, we map a quasi-run of a PDA onto a word of \( L_D \). Intuitively, the mapping associates, quite naturally, \( \bar{a} \) to each push action of the run and \( a \) to each pop. For instance, replacing the topmost stack symbol \( \gamma \) by \( \gamma \), using an action \( (q, b, \gamma) \mapsto (p, \gamma) \) corresponds to \( \bar{a} a \), pushing two symbols using an action \( (q, b, \gamma) \mapsto (p, \gamma \gamma) \) corresponds to \( a \bar{a} a \), etc. Given the LIFO policy of the stack, we see that a quasi-run is mapped onto a word of \( L_D \), the shortest such word being \( \bar{a} a \).

Next, we provide the formal definition of the mapping. We first start by observing that quasi-runs with more than one move can always be disassembled into a first move and subsequent quasi-runs. We need the following notation: Given two IDs \( I \) and \( I' \) such that \( stack(I) = \xi \) \( stack(I') \) holds for some \( \xi \in \Gamma^* \) define \( I/I' = (\text{state}(I), \text{tape}(I), \xi) \). In what follows, we formalize the disassembly of quasi-runs. We assume PDA has only one state \( q \).

Lemma 3 (Disassembly of quasi-runs). Let \( r = I_0, I_1, \ldots, I_m \) be a quasi-run with \( m > 1 \). Then we can disassemble \( r \) into its first move \( I_0 \vdash I_1 \) and \( d \) quasi-runs \( r_1, \ldots, r_d \) where \( d = \lvert stack(I_1) \rvert \) as follows:

\[
r_1 = I_{p_0}/I_{p_1}, \ldots, I_{p_1}/I_{p_1}, \ldots, r_i = I_{p_{i-1}}/I_{p_i}, \ldots, I_{p_i}/I_{p_i}, \ldots, r_d = I_{p_{d-1}}/I_{p_d}, \ldots, I_{p_d}/I_{p_d},
\]
where \( p_0 = 1 \) and \( p_1, \ldots, p_d \) are defined as the least positions such that \( \text{stack}(I_{p_i}) = \text{stack}(I_{p_{i+1}}) \). Necessarily, \( p_d = m \) and each quasi-run \( r_i \) starts with \( \text{stack}(I_1) \) as its initial stack content.

In the following example, we show what does the above formalized disassembly look like when the quasi-run starts with a move that pushes two symbols onto the stack.

**Example 5.1.** On Figure 1 we see a PDA accepting the language \( L = \{ a^i b^{i+1} \mid i \geq 1 \} \). The set \( \delta \) of this PDA consists of four actions: \((q_0, a, \gamma_0) \rightarrow (q_1, \gamma \gamma), (q_1, a, \gamma) \rightarrow (q_1, \gamma \gamma), (q_1, b, \gamma) \rightarrow (q_2, \varepsilon)\) and \((q_2, b, \gamma) \rightarrow (q_2, \varepsilon)\), as shown on the arcs on Figure 2. On Figure 2 we see a quasi-run \( r = [0, 1, 2] \), which consists of four actions: \((q_0, a, \gamma_0) \rightarrow (q_1, \gamma \gamma), (q_1, a, \gamma) \rightarrow (q_1, \gamma \gamma), (q_1, b, \gamma) \rightarrow (q_2, \varepsilon), (q_2, b, \gamma) \rightarrow (q_2, \varepsilon)\).

Next, we define the footprint of quasi-runs based on the previous disassembly.

**Definition 2.** Given a quasi-run \( r = [0, 1, \ldots, m] \) of a PDA \( P \) and its disassembly as in Lemma 3, define \( \alpha'(r) \) as follows:

- If \( m = 1 \) then \( \alpha'(r) = a \)
- If \( m > 1 \) and \( \text{stack}(I_1) = \varepsilon \) then \( \alpha'(r) = a \cdots a \alpha'(r_1) \alpha'(r_2) \cdots \alpha'(r_d) \). (But not \( \alpha'(r_1) \)).

Define the footprint of \( r \), also denoted \( \alpha(r) \), as \( \alpha(r) = \alpha' \alpha'(r) \).

Going back to Example 5.1, definition 2 applied on \( r \) yields \( \alpha'(r) = a \bar{a} a \bar{a} \bar{a} \alpha'(r_1) \alpha'(r_2) = a \bar{a} a \bar{a} a \bar{a} a \bar{a} a \).

**Lemma 4.** Let \( r \) be a quasi-run run of \( P \) in reduced form and let \( r_1, r_2 \) be the disassembly of the quasi-run as in Lemma 3. Then \( \text{osc}(r) = k \) if one of the following is satisfied:

- \( \hat{h}_{k-1} \leq \alpha(r_1) \) and \( \hat{h}_{k-1} \leq \alpha(r_2) \) and \( \hat{h}_{k} \neq \alpha(r_1) \), \( i = 1, 2 \).
- \( \hat{h}_{k} \leq \alpha(r_1) \) and \( \hat{h}_{k+1} \neq \alpha(r_1) \), or \( \hat{h}_{k} \leq \alpha(r_2) \) and \( \hat{h}_{k} \neq \alpha(r_2) \) and \( \hat{h}_{k+1} \neq \alpha(r_1) \).

To relate footprint of trees and runs, we define a transformation from the device generating trees (CFG) to the device generating runs (PDA). We thus define a transformation from a grammar to pushdown automaton such that they accept the same language (for space reason the proof is given in appendix but the transformation is quite standard).

**Definition 3 (CFG2PDA transformation).** Let \( G = (V, \Sigma, S, R) \) be a context-free grammar. Define the PDA \( P = (\{ q \}, \Sigma, \Gamma, \delta, q_0, \gamma_0) \) where \( \Gamma = V \cup \Sigma \cup \{ \varepsilon \} \) (\( \varepsilon \not\in V \cup \Sigma \)), \( \gamma_0 = S \), and, moreover, the transition function \( \delta \) consists exactly of the following actions:

- \( \delta \) contains \((q, \varepsilon, X) \leftrightarrow (q, w)\), for each rule \((X, w) \in R\), with \( w \neq \varepsilon \).
Lemma 5. Let \( \delta \) contains \((q, \varepsilon, X) \mapsto (q, e)\), for each rule \((X, \varepsilon) \in R\),
\( \delta \) contains \((q, b, b) \mapsto (q, e)\), for each terminal \(b \in \Sigma\),
\( \delta \) contains \((q, \varepsilon, e) \mapsto (q, \varepsilon)\), for \(e \in \Gamma\).

Definition 5. The stack alphabet \( \Gamma \) used to define \( P \) of words of \( L \)
the PDA used to define \( P \). We say a language \( L \) is \( k \)-oscillating if there exists a PDA \( P \) such that \( L \) is \( k \)-oscillating pushdown automaton.

Proposition 2. Let \( G = (V, \Sigma, \delta) \) be a context-free grammar and \( P = (\{q\}, \Sigma, \delta, \{q, s\}) \) the PDA obtained through CFG2PDA transformation. Given a parse tree \( t \), there exists a run \( r \) on input \( \hat{\gamma}(t) \) such that \( \alpha(t) = \alpha(r) \).

