The engulfment of a photoautotrophic cyanobacterium by a primitive mitochondria-bearing eukaryote traces back to more than 1.2 billion years ago. This single endosymbiotic event not only provided the early petroalgae with the metabolic capacity to perform oxygenic photosynthesis, but also introduced a plethora of other metabolic routes ranging from fatty acids and amino acids biosynthesis, nitrogen and sulfur assimilation to secondary compounds synthesis. This implicated the integration and coordination of the newly acquired metabolic entity with the host metabolism. The interface between the host cytosol and the plastidic stroma became of crucial importance in sorting precursors and products between the plastid and other cellular compartments. The plastid envelope membranes fulfill different tasks: they perform important metabolic functions, as they are involved in the synthesis of carotenoids, chlorophylls, and galactolipids. In addition, since most genes of cyanobacterial origin have been transferred to the nucleus, plastidial proteins encoded by nuclear genes are post-translationally transported across the envelopes through the TIC–TOC import machinery. Most importantly, chloroplasts supply the photoautotrophic cell with photosynthates in form of reduced carbon. The innermost bilayer of the plastidic envelope represents the permeability barrier for the metabolites involved in the carbon cycle and is literally stuffed with transporter proteins facilitating their transfer. The intracellular metabolite transporters consist of polytopic proteins containing membrane spans usually in the number of four or more α-helices. Phylogenetic analyses revealed that connecting the plastid with the host metabolism was mainly a process driven by the host cell. In Arabidopsis, 58% of the metabolite transporters are of host origin, whereas only 12% are attributable to the cyanobacterial endosymbiont. This review focuses on the metabolite transporters of the inner envelope membrane of plastids, in particular the electrochemical potential-driven class of transporters. Recent advances in elucidating the plastidial complement of metabolite transporters are provided, with an update on phylogenetic relationship of selected proteins.

Keywords: endosymbiosis, envelope membrane, translocator
containing four Mn atoms and a Ca atom capable of sequentially removing four electrons from two water molecules. This process ultimately releases molecular oxygen as by-product. The accumulation of O₂ converted the atmosphere into an oxidizing one, permitting the development of more complex life forms that utilize oxygen as electron acceptor during the aerobic respiration.

This all posed the bases for the next level of complexity: endosymbiotic associations. Eukaryotic origin is defined as being concomitant with the acquisition of mitochondria, likely an α-proteobacterium, either by a nucleus-bearing amitochondriate cell, or by a prokaryotic host cell, later evolving eukaryote-specific features (Embley and Martin, 2006).

Later on the engulfment of a photoautotrophic cyanobacterium by a primitive mitochondriate eukaryote established the lineage of the Archaeplastida, also known as the Plantae (Gould et al., 2008; Keeling, 2010). All plastids are believed to have originated after a single endosymbiotic event, more than 1.2 billion years ago (Björn, 2009). One exception is provided by Paulinella chromatophora, which represents a case of ongoing primary endosymbiosis between an amoeba and a cyanobacterium-like endosymbiont (Figure 1; Kies, 1974). Soon after the primary endosymbiosis, three major autotrophic lineages arose: the glaucophytes, the green algae, and the red algae (Figure 1; Adl et al., 2005).

Glaucophytes are a small group of unicellular, chlorophyll a containing freshwater algae consisting of four genera with at least seven species. They were the first lineage branching off and contain a plastid (muroplast) with a thin peptidoglycan wall between the two envelope membranes (Martin and Herrmann, 1998; Steiner and Löffelhardt, 2002; Sato et al., 2009). The peptidoglycan layer is believed to be a relic of the cyanobacterial cell wall, thus supporting the endosymbiotic theory of plastid origin. Other similarities to the cyanobacterial progenitors are the maintenance of phycobilisomes as light-harvesting antenna and a carboxysomal-like carbon-concentrating mechanism (Burey et al., 2007). Red algae (rhodophytes) also possess plastids with phycobilisomes but

![FIGURE 1 | Plastid evolution in photosynthetic eukaryotes.](image)
lack any remnant of the peptidoglycan wall and carboxysomes. In addition, they possess membrane-intrinsic light-harvesting complexes (LHCs) similar to those of the chloroplasts of the Viridiplantae associated with the PSI, thus representing a transitional state between cyanobacteria and chloroplasts (Wolfe et al., 1994). Rhodophyta have furthermore contributed to at least six other algal lineages by secondary endosymbiosis, as indicated by the presence of up to four membranes surrounding their plastids. These include members from the chromalveolates supergroup: the cryptophytes (still retaining a remnant nucleus, the nucleomorph), the haptophytes, the plastid-containing heterokontophyta (e.g., diatoms), and the alveolates. (Figure 1; Reyes-Prieto et al., 2007; Archibald, 2009).

The green lineage (chlorophyta) is represented by the green algae and the land plants. This is the most derived lineage. In contrast to glaucophytes and red algae (collectively termed biliphytes) their photosynthetic plastids lack the phycobilisomes; they possess instead chlorophyll b-containing LHCs associated with both photosystems as well as other accessory pigments (Keeling, 2010). A secondary endosymbiotic event involving one member of the green algae has been proposed to have occurred once, leading to the Cabozoa which include the euglenophyta and the green lineage has been proposed to have occurred once, leading to the Cabozoa which include the euglenophyta and the chlororachniophyta (Figure 1).