The proof is a simple induction on the height of \( t \). In a similar way, it can be shown that the converse also holds: starting from a run of a PDA, using the classical conversion from PDA to CFG, we obtain a CFG such that the same equality of footprints holds. This enables us to define the oscillation of the run of a pushdown automaton in the same way we defined the oscillation of the parse tree of a context-free grammar.

Definition 4. Given a (quasi-)run \( r \) of a PDA \( P \), define its oscillation as that of its footprint: \( \text{osc}(r) = \text{osc}(\alpha(r)). \) For \( k \geq 0 \), a run \( r \) is said to be \( k \)-oscillating whenever \( \text{osc}(r) = k \). Define \( L^{(k)}(P) \) to be the set of words of \( L(P) \) that are accepted by some \( k \)-oscillating run. We call \( L^{(k)}(P) \) the \( k \)-oscillating language of \( P \). We say a language \( L \) is \( k \)-oscillating if there exists a PDA \( P \) such that \( L = L^{(k)}(P) \). With the term bounded-oscillation run/language we refer to a \( k \)-oscillating run/language, when \( k \) is not important.

6 Syntactic Characterization of Bounded-oscillation languages

In this section, for a given \( k \), we define \( k \)-oscillating pushdown automaton which we denote with \( P^{(k)} \).
\( P^{(k)} \) generates (quasi-)runs of oscillation exactly \( k \). First, we give an informal description of the notation used to define \( P^{(k)} \).

The actions of \( P^{(k)} \) are derived from the actions of \( P \) by annotating the stack symbols of \( P \). In particular, the stack alphabet \( \Gamma^{(k)}(P) \) of \( P^{(k)} \) is given by \( \Gamma^{(k)}(P) := (\hat{\Gamma}^{(k)}(P) \cup \hat{\Gamma}^{(k)}(P)) \), where \( \Gamma^{(k)}(P) := \{ \hat{\gamma} \mid \gamma \in \Gamma \} \) and \( \hat{\Gamma}^{(k)} := \{ \hat{\gamma} \mid \gamma \in \Gamma \} \). Let \( \hat{\gamma} \in \hat{\Gamma}^{(k)} \), define \( \text{annot}(\hat{\gamma}) \) as \( d \) if \( \hat{\gamma} \in \hat{\Gamma}^{(k)}(d) \) and \( \tilde{d} \) if \( \hat{\gamma} \in \tilde{\hat{\Gamma}}^{(k)}(d) \).

The goal we seek to achieve by annotating the stack alphabet is given by the next lemma.

Lemma 5. Let \( r = l_0, \ldots, l_m \) be a quasi-run of \( P^{(k)} \).
- if \( \text{annot}(	ext{stack}(l_i)) = d \) then \( r \) is \( d \)-oscillating, that is \( h_d \leq \alpha(r) \) and \( h_{d+1} \not\leq \alpha(r) \)
- if \( \text{annot}(	ext{stack}(l_i)) = \tilde{d} \) then \( \tilde{h}_d \leq \alpha(r) \) and \( \tilde{h}_{d+1} \not\leq \alpha(r) \).

Next, we give the construction of \( P^{(k)} \) when \( P \) is in reduced form. In appendix we give the construction of \( P^{(k)} \) given a PDA \( P \) not necessarily in reduced form.

Definition 5 (k-oscillating pushdown automaton). Let \( P = (\{q\}, \Sigma, \delta, q, \gamma_0) \) be a PDA in reduced form, and let \( k \) be a positive integer. We define the \( k \)-oscillating PDA \( P^{(k)} = (\{q\}, \Sigma, \Gamma^{(k)}, \delta^{(k)}, q, \gamma_0^{(k)}) \) as follows:
1. If \((q, b, \gamma) \mapsto (q, e) \in \delta\), then \((q, b, \gamma^{(0)}) \mapsto (q, e), (q, b, \gamma^{(0)}) \mapsto (q, e)\) \( \subseteq \delta^{(k)} \)
2. If \((q, b, \gamma) \mapsto (q, \xi) \in \delta\), with \( \xi \in \Gamma^{(k)}(2) \), then \( \delta^{(k)} \) contains the following actions where \( d \) is any value between 1 and \( k \) and \( \ell \) is any value between 0 and \( d - 1 \):
   - \((q, b, \gamma^{(d)}) \mapsto (q, \xi^{(d)}) \mapsto (q, \xi^{(d)})\)
   - \((q, b, \gamma^{(d)}) \mapsto (q, \xi^{(d)}) \mapsto (q, \xi^{(d)})\)
   - \((q, b, \gamma^{(d)}) \mapsto (q, \xi^{(d)}) \mapsto (q, \xi^{(d)})\)
   - \((q, b, \gamma^{(d)}) \mapsto (q, \xi^{(d)}) \mapsto (q, \xi^{(d)})\)
   - \((q, b, \gamma^{(d)}) \mapsto (q, \xi^{(d)}) \mapsto (q, \xi^{(d)})\)

Bounded-oscillation Pushdown Automata
Let us explain the intuition behind the definition. Assume a quasi-run $r$ of a reduced PDA and

$$\alpha(r) = \tilde{a} \overset{a}{\rightarrow} \tilde{a} \overset{a}{\rightarrow} \tilde{a} \overset{a}{\rightarrow} (\alpha'(r_1)) \overset{a}{\rightarrow} \alpha'(r_2) \overset{a}{\rightarrow} \alpha'(r_2) \overset{a}{\rightarrow} \alpha'(r_2).$$

We deduce from $\alpha(r)$ that the first action of $r$ is pushing two symbols yielding quasi-runs $r_1$ and $r_2$. We call the two symbols $(\xi_1)$ and $(\xi_2)$ as in Definition 5. Now, suppose we want $\text{osc}(r) \geq d$, that is $h_d \leq \alpha(r)$. By definition of the harmonics, we have that $h_d = \tilde{a} h_{d-1} a \tilde{a} h_{d-1} a = h_{d-1} \tilde{h}_{d-1}$. By Lemma 4, one way to achieve $\text{osc}(r) \geq d$ is to have $h_{d-1} \leq (\alpha'(r_1))$ and $\tilde{h}_{d-1} \leq (\alpha'(r_2))$. This situation is dealt with by the actions defined at point 2.e. Observe that we have a stronger requirement on $(\alpha'(r_2))$ than on $(\alpha'(r_1))$. Indeed, we require $\tilde{h}_{d-1} \leq (\alpha'(r_2))$ because in $\alpha(r)$ we have $\tilde{a} \alpha'(r_1) a \leq \alpha(r)$. The purpose of the hat annotation is to convey that stronger requirement. This is why we push $(\xi_2) \in \Gamma'$ such that $\text{annot}((\xi_2)) = d-1$. Another way to have $h_d \leq \alpha(r)$ is to have $h_{d} \leq (\alpha'(r_i))$ for some $i = 1, 2$. This situation is dealt with by the actions defined at points from 2.a to 2.d.

The correctness of the transformation from $P$ to $P^{(k)}$ is captured by the next statement.

**Theorem 2.** Let $P$ be a PDA in reduced form and $k \geq 0$. The following is true.

(a) If $r$ is a run of $P^{(k)}$ on input word $w$ then $\text{osc}(r) = k$ and there is a run $r'$ of $P$ such that it accepts $w$ and $\text{osc}(r') = k$; and

(b) If $r$ is a run of $P$ on input $w$ and $\text{osc}(r) = k$ then there is a run $r'$ of $P^{(k)}$ such that it accepts $w$.

Note that, as a consequence of the theorem, the following equality holds: $L^{(k)}(P) = L(P^{(k)})$.

We conclude this section by giving upper-bounds on the size of the PDA $P^{(k)}$ relatively to the size of $P$. The size $|P|$ of a PDA $P$ is defined as $|Q| + |\Sigma| + |\Gamma| + |\delta|$. Relatively to $P$, $P^{(k)}$ has $\Gamma'(k)$, its stack alphabet, such that $|\Gamma'(k)| = O(k \cdot |\Gamma|)$; $\delta^{(k)}$, its actions, such that $|\delta^{(k)}| = O(|\delta| \cdot k^2)$, where 2 comes from the length of the sequence $\xi$ pushed onto the stack. Hence we find that the size of $P^{(k)}$ is $O(|P| \cdot k^2)$. The bounds for the size of $P^{(k)}$ in the general case and the calculations of those bounds can be found in the appendix.

7 Operations and Decision Problems

In this section, we first study the complexity of $k$-emptiness problem that asks, for a given $k$ and PDA $P$, whether $P$ has a $k$-oscillating run. Then we study closure properties, for boolean operations, of the class of bounded-oscillation languages.

7.1 Emptiness Check

We give a non-deterministic algorithm, called query, with three arguments: a stack symbol $\gamma$, an integer $k$ and a 2-valued variable $h$ which can be set to HAT or NO_HAT. Together the three arguments represent a stack symbol of $P^{(k)}$, e.g., $\gamma$, $k$ and HAT stand for $\tilde{\gamma}^{(k)}$.

Intuitively, the non-deterministic algorithm searches for a $k$-oscillating run of $P$ by building a run of $P^{(k)}$ (Theorem 2). It first guesses an action $(q, b, \gamma) \rightarrow (q, (\xi_1), (\xi_2))$ of $P$, then it further guesses, through the switch statement, a case of definition 5 point 2. In a sense, given the actions of $P$ the algorithm constructs the actions of $P^{(k)}$ on-the-fly.

**Theorem 3.** Given a PDA $P$ in reduced form and a natural number $k \geq 0$ there exists a NSPACE($k \log(|P|)$) decision procedure for the $k$-emptiness problem.

**Proof.** We prove the following: query($\gamma_0$, $k$, NO_HAT) returns iff $L^{(k)}(P) \neq \emptyset$, or equivalently query($\gamma_0$, $k$, NO_HAT) has an execution that returns iff $P$ has a $k$-oscillating run. As usual with induction, we prove a stronger statement: given an ID $I$ with stack($I$) $\in \Gamma$,
query(γ, k, h)
Data: γ ∈ Γ; k: an integer; h: a 2-valued variable over {HAT, NO_HAT}
Result: if L(k)(P) ≠ ∅ then query(γ, k, NO_HAT) has an execution that returns; otherwise all of
its executions are blocked at some assume statement.

if k < 0 then assume false pick ξ ∈ Γ2 ∪ {ε};
assume (q, b, γ) ← (q, ξ) ∈ δ for some b ∈ Σ ∪ {ε};
if ξ = ε then
    assume k = 0;
    return;
/* pushing two symbols onto the stack, ξ ∈ Γ2 */
pick k ∈ {0, 1, ..., k − 1};
switch * do // non-deterministically executes one case
    case (a)
        /* top stack symbol annotated with a */
        assume h = HAT; query((ξ), 2, NO_HAT); query((ξ), 1, NO_HAT);
    case (b)
        assume h = HAT; query((ξ), 1, NO_HAT); query((ξ), 2, HAT);
    case (c)
        /* top stack symbol without a annotation */
        assume h = NO_HAT; query((ξ), 2, NO_HAT); query((ξ), 1, NO_HAT);
    case (d)
        assume h = NO_HAT; query((ξ), 1, NO_HAT); query((ξ), 2, k, NO_HAT);
    case (e)
        assume h = NO_HAT; query((ξ), 1, k − 1, NO_HAT); query((ξ), 2, k − 1, HAT);

Algorithm 1: query(γ, k, h), for a PDA P = (q, Γ, δ, q0, HAT) in reduced form

- query(stack(I), k, NO_HAT) returns iff there exists a quasi-run r from I such that h_k ≤ α(r) and
  h_{k+1} ≠ α(γ); and
- query(stack(I), k, HAT) returns iff there exists a quasi-run r from I such that h_k ≤ α(r) and
  h_{k+1} ≠ α(γ).

The proof of right-to-left direction goes by induction on the number m of steps in the quasi-run from
I. If m = 1, then the quasi-run r is such that I ⊢ l'. In this case, both query(stack(I), 0, NO_HAT) and
query(stack(I), 0, HAT) return by picking ξ = ε and the same action as the one used to produce l'.

Next consider m > 1. Since P in in reduced form the first step in r is given by I_{0} ⊢ I_{1} where
stack(I_{1}) = ξ, ξ ∈ Γ^2. Thus we can disassemble r as in Lemma[3] the first move and two quasi-runs
r_1 = J₀ ... Jₘ and r_2 = K₀ ... Kₘ such that stack(J₀) = (ξ), stack(K₀) = (ξ), m_f, m_e < m. First assume
that h_k ≤ α(γ) and h_{k+1} ≠ α(γ). As before, from Lemma[4] we can reason about footprints of r_1 and
r_2 through the two cases as listed in the lemma. First consider the first case where osc(α(r_1)) = k − 1
and osc(α(r_2)) = k − 1 with h_{k−1} ≤ α(r_2). The induction hypothesis shows that query(stack(J₀), k − 1,
NO_HAT) and query(stack(K₀), k − 1, HAT) both return. A close examination of query shows that
query(stack(I₀), k, NO_HAT) returns.

Considering the second case, the reasoning goes along the same lines as in the first one.

The proof for the case h_k ≤ α(γ) and h_{k+1} ≠ α(γ) is similar.

For the left-to-right direction we proceed by induction on the number m of calls to query along an
execution that returns. For m = 1 we necessarily have that either query(stack(I), 0, NO_HAT) or
query(stack(I), 0, HAT) was invoked. Then, clearly, there exists a one-move, quasi-run r from I such that
\( \hat{h}_0 \leq \alpha(r) \) and \( h_1 \not\in \alpha(r) \).

When \( m > 1 \), it implies that one of the case of the switch statement has been taken followed by two calls to \texttt{query}. Applying the induction hypothesis on each of these calls returns quasi-runs \( r_1 \) and \( r_2 \). It is not difficult to see that they can be stitched together into a larger quasi-run \( r \). As before, through reasoning about the footprint and relation \( \preceq \) it is possible to show the desired property on \( \alpha(r) \).