Even if the presence of the plastid is often associated with the capability to perform photosynthesis, a diverse number of lineages reduced the plastids metabolic capability to the point where photosynthesis was lost. These include for example the red algal-derived apicoplast of the malaria parasite Plasmodium (which still retains important anabolic pathways providing the host cell with fatty acids, isoprene units, and haem; Ralph et al., 2004) and secondary endosymbions containing plastids of green origin occurring in the excavata, such as the colorless euglenozoa.

Primary plastids are delimited by two membranes, whose composition reflects their bacterial origin: besides the already mentioned peptidoglycan layer, the outer envelope membrane contains galactolipids and β-barrel proteins (Jarvis et al., 2000; Schleiff et al., 2003). However, envelope membranes were subjected to extensive modifications: whereas the inner envelope derives from the cyanobacterial plasma membrane, the outer envelope is of chimeric origin, with the outer leaflet containing lipids derived from the host endomembrane system (Cavalier-Smith, 2000).

The events occurring at the interface between the endosymbiont and the host were of crucial importance for the establishment of the plastid. Insertion of host protein translocators into the envelope was necessary to take full advantage of the newly acquired metabolic entity. Besides the photosynthetic reactions that lead to carbon fixation, endosymbiosis introduced into the petroalgae a set of metabolic pathways, including nitrogen and sulfur assimilation, the biosynthesis of amino acids, fatty acids, vitamins, hormones, and a plethora of secondary compounds (Weber and Flügge, 2002; Weber et al., 2006; Weber and Fischer, 2007).

Plastidic phosphate translocators

The plastidic phosphate translocator (pPT) family comprises four members of the drug/metabolite transporters (DMT) superfamily (TC 2.A.7; Saier et al., 2006, 2009). These antiporters catalyze the exchange of phosphorylated C3-, C5-, and C6-compounds for inorganic phosphate (Pi). The homo-exchange guarantees a balance in the phosphate content of the stroma and the cytosol and ensures a constant provision of phosphate to sustain ATP synthesis (Weber et al., 2005).

Phylogenetic analyses revealed that pPTs are monophyletic and originated from an existing endomembrane translocator (Weber et al., 2006). The major plant plastid translocators co-localize in branches containing homologs from red and green algae, supporting their monophyly and an origin of the translocators in their common ancestor (Weber et al., 2006). pPTs are more closely related to the nucleotide sugar transporters (NSTs) than to other families of the DMT superfamily (Knappe et al., 2003a).

This is in agreement with the need of the petroalgae to export the adenosine-diphosphogluco (ADP-Glc) produced by the cyanobiont into the host cytosol. The first metabolic connection between the two compartments would thus have been through an ADP-Glc translocator. Indeed, it was recently shown that members of the NSTs possess an innate ability to transport ADP-Glc, filling the link between the carbon metabolism of endosymbiont and host cell (Colleoni et al., 2010). The establishment of a carbon flux was thus a host-driven process, by recruiting a translocator of its endomembrane system and redirecting it to the endosymbiont, later on evolving into the pPT family of transporters (Weber et al., 2006; Tyra et al., 2007; Colleoni et al., 2010). This hypothesis, however, awaits support from analyzing the plastid permeome of a member of the third lineage of the Archaeplastida, the
glaucothyta. The host contribution to the establishment of the endosymbiosis was further supported by a work in which transporter proteins broadly distributed in the plantae kingdom were subjected to phylogenetic analysis: out of 83 proteins scrutinized, 58% were shown to be of host origin (Tyra et al., 2007).

THE TRIOSE PHOSPHATE/PHOSPHATE TRANSLOCATOR

The plastid provides the cell with reduced carbon compounds by the assimilation of carbon dioxide during photosynthesis. In plants the photoassimilates are either exported in their phosphorylated form by members of the PPT family to fuel sucrose biosynthesis in the cytosol, or they are retained in the plastid to drive starch synthesis (Figure 2). The daily path for carbon export occurs in form of triose phosphates (TP) via the triose phosphate/phosphate translocator (TPT). TPT accepts TPs (dihydroxyacetone phosphate, DHAP, and glyceraldehyde 3-phosphate) as well as 3-phosphoglycerate (3-PGA) as substrates (Table 1; Fliege et al., 1978; Flügge and Heldt, 1984). In addition to its role in allocating the carbon between the stroma and the cytosol, the TPT has the ability to export reducing equivalents to the cytosol. The TP/3-PGA shuttle exports TPs, which are then converted by the glyceraldehyde phosphate dehydrogenase to 3-PGA, reducing one molecule of NADP⁺ to NADPH, required for biosynthetic processes. The 3-PGA is then transported back to the chloroplast stroma by the TPT and can re-enter the Calvin–Benson cycle (Figure 2; Flügge and Heldt, 1984).