To complete the proof of the theorem, we still have to show that the algorithm runs in \( \text{NSPACE}(k \cdot \log |P|) \). Again we observe that, in each call of \texttt{query}, the algorithm chooses non-deterministically between cases (a) to (e), each of which one has two calls to \texttt{query}. We observe that in all cases, the second call to \texttt{query} is tail-recursive and thus can be compiled away using extra variables and an unconditional jump.

As for the first call, the integer being passed to \texttt{query} in cases (a) to (d) is \( \ell < k \). In the case (e), the parameter that is passed to the first \texttt{query} call is decreased by one: \( k - 1 \). Therefore, we see that among every execution we need at most \( k \) stack frames to track the stack symbol which can be encoded with \( \log |P| \) bits. Hence that \( L^{(k)}(P) \neq 0 \) can be decided in \( \text{NSPACE}(k \log |P|) \).

Deciding the \( k \)-emptiness problem with \( P \) in reduced form is in \( \text{NSPACE}(k \log (|P|)) \), hence it is in \( \text{NLOGSPACE} \) when \( k \) is fixed and not part of the input. We claim that even if \( P \) is not in reduced form then the \( k \)-emptiness problem where \( k \) is not part of the input is also in \( \text{NLOGSPACE} \). To see this, we use the fact that if a decision problem \( B \) is logspace reducible to a decision problem \( C \), and \( C \in \text{NLOGSPACE} \), then \( B \in \text{NLOGSPACE} \) (see the proof of Lemma 4.17, point 2., in Arora and Barak [2] for \( \text{LOGSPACE} \), the proof for \( \text{NLOGSPACE} \) is the same). Our claim then follows from Theorem 3 and the fact we can reduce, in deterministic logarithmic space, the \( k \)-emptiness problem for the general form \( P \) to the \( k \)-emptiness problem for the reduced \( P \).

Let us briefly describe how to obtain the reduced form \( P \) from the general form and argue it can be computed in deterministic logarithmic space. To obtain the reduced form \( P_r \) from the general form \( P \) we apply two transformations.

First, we reduce \( P \) to a form (denoted with \( P' \)) such that each action either pops a symbol or pushes two symbols onto the stack. This is done by splitting actions whose stack words on the right-hand side have more than 2 symbols into actions with stack words of exactly two symbols (or adding a “dummy” symbol that will be pushed and immediately popped in case of a stack word of length 1). For example, the action of \( P \) \( (p, b, \gamma) \rightarrow (q, x_1, x_2, x_3) \) yields, in \( P' \), two actions in \( P' \) \( (p, e, \gamma) \rightarrow (p_1, x_1', x_3) \) and \( (p_1, b, x_1') \rightarrow (q, x_2, x_3) \), where \( p_1 \) and \( x_1' \) are fresh state and stack symbol. For this, the Turing machine enumerates the actions of \( P \), one by one, and split them when needed. Since, to split an action, it is enough to maintain indices pointing at the input tape, \( P' \) can be computed from \( P \) in deterministic logarithmic space.

Second, we transform \( P' \) into \( P_r \) by encoding the states of \( P' \) into stack symbols of \( P_r \). From \( P' \), we thus obtain a reduced \( P_r \) with only one state, which we call \( q_r \). Applying this transformation on the actions as given above, we obtain: \( (q_r, e, [p \gamma]) \rightarrow (q_r, [p_1 x_1', s x_3 r]) \) and \( (q_r, b, [p_1 x_1']) \rightarrow (q_r, [q x_2, s x_3 r]) \) for all states \( r, s \) of \( P' \). A Turing machine computes \( P_r \) given \( P' \) essentially by enumerating, for each action of \( P' \), the states of \( P_r \). Again it is enough to maintain indices and thus \( P_r \) can be computed from \( P' \) in deterministic logarithmic space. From Lemma 4.17, point 1., in Arora and Barak [2], we conclude that the reduction that composes the previous two can be performed in deterministic logarithmic space.

Note that reducing \( P \) to \( P_r \) clearly results in change of footprints of a run of \( P \) and the corresponding run of \( P_r \). However, it can easily be seen that this change of footprints will have no effect on the oscillation of the run. That is because the reduction of \( P \) affects the change of stack during a run in such a way that it only splits longer stack words into words of length 2 that are consecutively pushed onto the stack, so the net result stays the same. To illustrate this, let us take a look at a simple example.

**Example 7.1.** Applying the action \( (p, b, \gamma) \rightarrow (q, x_1, x_2, x_3) \) of \( P \) results in the footprint \( \alpha_1 = a \bar{a} \bar{a} \bar{a} \).
After that action has been split into two actions (as it has been done above), the resulting footprint is: $$\alpha_0 = a \tilde{a} \bar{a} a \tilde{a} \bar{a}$$. Observe that the symbols $$(\bar{\alpha}_2)_3$$ and $$(\alpha_2)_4$$ form a matching pair (since they correspond to pushing and popping the symbol $$\bar{\xi}_1$$) and their deletion would yield the footprint equal to $$\alpha_1$$. Hence that, when determining the rank of the footprint, they do not contribute to it.

Observe that we can modify query to solve the k-membership problem that asks given a word $$w$$, a PDA $$P$$ and a number $$k$$ whether $$w \in L^{(k)}(P)$$. The modification consists in adding an array containing the input word $$w$$, and two indices. The details are easy to recover.

**Lemma 6.** Assume a PDA $$P$$ such that the maximum stack height in any run of $$P$$ is $$k$$. Then $$P$$ is at most $$k$$-oscillating.

**Proof.** Assume $$r$$ is $$(k+1)$$-oscillating. Then $$h_{k+1} \leq \alpha(r)$$. Since $$h_{k+1} = \bar{a} \tilde{a} \bar{a} \ldots a \ldots$$, the maximum stack height during $$r$$ is at least $$k+1$$, hence we have a contradiction. 

**Theorem 4.** Given a PDA $$P$$ and a positive integer $$k$$, the problem of deciding whether $$P$$ has a $$k$$-oscillating run is NLOGSPACE-complete when $$k$$ is not part of the input.

**Proof.** We reduce PATH to $$k$$-emptiness problem to show it is NLOGSPACE-hard. The problem PATH is defined as: Given a directed graph $$G$$ and nodes $$s$$ and $$t$$ of $$G$$, is $$t$$ reachable from $$s$$? PATH can be easily reduced to the emptiness problem of a PDA $$P$$ with one state $$q$$. We encode the existence of an edge between two nodes of $$G$$ in actions of $$P$$. For example, if there exists an edge between the nodes $$v_1$$ and $$v_2$$ of $$G$$, then $$P$$ has an action $$(q, \varepsilon, v_1) \rightarrow (q, v_2)$$. Additionally, $$P$$ has an action $$(q, \varepsilon, t) \rightarrow (q, \varepsilon)$$. Hence, $$P$$ accepts by empty stack iff there is a path from $$s$$ to $$t$$ in $$G$$. It is easy to see that the maximum stack height during any run of $$P$$ is 1, hence Lemma 6 shows that $$P$$ is 1-oscillating. Finally, we conclude from Theorem 4 that the $$k$$-emptiness problem, for a fixed $$k$$ not part of the input, is in NLOGSPACE and we are done. 