In the red alga Galdieria sulphuraria the TPT shows narrower substrate specificity, being able to transport TPs but not 3-PGA (Figure 3B). Moreover, the GsTPT displays a three-fold higher affinity to P₁ and the substrate DHAP has a two-fold higher affinity to the P₁ binding site than its counterpart from the chlorophytes (Table 1; Linka et al., 2008a). While in organisms descending from the green lineage the products of the carbon fixation are stored in insoluble starch granules inside the chloroplasts, rhodophytes accumulate a starch-like polymer in the cytosol through the use of UDP-glucose, called floridean starch, resembling amylopectin in its structure (Ball and Morell, 2003; Patron and Keeling, 2005). The heteroside floridoside is synthesized from UDP-Gal and glyceraldehyde 3-phosphate (Gly-3-P) in the cytosol as well and represents the main soluble pool of fixed carbon in analogy with sucrose in chlorophytes (Figure 3B; Viola et al., 2001). This means that the partitioning of the photoassimilates in red algae occurs exclusively in the cytosol, with GsTPT acting only as TP-exporter. This also explains the higher affinity of GsTPT for its substrates, enabling the export of TPs even at low concentrations (Linka et al., 2008a).
Table 1 | Phosphate translocators of the plastidic inner envelope membrane.

| Substrates | Green plants | Red algae | Glaucophytes | Apicomplexas | cryptomonads |
|------------|--------------|-----------|--------------|-------------|-------------|
| Kinetic constant | Substrate | $K_m$ (app) | $K_i$ (app) | $K_i$ (app) | $K_i$ (app) | $K_i$ (app) |
| Phosphate | 1.0 | 0.8 | 1.1 | 1.0 |
| TrioseP | 1.0 | 8.0 | 0.6 | 0.4 |
| 3-PGA | 1.0 | 4.6 | 1.8 | 10.6 |
| PEP | 3.3 | 0.3 | 2.9 | 2.1 |
| Glc-6-P | >50 | >50 | 1.1 | 6.6 |
| Ery-4-P | 3.3 | 0.8 | 3.3 |
| Xul-5-P | 3.5 |
| Ru-5-P |

Apparent $K_m$ (phosphate) and $K_i$ values expressed in millimolar for various phosphorylated metabolites. Transport activities of the recombinant translocators from green plants were measured in a reconstituted system using proteoliposomes pre-loaded with inorganic phosphate (Fischer et al., 1997; Kammerer et al., 1998; Eicks et al., 2002).

In addition to its ability to grow heterotrophically, *G. sulphuraria* can grow on more than 50 different carbon sources (Gross and Schnarrenberger, 1995; Barbier et al., 2005). Unlike land plants, where TPT is expressed in photosynthetic active tissues, GsTPT is also expressed in heterotrophically grown cells (Schulz et al., 1993; Linka et al., 2008a). Whereas plants provide heterotrophic plastids with glucose 6-phosphate (Glc6P) through the Glucose 6-phosphate/phosphate translocator (GPT), red algae do not appear to have pentose phosphate or hexose phosphate translocators (Oesterhelt et al., 2002).

Since the GsTPT is unable to transport 3-PGA, its role in the abovementioned NADPH shuttle can be excluded. While in plants the enzyme fructose-1,6-bisphosphatase is redox regulated and inactivated by oxidation, the *G. sulphuraria* homolog lacks redox modulation (Reichert et al., 2003). In this way the TPs can be converted into hexose phosphates in heterotrophic growth conditions and in the dark by the plastidic FBPase, ensuring the production of reduction equivalents (Reichert et al., 2003; Oesterhelt et al., 2007).

The expression pattern of GsTPT thus reflects the route for carbon import into heterotrophically grown cells with GsTPT as unique mediator of the carbon flux between plastid and cytosol (Linka et al., 2008a).

The lineage of the glaucophytes is best studied in the freshwater alga *Cyanophora paradoxa* (Löffelhardt et al., 1997). As for the red algae, glucophytes synthesize and store the starch in the cytosol through an UDP-glucose pathway (Plancke et al., 2008). Transport assays with isolated cyanelles demonstrated the activity of a translocator transferring phosphate, DHAP, and 3-PGA, in analogy with chloroplasts of higher plants (Figure 3A; Schlichting and Bothe, 1993). It is expected that the ongoing *C. paradoxa* genome sequencing project will soon provide clues as to whether a TPT ortholog also exists in glucophytes.

The plastids of organisms derived by secondary endosymbiosis can have up to four envelope membranes, like the apicoplast of the malaria parasite *Plasmodium falciparum*. The apicoplast is no longer able to perform photosynthetic carbon fixation, but retained the capacity to synthesize fatty acids, heme, iron sulfur clusters, and isoprene subunits (Ralph et al., 2004). The compartmentalization of these biosynthetic pathways poses as prerequisite the net import of carbon skeletons, ATP, and reducing equivalents. Indeed, *P. falciparum* has two TPTs, PfoTPT, and PfiiTPT, previously shown to reside in the outermost and innermost membranes of the apicoplast (Figure 4A; Mullin et al., 2006). They both have a substrate preference for DHAP, 3-PGA, and phosphoenolpyruvate (PEP), suggesting that they operate in tandem (Table 1; Lim et al., 2010). The discovery of PEP as substrate of a member of the TPTs is unprecedented and provides a plausible strategy to solve the needs of the apicoplast anabolism. PEP can be converted to pyruvate yielding one molecule of ATP by substrate-level phosphorylation. Pyruvate can then be channeled to fatty acid biosynthesis further producing NADH (Lim et al., 2010). It still remains unclear how the C3 compounds cross the two internal membranes. In another apicomplexan, *Toxoplasma gondii*, a pfoTPT homolog (TgAPT1) has been proposed to reside in more than one membrane, providing a solution to the issue of transport (Karnatak et al., 2007).

The cryptomonad *Guillardia theta* harbors a complex plastid which retained a vestigial nucleus (nucleomorph) from the
engulfed red alga. The nucleomorph resides in the periplastid compartment, the former algal cytoplasm. This intermembrane space is also the site of starch accumulation (Haferkamp et al., 2006). The genome of *G. theta* encodes for two putative TPTs, able to import P\(_i\) in counter-exchange to DHAP but not 3-PGA (Table 1). Interestingly, the genes encoding these phosphate translocators (TPT1 and TPT2) are regulated in opposite directions. TPT1 transcripts accumulate during the night phase, whereas TPT2 accumulates during the light phase (Haferkamp et al., 2006). It has been proposed that this expression pattern reflects the metabolic involvement of the corresponding carrier proteins, if TPT2 resides in the innermost membrane and favors the export of TPs in the intermembrane space during the day. On the other hand, TPT1 could reside in the first or second outermost membrane and function as exporter of the starch degradation products during the night (Figure 4C; Haferkamp et al., 2006).

**THE GLUCOSE 6-PHOSPHATE/PHOSPHATE TRANSLOCATOR**

In contrast to photosynthetic plastids which are able to synthesize carbon skeletons and reducing equivalents, heterotrophic plastids of sink tissues rely on the import of photosynthates. The phosphorylated C3 sugar phosphates synthesized in the stroma of photosynthetically active chloroplasts are exported to the cytosol through the TPT and converted into sucrose, which is in turn loaded into the phloem and redirected to sink tissues such as tubers, fruits, and seeds. Here sucrose is cleaved by the action of invertase or sucrose synthase and converted into hexose phosphates. Glucose 6-phosphate is ultimately imported into the plastid through the GPT (Figure 5).

Glucose 6-phosphate/p phosphate translocator is preferentially expressed in non-green tissues and mediates the import of glucose 6-P (Glc6P) as well as TPs and 3-PGA (Table 1; Kammerer et al., 1998). Glc6P is further channeled into the starch biosynthetic pathway or into the oxidative pentose phosphate pathway (OPPP), producing reduction equivalents required for diverse anaerobic pathways (Figure 5; Flügge et al., 2011). The importance of GPT in plant metabolism is demonstrated by the lethal phenotype resulting after disruption of the AtGPT1 homolog of *Arabidopsis thaliana* (Niewiadomski et al., 2005). Mutant plants are severely impaired in the gametogenesis, due to the lack of NADPH produced by the OPPP to sustain fatty acid biosynthesis. Shortage of Glc6P as substrate for the OPPP results in reduced formation of lipid bodies and non-physiological cell death (Niewiadomski et al., 2005). In a recent report the GPT2 ortholog of oil palm (*Elaeis guineensis* Jacq) could be associated with a function in fatty acid biosynthesis and oil accumulation in the mesocarp (Bourgis et al., 2011). Oil palm can accumulate up to 90% oil in its mesocarp. This is achieved through a high flux of glycolytic intermediates.
Facchinelli and Weber

Update on plastid envelope membrane transporters

FIGURE 4 | Substrates of the triose phosphate/phosphate translocators (TPTs) and nucleoside triphosphate transporters (NTTs) of the apicoplast of Plasmodium falciparum (A), of the diatom plastids from Thalassiosira pseudonana and Phaeodactylum tricornutum (B), and of the crytomonad plastid from Guillardia theta (C). Overview of the metabolite transport processes for the characterized transporters of the chromalveolates. The presence of four envelope membranes reflects their secondary endosymbiotic origin. The TPT of the apicoplast of P. falciparum has a broader substrate specificity compared to the green counterpart, accepting also PEP (A). Diatom plastids are not able to synthesize nucleotides and therefore they depend on the import of nucleotides from the cytosol. They possess NTTs which catalyze a uniport mode of transport as in the chlamydial intracellular parasites from where these transporters were acquired (B). The cryptomonads contain a less reduced secondary endosymbiont, still harboring a vestigial nucleus in the periplasmic compartment, the former algal cytoplasm, where the starch is synthesized. The day and night path of carbon metabolism is regulated by differential expression of TPT genes whose products localize in different envelopes (C). Abbreviations: (d)NTP, (deoxy)nucleotide triphosphate; G3P, glycerol 3-phosphate; PEP, phosphoenolpyruvate; PfiTPT, P. falciparum innermost envelope TPT; PfoTPT, P. falciparum outermost envelope TPT; 3-PGA, 3-phosphoglycerate; Pi, inorganic phosphate; TP, triose phosphate; UDP-Glc, UDP-glucose.