### 7.2 Boolean Operations, Determinization and Boundedness

We show that $$k$$-oscillating languages are closed under union, but they are not closed under intersection and complement. Also, we show that the set of deterministic CFLs (DCFLs) is not a subset of $$k$$-oscillating languages, and vice versa.

**Union.** Let $$(L^{(k)}(P_1))$$ and $$(L^{(k)}(P_2))$$ be two $$k$$-oscillating languages for the PDAs $$P_1$$ and $$P_2$$, respectively. Then $$(L^{(k)}(P_1) \cup L^{(k)}(P_2))$$ is also a $$k$$-oscillating language for the PDA that accepts the union $$L(P_1) \cup L(P_2)$$.

**Intersection.** Consider $$L_1 = \{a^nb^n|j| \geq 0 \}$$ and $$L_2 = \{a^nb^n|n, j \geq 0 \}$$. It is possible to construct 1-oscillating PDA $$P_i$$ such that $$L(P_i) = L_i$$ for $$i = 1, 2$$. However, $$L_1 \cap L_2 = \{a^nb|^n| n \geq 0 \}$$ is known not to be a CFL.

**Complement.** Let $$L_1$$ and $$L_2$$ to be $$k$$-oscillating CFLs. Suppose they are closed under complement. We know $$L_1 \cap L_2 = \overline{L_1} \cup \overline{L_2}$$ holds. However, that would mean $$L_1$$ and $$L_2$$ are closed under intersection, a contradiction.

**Determinism.** We give an example of a DCFL which is a $$k$$-oscillating language for no $$k$$, and vice versa. The languages of even-length palindromes given by the grammar $$G = (\{S\}, \{0, 1\}, S, \{S \rightarrow 0S0 \mid 1S1 \mid \varepsilon\})$$ is not a DCFL, but there exists 1-oscillating PDA accepting it. The Dyck language $$L_D = L(G_D)$$ that includes all of the harmonics $$\{h_i\}_{i \in \mathbb{N}}$$ is a $$k$$-oscillating CFL for no $$k$$, since harmonics form an infinite sequence of Dyck words. However, $$L_D$$ is a DCFL.
Boundedness. Given a context-free language, is it a bounded-oscillation language? We only sketch the proof arguments showing this problem is undecidable. Let us start with the result of J. Gruska who proved undecidability of the question asking whether a given context-free language is a bounded-index language [9]. On the other hand, Luttenberger and Schlund [10] proved a result implying the index of a CFL is bounded iff so is its dimension. Because Theorem 1 implies that the dimension of a CFL is bounded iff its oscillation is, we conclude that the problem whether a given CFL is a bounded-oscillation language is undecidable.

A Appendix

A.1 Proof of Prop 1

Proof. We show that given a word of $L(G_D)$, it has a unique parse tree or equivalently, a unique leftmost derivation.

In the proof, we denote by $r_1$ the production rule $S \rightarrow \bar{a} S a S$ and by $r_2$ the production $S \rightarrow \varepsilon$. Also, denote a step sequence with $i$ steps by $\Rightarrow^i_G$. Let us assume, by contradiction, that the grammar $G_D$ is ambiguous. Hence, there exist two distinct leftmost derivations $D_1$: $S \Rightarrow^i_G w_1$ and $D_2$: $S \Rightarrow^j_G w_2$ such
that \( w_1 = w_2 \in \{a, \bar{a}\}^* \). Let \( i \) be the least position in the step sequence such that \( D_1 \) and \( D_2 \) differ at \((i+1)\)-st step. Therefore, we have: \( S \Rightarrow_G^i u_i \), and we apply \( r_i \) to \( (u_i)_{p_i} \) such that there is no \( j < p_i \) for which \( (u_i)_{p_i} = S \). Since \( |R| = 2 \), to obtain \( D_1 \neq D_2 \) we apply \( r_1 \) to \( D_1 \) and \( r_2 \) to \( D_2 \), or the other way around. Assume the first case (the other one is treated similarly). Then we have:

\[
D_1 : S \Rightarrow_G^i u_i \Rightarrow_G^1 (u_i)_1 \ldots (u_i)_{p_i-1} \bar{a} S a S (u_i)_{p_i+1} \ldots (u_i)_{|w_i|} \Rightarrow_G^* w_1
\]

\[
D_2 : S \Rightarrow_G^i u_i \Rightarrow_G^1 (u_i)_1 \ldots (u_i)_{p_i-1} \varepsilon (u_i)_{p_i+1} \ldots (u_i)_{|w_i|} \Rightarrow_G^* w_2
\]

Observe that in \( D_1 \) we have that \( (u_i+1)_{p_i} = \bar{a} \) while in \( D_2 \) we have that \( (u_i+1)_{p_i} = (u_i)_{p_i+1} = a \), hence \( w_1 \neq w_2 \).

\[\square\]

A.2 Proof of Lemma 1

Proof. Reflexive If \( w_1 \in L_D \), then \( w_1 \preceq w_1 \) for all \( w_1 \in L_D \). Follows from the definition.

Transitive For three words \( w_1, w_2 \) and \( w_3 \) from the Dyck language, if \( w_1 \preceq w_2 \) and \( w_2 \preceq w_3 \), it follows \( w_1 \preceq w_3 \). From \( w_1 \preceq w_2 \) it follows that \( w_2 \) can be reduced to \( w_1 \) by successive deletion of \( n_1 \) matching parentheses, and from \( w_2 \preceq w_3 \) it follows that \( w_3 \) can be reduced to \( w_2 \) by successive deletion of \( n_2 \) matching parentheses. Thus, it is possible to reduce \( w_3 \) to \( w_1 \) by successive deletion of \( n_1 + n_2 \) matching parentheses.

Antisymmetric If \( w_1 \preceq w_2 \) and \( w_2 \preceq w_1 \), then \( w_1 = w_2 \). Follows straightforwardly from the definition of the order.

\[\square\]

A.3 Proof of Lemma 2

Proof. • We prove \( (\alpha(n))_\rho \in L_D \) by induction on the height of the tree \( t \). If the height is 0, that is, \( t \) consists of only one node \( n \), then from the definition of footprint it follows: \( \alpha(n) = a \), hence \( (\alpha(n))_\rho = \varepsilon \in L_D \) and we are done with the base case. Now consider a tree of height \( h+1 \) with root \( n \). Assuming \( n \) has \( k \) children, following the definition of footprint we have \( k \) times:

\[\alpha(n)_\rho = \bar{a} \ldots \bar{a} \alpha(n_1) \ldots \alpha(n_k) \].

Next, because \( \alpha(n_i) = (\alpha(n_i))_1 \alpha(n_i)_\rho \), \( (\alpha(n_i))_1 = a \) and by induction hypothesis \( \alpha(n_i)_\rho \in L_D \), we find that \( \alpha(n)_\rho \in L_D \).