providing pyruvate for oil synthesis. Up-regulation of GPT2 and PPT supplies glycolytic substrates and intermediates to the plastid by transport from the cytosol, funneling carbon compounds toward pyruvate to sustain the high demand of substrates for fatty acid biosynthesis during mesocarp ripening (Bourgis et al., 2011). Reconstituted G. sulphuraria membranes showed high activity of phosphate/phosphate and phosphate/DHAP counter-exchange, whereas 3-PGA, 2-PGA, PEP, and Glc 6-P transport rates did not vary from that of the negative controls (Weber et al., 2004). Indeed, uptake experiments with reconstituted liposomes containing a recombinant protein with significant homology to higher plant GPT demonstrated that Glc6P is not a relevant substrate and suggests that G. sulphuraria and likely red algae in general do not possess a plastidic hexose-P importer (Linka et al., 2008a). As mentioned above, GPT supplies heterotrophic plastids of green plants due to the absence of FBPass activity. Since in G. sulphuraria the FBPass is not redox regulated, import of TPs mediated by GsTPT could ensure the supply of hexose-P for NADPH production during the night or under heterotrophic growth conditions.

THE XYLULOSE 5-PHOSPHATE/PHOSPHATE TRANSLOCATOR

The XPT of Arabidopsis was the last member of plant pPT to be identified and is able to transport inorganic phosphate, TPs, 3-P-glycerate, xylulose 5-P (Xul 5-P), and, to a lesser extent, erythrose 4-P (Ery 4-P) and ribulose 5-P (Ru 5-P; Table 1; Eicks et al., 2002). The XPT protein displays high homology to the GPT, and most likely derived from the latter by retrotranscription and genome insertion, as suggested by the lack of introns in the XPT gene (Knappe et al., 2003a). Phylogenetic analysis of the phosphate transporters of the red algae G. sulphuraria and Cyanidioschyzon merolae showed that members of this family are present which localize within the branch of the GPT/XPT group of transporters (Weber et al., 2006).
Facchinelli and Weber

Update on plastid envelope membrane transporters

Non-photosynthetic plastids rely on the import of photosynthates to drive the metabolic reactions in the sink tissues. Glucose 6-phosphate is transported by GPT to provide heterotrophic plastids with substrates further used to produce reducing equivalents and storage compounds. In maize, the substrate for starch synthesis, ADP-glucose, is produced in the cytoplasm and shuttled to the seeds by the brittle-1 ADP-glucose carrier. Abbreviations: ADP-Glc, ADP-glucose; BT1, Brittle-1 ADP-glucose carrier; Glc 1-P, glucose 1-phosphate; Glc 6-P, glucose 6-phosphate; GPT, glucose 6-phosphate/phosphate translocator; Malt, maltose; NTT, nucleoside triphosphate transporter; OPPP, oxidative pentose phosphate pathway; 3-PGA, 3-phosphoglyceric acid; PEP, phosphoenolpyruvate; P1, inorganic phosphate; PPI, pyrophosphate; PPT, PEP/phosphate translocator; XPT, xylulose 5-phosphate/phosphate translocator; Xul 5-P, xylulose 5-phosphate.

The proposed function of XPT is to import pentose phosphates into the stroma in the form of Xyl 5-P to be further metabolized in the Calvin cycle and the OPPP (Figures 2 and 5). A further function of the XPT would be the supply of carbon skeletons intermediates withdrawn from the Calvin cycle and the OPPP and channeled into other biosynthetic pathways such as the synthesis of nucleotides and the shikimate pathway requiring Rib 5-P and Ery 4-P, respectively (Eicks et al., 2002).

**The Phosphoenolpyruvate/Phosphate Translocator**

The phosphoenolpyruvate/phosphate translocator (PPT) mediates the import of cytosolic PEP into the plastid stroma in exchange with P1 (Table 1; Fischer et al., 1997).

Since the chloroplasts and most plastids of non-green tissues lack the enzymes required to form PEP from TPs via the glycolytic pathway, PEP has to be imported from the cytosol (Stitt and Aprees, 1979; Borchert et al., 1993). The energy-rich compound PEP serves as substrate for the shikimate pathway, whose starting point is the condensation of one molecule of PEP and one of Ery 4-P (Figure 2). The shikimate pathway is exclusively localized within the plastid and is involved in the biosynthesis of aromatic amino acids and of a variety of secondary compounds such as lignin, alkaloids, and flavonoids (Herrmann, 1995; Herrmann and Weaver, 1999). PEP can also be metabolized to pyruvate and acetyl-CoA which serves as precursor for the biosynthesis of fatty acids, as already mentioned for the GPT (Figures 2 and 4; Rajasekharan and Nachiappan, 2010; Bourgis et al., 2011).