• From the inductive definition of the footprint, it follows \( \alpha(t_1) \preceq \alpha(t) \). The definition of rank and \( (L_D, \preceq) \) being a partial order concludes the proof.

\[\square\]

A.4 Dimension of a Tree: a Dyck Word Based Approach

Given a quasi-tree \( t \), we define its flattening, denoted \( \beta(t) \), inductively as follows:

• If \( n \) is a leaf then \( \beta(n) = \varepsilon \).

• If \( n \) has \( k \) children \( n_1 \) to \( n_k \) (in that order) then

\[
\beta(n) = \bar{a} \beta(n_1) a \bar{a} \beta(n_2) a \ldots \bar{a} \beta(n_k) a.
\]

Finally, \( \beta(t) = \beta(n) \) where \( n \) is the root of \( t \).

It is easy to see that \( \beta(t) \in L_D \) for every tree \( t \) since the matching relation is inductively given by

\[
\beta(n) = \bar{a} \beta(n_1) a \bar{a} \beta(n_2) a \ldots \bar{a} \beta(n_k) a.
\]

Thus we can prove the following property.
Lemma 7. Let $t$ be a tree, $\text{dim}(t) = \text{rank}(\beta(t))$.

Proof. The proof is an induction on the height of the tree $t$. If the height is 0 and $n$ is the root of $t$, then $\beta(n) = \beta(t) = \epsilon$. Since $h_0 \leq \epsilon$ and $h_1 \not\leq \epsilon$, it follows $\text{rank}(\beta(t)) = 0 = \text{dim}(t)$.

Next assume the height of $t$ is $h+1$ and the root $n$ of $t$ has $k$ children $n_1$ to $n_k$. The induction hypothesis states: $\text{dim}(t_i) = \text{rank}(\beta(t_i))$ where $t_i$ is the subtree of $t$ with root $n_i$. If there is a unique maximum $d_{\text{max}} = \max_{i \in \{1, \ldots, k\}} \text{dim}(t_i)$, then from the definition of dimension it follows $\text{dim}(t) = d_{\text{max}}$. On the other hand, from the induction hypothesis it follows there is a unique $i$ such that $\text{rank}(\beta(t_i)) = d_{\text{max}}$. Hence, from the definition of the rank we see that $h_{d_{\text{max}}} \leq \beta(t)$ and $h_{d_{\text{max}}+1} \not\leq \beta(t)$, thus $\text{rank}(\beta(t)) = d_{\text{max}}$. If the maximum is not unique, that is, $d_{\text{max}}$ is the dimension of more than one child of the node $n$, then by the definition of dimension we have $\text{dim}(t) = d_{\text{max}} + 1$. From induction hypothesis and the definition of the flattening it follows that $h_{d_{\text{max}}+1} \leq \beta(t)$ and $h_{d_{\text{max}}+2} \not\leq \beta(t)$, hence that $\text{rank}(\beta(t)) = d_{\text{max}} + 1$ and we are done with the inductive case. \qed

A.5 Proof of Lemma 4

Proof. One direction follows easily - if one of the above is satisfied, after writing out the footprint of $r$ accordingly to Definition 2 we can easily establish that $\text{osc}(r) = k$. The other direction we prove by induction on the length $m$ of the quasi-run.

Basis. Necessarily, $m = 1$, $r$ is already in disassembled form and by definition 2 $\alpha(r) = \bar{a} \bar{a}$. Hence, $h_0 \leq \alpha(r)$ and $h_1 \not\leq \alpha(r)$, and therefore, $\text{osc}(r) = 0$.

Induction. Following Definition 2 the footprint of the quasi-run $r$ is such that:

$\alpha(r) = \bar{a} \bar{a} \bar{a} \bar{a} \alpha'(r_1) \alpha'(r_2)$,

where $r_1$ and $r_2$ are quasi-runs with less than $m$ moves obtained through disassembly as in Lemma 5. We can thus apply the induction hypothesis on them. Assume $\text{osc}(r) = k$. Then we can reason about the oscillation of the quasi-runs $r_1$ and $r_2$ by distinguishing the following two cases:

- In the first case, we can apply induction hypothesis to $r_1$ and $r_2$ and we have $h_{k-1} \leq \alpha(r_1)$, $h_{k-1} \leq \alpha(r_2)$ and $h_k \not\leq \alpha(r_1), i = 1, 2$. We thus find that $r_1$ is $(k-1)$-oscillating and $r_2$ is $(k-1)$-oscillating. Going back to $\alpha(r) = \bar{a} \bar{a} \bar{a} \bar{a} \alpha'(r_1) \alpha'(r_2)$, we find that $h_k \leq \alpha(r)$ since $h_{k-1} \leq \alpha(r_1)$ and $h_{k-1} \leq \alpha(r_2)$. We also find that $h_{k+1} \not\leq \alpha(r)$ since $h_k \not\leq \alpha(r_1), i = 1, 2$.

- In the second case, after applying induction hypothesis, we have $h_k \leq \alpha(r_1)$, $h_{k+1} \not\leq \alpha(r_1)$ and $h_k \not\leq \alpha(r_2)$ (the other case is treated similarly). We thus find that $r_1$ is $k$-oscillating and $r_2$ is $\ell$-oscillating, with $\ell \leq k$ (note that, if $r_2$ is $k$-oscillating, then there can be no extra matching pair around $h_k$ in $\alpha(r_2)$). Going back to $\alpha(r) = \bar{a} \bar{a} \bar{a} \bar{a} \alpha'(r_1) \alpha'(r_2)$, we find that $h_k \leq \alpha(r)$ since $h_k \leq \alpha(r_1)$ and $h_{k+1} \not\leq \alpha(r)$ since $h_k \not\leq \alpha(r_2)$.

Notice that these are the only possibilities that yield the quasi-run $r$ such that $\text{osc}(r) = k$. \qed

A.6 Proof of Proposition 2

A.6.1 Correctness proof of the CFG2PDA transformation

We use the following notation in the proofs that follow. Given $w_1, w_2 \in \Sigma^*$ such that $w_1$ is a prefix of $w_2$, we write $w_1^{-1}w_2$ to denote the word $w \in \Sigma^*$ such that $w_2 = w_1w$ holds.
**Lemma 8.** Let $G = (V, \Sigma, S, R)$ be a grammar and $t$ be a quasi-tree with root $X \in V \cup \Sigma \cup \{\varepsilon\}$. Let $P$ be the PDA resulting from the CFG2PDA transformation (definition 3). Then there exists a quasi-run $I \vdash_P^* I'$ such that $\text{tape}(I) = \Upsilon(t)$ and $\text{tape}(I') = \varepsilon$.

**Proof.** The proof is by induction on the height of $t$.

**Basis.** The height of $t$ is 0 and therefore $t$ consists of a single node labelled with $b \in \Sigma$ or $\varepsilon$. We conclude from definition 3 that $(q, b, b) \vdash_P (q, \varepsilon, \varepsilon)$ and $(q, \varepsilon, \varepsilon) \vdash_P (q, \varepsilon, \varepsilon)$ both of which are quasi-runs with the desired properties.