*Arabidopsis* contains two PPT genes (PPT1 and PPT2) which differ in their expression pattern (Knappe et al., 2003b). *PPT1* is expressed in the leaf vasculature and in some root tissues. The abolishment of its activity in the cue1 mutant causes a reticulate leaf phenotype with abnormally developed mesophyll cells (MC) (Streatfield et al., 1999). The expression pattern of *PPT1* and the observation that the biosynthesis of aromatic amino acids is not severely affected in the *cue1* mutant led to the suggestion that it might be involved in the development of the MCs through a not yet identified signaling molecule likely derived from the shikimate pathway. AtPPT1 is presumably involved in the synthesis of secondary metabolites that regulate leaf development, whereas AtPPT2 which is ubiquitously expressed in leaves could have a more housekeeping function in supplying the plastidic shikimate pathway with PEP (Knappe et al., 2003b; Voll et al., 2003).
Another way to provide plastids with PEP is from plastidic pyruvate by pyruvate, orthophosphate dikinase (PPDK). This reaction is an essential step in C₄- and CAM-plants where PEP is exported to the cytosol of MCs and serves as substrate for the PEP-carboxylase during CO₂ fixation (Bräutigam et al., 2008). In C₄ and CAM-plants PPT is therefore an exporter of PEP (Weber and Von Caemmerer, 2010).

In the red alga *G. sulphuraria*, preliminary uptake experiments with isolated total membranes did not show pronounced PPT activity (Weber et al., 2004). However, phylogenetic analysis revealed the presence of a candidate ortholog in the red algal genome, suggesting the presence of a potential coding capability for PPT (Weber et al., 2006). Indeed, the recombinant protein was functionally characterized in reconstituted liposome membranes and displayed the signature of PPT activity (Linka et al., 2008a). As its green counterpart, the *G. sulphuraria* PPT is highly specific for P₇ and PEP (Table 1).

PEP synthesis inside the rhodoplast is assumed to be unlikely since the isozymes of both routes for synthesizing PEP in the plastid (i.e., the glycolytic pathway through phosphoglyceromutase and enolase, and the conversion of pyruvate to PEP by the PPDK) do not possess obvious subcellular targeting sequences and are predicted to be cytosolic (Linka et al., 2008a). Since fatty acid biosynthesis and the shikimate pathway in red algae are predicted to be similar to those of the green lineage of Archaeplastida, it is assumed that conversion of TP to PEP is not possible in *G. sulphuraria*, thus depending on PEP import from the cytosol to drive PEP-dependent reactions in the stroma (Figure 3B; Weber et al., 2004; Richards et al., 2006; Linka et al., 2008a).

**THE GLUTATHIONE TRANSPORTER**

Recently, a new transporter member of the DMT superfamily has been characterized as glutathione transporter in *Arabidopsis*. In plants, glutathione is in the center of an antioxidant network that buffers the reactive oxygen species (ROS) originating as by-product of the aerobic energy metabolism. Glutathione is a tripeptide enzymatically synthesized by the glutamate–cysteine ligase (GSH1) and the glutathione synthase (GSH2). In *Arabidopsis*, GSH1 is plastid localized, while GSH2 is targeted to both plastid and cytosol (Meister, 1995; Wachter et al., 2005). Consequently, the pathway intermediate, γ-glutamylcysteine (γ-EC), must be exported from the plastid to allow for cytosolic GSH biosynthesis (Figure 2). In a mutant screening designed to select mutants resistant to 1-buthionine-SR-sulfoximine (BSO), an inhibitor of GSH1, the gene At5g19380, encoding a predicted membrane transport protein, was identified as responsible for the revertant phenotype (Maughan et al., 2010). The gene was found to be related to the chloroquine resistance transporter (PfCRT) of the malaria parasite *P. falciparum* and was consequently designated CRT-like transporter 1 (CLT1). *Arabidopsis* mutants lacking CLT1 are heavy metal-sensitive, GSH-deficient, and hypersensitive to *Phytophthora* infection. CLT1 is a member of a small gene family comprising three members in *Arabidopsis* and all localize to the plastid envelope. Expression of the transporter in *Xenopus* oocytes confirmed that it can mediate GSH1 uptake (Maughan et al., 2010). Homology search revealed related genes in higher plants, in the moss *Physcomitrella patens*, in green algae and in parasitic protozoans, suggesting an ancient ancestry for this transporter.

**THE ATP:ADP ANTIPORTER FAMILY**

Members of the ATP:ADP Antiporter (AAA) Family (TC 2.A.12), also called nucleoside triphosphate transporters (NTT) catalyze a counter-exchange mode of transport and may be distantly related to members of the major facilitator superfamily (MFS; TC 2.A.1). They are not related to the mitochondrial ATP/ADP exchangers of the mitochondrial carrier family (MCF; TC 2.A.5), which pump ATP out of mitochondria in accordance with the polarity of the mitochondrial membrane potential. In Arabidopsis the plant mitochondrial adenylate translocator is highly sensitive to specific inhibitors, whereas the plastidic ATP/ADP translocator is only slightly sensitive to them (Vignais et al., 1976; Ardila et al., 1993; Schunemann et al., 1993; Winkler and Neuhaus, 1999).

In prokaryotes these transporters enable “energy parasitism,” as in *Rickettsia* and *Chlamydia* (Neuhaus et al., 1997). In addition, putative nucleotide transport proteins with weak sequence similarities to the NTT family of transporters have been identified in the nuclear genome of the obligate intracellular parasite *Encephalitozoon cuniculi* (Katinka et al., 2001). The bacterial nucleotide carriers have conspicuous sequence similarity to the NTT proteins from chloroplasts of higher plants (Neuhaus et al., 1997).