**Induction.** Now assume the height of $t$ is $h + 1$ and the first layer has $k \geq 1$ children and we denote by $Y_1$ to $Y_k$ their respective labels. Observe that each $Y_i \in V \cup \Sigma \cup \{\varepsilon\}$ and some $Y_j \in V$ since $h \geq 1$. We denote with $t_i$ the quasi-tree rooted at the node labelled with $Y_i$. By induction hypothesis, we have the following quasi-runs: $(q, \Upsilon(t_i), Y_i) \vdash^* (q, \varepsilon, \varepsilon)$, for $1 \leq i \leq k$. Furthermore, it is easy to see that we can “chain” the quasi-runs as follows:

$$
(q, \Upsilon(t), Y_k) \vdash_P (q, \varepsilon, \varepsilon) \\
(q, \Upsilon(t_{k-1}), Y_{k-1}Y_k) \vdash_P (q, \Upsilon(t), Y_k) \\
\vdots \\
(q, \Upsilon(t), Y_1 \ldots Y_k) \vdash_P (q, \Upsilon(t_{1})^{-1}\Upsilon(t), Y_2 \ldots Y_k) \\
\Upsilon(t) = \Upsilon(t_1) \ldots \Upsilon(t_k)
$$

Following definition 3 the production $X \rightarrow Y_1 \ldots Y_k$ yields an action $(q, \varepsilon, X) \leftrightarrow (q, Y_1 \ldots Y_k)$. Hence we have $(q, \Upsilon(t), X) \vdash_P (q, \Upsilon(t), Y_1 \ldots Y_k)$. Putting everything together, we thus conclude that

$$(q, \Upsilon(t), Y_1 \ldots Y_k) \vdash_P^* (q, \varepsilon, \varepsilon),$$

is a quasi-run with the desired properties and we are done with the inductive case. $\square$

**Proposition 3.** Let $G = (V, \Sigma, S, R)$ be a grammar and let $P$ be the PDA resulting from the CFG2PDA transformation (definition 3): $L(G) = L(P)$.

**Proof.** For the left-to-right inclusion, let $t$ be a parse tree of $G$. It follows from Lemma 8 with $X$ set to $S$ that $\text{stack}(I) = S$, hence that $P$ has a run on input $\Upsilon(t)$, and finally that $L(G) \subseteq L(P)$.

The other direction $L(P) \subseteq L(G)$ also holds. It follows from classical textbook material about the conversion between CFG and PDA. $\square$

**Proof of Proposition 2** The proof goes by induction on the height of $t$. As usual with induction, we prove a slightly different statement. First, the equality is given by $(\alpha(t))_\ll = (\alpha(r))_\ll$. The equality $\alpha(t) = \alpha(r)$ follows from the fact that $\alpha(t), \alpha(r) \in L_D$. Second, we prove the statement for quasi-trees and quasi-runs. More precisely, given a quasi-tree $t$ there exists a quasi-run $r = I \vdash_P^* I'$ such that $\text{tape}(I) = \Upsilon(t)$, $\text{tape}(I') = \varepsilon$, and $(\alpha(t))_\ll = (\alpha(r))_\ll$.

**Basis.** Let $t$ be a quasi-tree of height 0. Necessarily, $t$ consists of a single node labelled by a terminal $b \in \Sigma$ or $\varepsilon$. It follows from definition of the footprint of a quasi-tree that $\alpha(t)_\ll = a$. As we showed in the proof of lemma 8 there exists a quasi-run $r$ given by $(q, b, b) \vdash_P (q, \varepsilon, \varepsilon)$ for the case $b \in \Sigma$ and $(q, \varepsilon, \varepsilon) \vdash_P (q, \varepsilon, \varepsilon)$ for the case $\varepsilon$.

In either case, the footprint of the quasi-run $r$ is such that $\alpha(r)_\ll = a$ and we are done with the base case.
A.7.1 The Size of $P_{or b}$ for a single action of that type in the original automaton

From definition 6, we can calculate the size of the automaton $P_{or b}$ has an action as at point 1 in definition 6, then $P_{or b}$ has two actions: one for the stack symbol $t$ such that $\text{annot}(t) = 0$, and another one in case when $\text{annot}(t) = 1$.

Similarly, by looking at the point 2 in definition 6, we can conclude that the PDA $P_{or b}$ has $2k$ actions for a single action of that type in the original automaton $P$.

The third case in the definition 6 contributes most to the expansion of the size of $P_{or b}$. From the point 3a in the definition 6, an action of $P$ of this type gives, for a fixed $d$, $1 < d \leq k$, the following number of actions of $P_{or b}$:

$$\sum_{l=1}^{n} \binom{n}{l} (l-1)(d-1)^{n-l},$$
where \( n = |\xi| \). For \( d = 1 \), the number of actions is \( n - 1 \), hence the total number of actions in \( P^{(k)} \) obtained by the construction rule 3.a is:

\[
\sum_{d=2}^{k} \sum_{l=2}^{n} \binom{n}{l} (l-1)(d-1)^{n-l} + (n-1).
\]

In the similar fashion we calculate the number of actions of \( P^{(k)} \) for the point 3.b in definition 6:

\[
\sum_{d=2}^{k} \sum_{l=2}^{n-1} \binom{n}{l} (l-1)(d-1)^{n-l} + (n-2).
\]

From the point 3.c, we obtain that \( P^{(k)} \) has \( nd^{n-1} \) actions for a fixed \( d, 1 \leq d \leq k \) and a symbol \( \gamma \) in left side of the action such that \( \text{annot}(\gamma) = d \). Similarly, it has \( nd^{n-1} \) for \( \gamma \) such that \( \text{annot}(\gamma) = \hat{d} \). Thus, the total number of actions obtained from one action as at point 3.c in \( P \) is:

\[
\sum_{d=1}^{k} 2nd^{n-1} = 2n \sum_{d=1}^{k} d^{n-1}.
\]

To conclude, if the original PDA has \( m_1, m_2 \) and \( m_3 \) actions of type 1, 2 and 3, accordingly to the Definition 6, the automaton \( P^{(k)} \) has the following number of actions:

\[
2m_1 + 2k m_2 + m_3 \left[ 2 \sum_{d=2}^{k} \sum_{l=2}^{n} \binom{n}{l} (l-1)(d-1)^{n-l} + (n-2) + 2n \sum_{d=1}^{k} d^{n-1} \right]
\]

The above calculated size of \( \delta^{(k)} \) can be bounded above by \( O(|\delta| \cdot k^n) \), where \( n \) is the maximum size of all \( \xi \) through all of the actions \((q, b, \gamma) \rightleftharpoons (p, \xi)\) of \( P \).

In addition to the actions, the stack alphabet of \( P^{(k)} \) is obtained by altering and expanding the stack alphabet \( \Gamma \) of \( P \). For each \( \gamma \in \Gamma \), we define \( \gamma^{(d)} \) and \( \hat{\gamma}^{(d)} \), for all \( d \in \{0, \ldots, k\} \). Thus \( |\Gamma^{(k)}| = 2|\Gamma|(k+1) \).

### A.7.2 Proof of Lemma 5

**Proof.** The proof is an induction on \( m \), the length of the run.

**Basis.** Necessarily, \( m = 1 \) and \( \text{annot}(\text{stack}(I_0)) \in \{0, \hat{0}\} \) by definition 3. Also \( \alpha(r) = \hat{a} a \) by definition 2. Hence, \( \hat{h}_0 \leq \alpha(r) \) and \( h_1 \not\leq \alpha(r) \), and therefore, \( \text{osc}(r) = 0 \).

**Induction.** Following definition 2, the footprint of the quasi-run \( r \) is such that:

\[
\alpha(r) = \hat{a} a \hat{a} \alpha'(r_1) \alpha'(r_2),
\]

where \( r_1 \) and \( r_2 \) are quasi-runs with less than \( m \) moves obtained through dissassembly as shown in Lemma 3. We can thus apply the induction hypothesis on them. Let us rewrite them as \( r_1 = J_0, \ldots, J_m \) and \( r_2 = K_0, \ldots, K_n \).

We distinguish two cases whether \( \text{annot}(\text{stack}(I_0)) = d \) or \( \text{annot}(\text{stack}(I_0)) = \hat{d} \).
• By Definition 5, there is an action of type either (c), (d) or (e).
If we are in the case (c) (the case (d) is treated similarly) then we have that \( \text{annot}(\text{stack}(J_0)) = d \),
\( \text{annot}(\text{stack}(K_0)) = \ell \) with \( \ell \) between 0 and \( d - 1 \). We thus find that \( r_1 \) is \( d \)-oscillating and \( r_2 \) is \( \ell \)-oscillating. Going back to
\[
\alpha(r) = \bar{a} \ a \ \bar{a} \ (r_1) \alpha'(r_2)
\]
we find that \( h_d \leq \alpha(r) \) since \( h_d \leq \alpha(r_1) \); we also find that \( h_{d+1} \neq \alpha(r) \) because \( h_{\ell+1} \neq \alpha(r_2) \) and \( \ell + 1 \leq d \), hence \( h_d \neq \alpha(r_2) \).
If we are in the case (e) then we have that \( \text{annot}(\text{stack}(J_0)) = d - 1 \) and \( \text{annot}(\text{stack}(K_0)) = \widehat{d} - 1 \). We thus find that \( r_1 \) is \((d - 1)\)-oscillating and \( r_2 \) is such that \( h_{d-1} \leq \alpha(r_2) \) and \( h_d \neq \alpha(r_2) \). Going back to \( \alpha(r) = \bar{a} \ a \ \bar{a} \ (r_1) \alpha'(r_2) \), we find that \( h_d \leq \alpha(r) \) since \( h_{d-1} \leq \bar{a} \ \alpha(r_1) \ a \) and \( h_{d-1} \leq \alpha(r_2) \); we also find \( h_{d+1} \neq \alpha(r) \) since \( h_d \leq \alpha(r_1) \) for no \( i = 1, 2 \).
• We switch to the case where \( \text{annot}(\text{stack}(I_0)) = \widehat{d} \). The case (a) is similar to the case (c) by making the additional observation that \( \widehat{h}_d \leq \alpha(r) \) since \( h_d \leq \alpha(r_1) \) and \( \alpha(r_1) \) is surrounded by a matching pair (from \( (\alpha(r))_3 = \bar{a} \) to \( (\alpha'(r_2))_3 = a \)).
Finally, for the case (b) the induction hypothesis shows that \( \widehat{h}_d \leq \alpha(r_2) \), hence \( \widehat{h}_d \leq \alpha(r) \). We have
\[
\widehat{h}_{d+1} \neq \alpha(r) \text{ since } \widehat{h}_{\ell+1} \neq \alpha(r_1) \text{ and } \ell + 1 \leq d.
\]
\( \Box \)

A.8 Proof of Theorem 2

(a) Since every run is a quasi-run, follows as a direct consequence of Lemma 5. Also by removing from the run of \( P^{(k)} \) all the annotations from the stack symbols we obtain a run of \( P \).

(b) Our proof is by induction. As typical, we prove a stronger statement: given a quasi-run \( r \) of \( P \) from \( I \) with \( \text{stack}(I) = \gamma \) if \( h_k \leq \alpha(r) \) and \( h_{k+1} \neq \alpha(r) \) then there is a quasi-run of \( P^{(k)} \) from \( (\text{state}(I), \text{tape}(I), \gamma^{(k)}) \); and if, moreover, \( h_k \leq \alpha(r) \) then there is a quasi-run of \( P^{(k)} \) from \( (\text{state}(I), \text{tape}(I), \hat{\gamma}^{(k)}) \).

The statement of the theorem then consequentially generalizes to the runs of \( P \). The proof is an induction on the length \( m \) of the quasi-run \( r \) of \( P \).

Basis. Since \( m = 1 \), \( r \) is such that \( r = I \vdash I' \).

Hence, we have \( r = (q, b, \text{stack}(I)) \vdash_P (q, \varepsilon, \varepsilon) \) for some \( b \in \Sigma \cup \{ \varepsilon \} \). Furthermore, \( \text{osc}(r) = 0 \).
Following definition 5, there exists a quasi-run of \( P^{(0)} \) given by \( (q, b, \text{stack}(I))^{(0)} \vdash_{p^{(0)}} (q, \varepsilon, \varepsilon) \).

Induction. Since \( P \) is in reduced form the first step in \( r \) is given by \( I \vdash I_1 \) where \( \text{stack}(I_1) = \xi, \xi \in \Gamma^2 \). Thus we can disassemble \( r \) as in Lemma 5: the first move and two quasi-runs \( r_1 = J_0 \ldots J_m \) and \( r_2 = K_0 \ldots K_m \) such that \( \text{stack}(J_0) = (\xi)_1, \text{stack}(K_0) = (\xi)_2, m_j, m_k < m \). Hence we can apply Lemma 4 to \( r \) and we have two cases for the harmonics embedded in the footprints of \( r_1 \) and \( r_2 \) as in that lemma. Let us first look at the second case. Then \( h_k \leq \alpha(r_i), i \) being either 1 or 2. Assume \( i = 1 \), other case is treated similarly. From induction hypothesis we have that there exist quasi-runs \( r_1 \) of \( P^{(k)} \) from \( (\text{state}(J_0), \text{tape}(J_0), (\xi^{(k)})) \) and \( r_2 \) of \( P^{(k)} \) from \( (\text{state}(K_0), \text{tape}(K_0), (\xi^{(k)})) \). After applying action as defined at point 2.e in Definition 5 for the first move, we can assemble those two quasi-runs back into a quasi-run of \( P^{(k)} \). Now look at the first case. Similarly, from induction hypothesis applied to \( r_1 \) and \( r_2 \) and by action as defined at point 2.e in Definition 5 we obtain a quasi-run of \( P^{(k)} \). The case where \( \text{annot}(\text{stack}(I_0)) = \hat{k} \) is treated similarly.