In plants, the main function proposed for the NTT family of transporters is to supply ATP-dependent reactions in non-photosynthetic plastids. Amyloplasts are heterotrophic plastids of sink tissues and contain various anabolic pathways, like the biosyntheses of starch and fatty acids or nitrogen assimilation. During starch biosynthesis in potato tubers, glucose 1-phosphate (Glc1P) is converted to ADP-Glc by the AGPase, a reaction which is ATP-dependent and relies on the supply of cytosolic ATP by NTT (Figure 5). This is corroborated by transgenic plants where repression of the potato NTT leads to decreased tuber yield and starch contents (Tjaden et al., 1998). In contrast to heterotrophic plastids, the role of NTTs in chloroplasts is not obvious. Rather than exporting ATP out of the photosynthetically active plastid during the day, NTT import ATP during the night or when photosynthetic ATP biosynthesis is not sufficient to fuel anabolic reactions requiring ATP (Reinhold et al., 2007).

*Arabidopsis* knock-out mutants demonstrated the involvement of NTT and ATP import in the assembly of magnesium chelatase, an enzyme involved in chlorophyll biosynthesis (Kobayashi et al., 2008). Plants repressing NTTs display necrotic lesions caused by photo-oxidation due to an accumulation of high amounts of the phototoxic chlorophyll biosynthesis intermediate protoporphyrin IX, which induces ROS production and phototoxic oxidative damage. Furthermore, the severity of the stress depended on the size of the plastidic starch pool, with plants grown in short day conditions being more affected (Reinhold et al., 2007). It has been proposed that the sensitivity to phototoxic oxidative stress in plants with limited plastidic ATP supply may link the appearance of the light harvesting complexes in the green lineage with the return of the storage polysaccharide to the plastid (Deschamps et al., 2008b). In plants, the main pathway of starch breakdown does not allow for the direct generation of
ATP within the plastid. However, hexose phosphates can be generated in the stroma by plastidial starch phosphorylase and further metabolized within the plastid to generate the required ATP pools, thereby circumventing protoporphyrin IX-induced oxidative stress (Deschamps et al., 2008b; Rathore et al., 2009). The authors propose that a sufficient supply of ATP was a potentially important protective innovation necessary for “safe” proliferation of LHCs.

The glaucophyte *C. paradoxa* also possesses a NTT, although the activity for ATP/ADP translocation could not be demonstrated in isolated muroplasts (Schlichting et al., 1990; Linka et al., 2003). In *C. paradoxa*, both fatty acids and starch biosynthesis are cytosol-localized, indicating that ATP import into the muroplast is not required for these reactions (Figure 3A; Ma et al., 2001; Plancke et al., 2008). Functional expression and reconstitution into membranes of the glaucophyte NTT ortholog will be required to elucidate its physiological role and demonstrate whether the protein is able to mediate ATP/ADP exchange.

The red algae *C. merolae* and *G. sulphuraria* contain each one gene coding for NTT (Tyra et al., 2007). In *Galdieria*, similarly to the plant NTT, the ortholog transporter is able to exchange ATP for ADP (Linka et al., 2003). In red algae the synthesis of storage carbon is confined in the cytoplasmic compartment, however, other anabolic reactions such as fatty acid biosynthesis require energy supply (Viola et al., 2001). The synthesis of fatty acids in *G. sulphuraria* has been postulated to occur in the plastid, as indicated by the presence of the subunits of the plastidic acetyl-CoA carboxylase, an ATP-dependent enzyme (Webber et al., 2004).

As mentioned above, the occurrence of a glycolytic pathway in the plastids of red algae is unlikely and ATP import would be required to drive fatty acid biosynthesis (Figure 3B; Linka et al., 2008a).

In contrast to higher plants, the secondary derived plastids of the diatoms are not able to synthesize nucleotides. Plants export newly synthesized nucleotides through a member of the MCF, an adenine nucleotide uniporter (Leroch et al., 2005). In diatoms, the synthesis of nucleotides is confined to the cytosol, implying the existence of an import mechanism. *Thalassiosira pseudonana* and *Phaeodactylum tricornutum* possess diverse members of the NTTs mediating the import of purine and pyrimidine nucleotides (Ast et al., 2009). In these organisms the NTTs are therefore involved in the nucleotide supply to maintain organelar metabolism (such as nucleic acids synthesis) rather than energy provision. Diatoms possess therefore plastidial NTT proteins with biochemical properties similar to those of some bacterial intracellular parasites, which catalyze nucleotide transport in a unidirectional mode, a feature not observed for any eukaryotic NTT (Figure 4B; Tjaden et al., 1999). This role in providing the plastid with externally synthesized nucleotides is similar to that of metabolically impaired intracellular bacteria such as *Chlamydia* which depend on host-derived metabolites. The functional relatedness of *Chlamydia* and plant NTTs reflects their common origin. The prokaryote transporters with the highest sequence similarity to plant NTT proteins occur in *Chlamydia* relatives and phylogenetic analyses of plant, *Chlamydiae* and *Rickettsiae* NTTs suggest that the translocator was transferred from *Chlamydia* to plants (Schmitz-Esser et al., 2004). The *Arabidopsis* AtNTT1 and AtNTT2 ATP/ADP transporters were shown to be monophyletic with the chlamydial translocators (Tyra et al., 2007). Moreover, free-living cyanobacteria are devoid of genes encoding for NTTs. Although *Chlamydiae* are not found in plants, an unexpected number of chlamydial genes display a high degree of similarity to their plant homologs. An analysis of bacteria–eukaryote protein similarities revealed that, beyond the well explainable abundance in cyanobacterial and α-proteobacterial sequences, a notable number of plant-like genes were found in the *Chlamydiaceae* genomes and, most intriguingly, the vast majority of these genes contain a plastid-targeting signal (Brinkman et al., 2002; Horn et al., 2004). A phylogenetic analysis of the *C. merolae* genome aimed at searching for genes that are evolutionary related to *Chlamydia* retrieved 21 genes which are broadly present in primary photosynthetic eukaryotes. The direction of transfer is proposed to be from the bacteria to the plants, since the genes are predominantly distributed in bacteria and the cyanobacterial homologs form a well supported group distinct from the chlamydial homologs (Huang and Gogarten, 2007). Genes of chlamydial origin are mainly restricted to photosynthetic eukaryotes and non-photosynthetic plastid-bearing lineages, an observation that supports an association between *Chlamydiae* and the plant ancestor. A deeper phylogenomic analysis of 17 plant genomes extended the list to 55 proteins of chlamydial origin, two-thirds of which are of plastid function (Moustafa et al., 2008). The scenario evolving from these comparative genomics surveys suggests a three-way partnership between the host, the cyanobacterial endosymbiont and an environmental *Chlamydia*. The chlamydial contribution may have consisted in facilitating the establishment of the cyanobacterial endosymbiont by providing the necessary transport systems required for the equilibration of their metabolism, like the ADP/ATP translocator needed for the energy flux into the organelle. Later on, when the organelle was fully established in the host cell, the bacterial parasite became dispensable and was eventually lost.

*Chlamydia* could have thus given a contribution in the early steps of endosymbiosis by providing the petriolgae with the genetic tools necessary to establish a favorable interaction.

**MITOCHONDRIAL CARRIER FAMILY**

Members of the MC family (TC 2.A.29) catalyze the passage of hydrophobic compounds across the inner mitochondrial membrane and preferentially catalyze the exchange of one solute acting as antiporters (Haferkamp, 2007; Palmieri et al., 2011). Members of the MCF are involved in transporting keto acids, amino acids, nucleotides, inorganic ions, and co-factors across the mitochondrial inner membrane. Although most are found in mitochondria, recently members of the MCF were found in peroxisomes, in hydrogenosomes of anaerobic fungi, and chloroplasts (Picault et al., 2004; Haferkamp, 2007; Linka et al., 2008b). In *Arabidopsis*, 58 genes encode for MCF proteins (Picault et al., 2004; Palmieri et al., 2011). The number in other sequenced plant genomes varies from 37 to 125, thus being larger than that of *Saccharomyces cerevisiae*, which encodes for 35 MCs and comparable with that of humans which contain 53 members (Palmieri et al., 1996; Palmieri, 2004).
Members of the MCF located in the plastid membrane represent transporters which are of host origin and were likely relocated to the envelope to substitute the pre-existing cyanobacterial transporters with the endomembrane-derived host transporters (Tyra et al., 2007). No homologs of mitochondrial carriers have ever been found in prokaryotes or archaea, meaning that MCFs are a later addition during the development of the eukaryotic cell (Kunji, 2004). In plants plastids, they mediate the transport of different substrates like folates, S-adenosylmethionine, NAD, ADP-glucose or ATP, ADP, and AMP (Haferkamp, 2007).

THE ADP-GLUCOSE TRANSPORTER BRITTLE-1

Besides the abovementioned NTT transporter, plastids contain another type of nucleotide transporter, the ADP-glucose transporter Brittle-1 (BT1), first identified in maize endosperm (Sullivan et al., 1991). The brittle1 mutant was named after the reduced starch content in the endosperm, resulting in collapsed, brittle kernels (Mangelsdorf and Jones, 1926). In the cereals endosperm, ADP-glucose pyrophosphorylase is localized in the cytosol (Denyer et al., 1996). The enzyme generates ADP-glucose, which must be exported into the plastid to drive starch biosynthesis. BT1 is localized to the inner envelope membrane of the amyloplast and transports ADP-glucose in antiport with the ADP released during starch biosynthesis, ensuring the balance of adenylates between stroma and cytoplasm (Figure 5; Sullivan and Kaneko, 1995; Kirchberger et al., 2007).

Another maize Brittle transporter protein, Brittle-1-2, and homologs of these transporters are found in other plants (Kirchberger et al., 2007). Interestingly, two types of Brittle-1 transporters can be identified: the BT1 from maize endosperm is present only in monocotyledonous plants and catalyzes ADP-glucose-ADP antiport, whereas the BT1-2 isoform has homologs also in dicotyledonous plants and transports nucleotides but not ADP-glucose (Leroch et al., 2005; Kirchberger et al., 2008). The StBT1 from potato and the AtBT1 from Arabidopsis locate to the inner plastid envelope and transport AMP, ADP, and ATP. Moreover, they show a unidirectional mode of transport rather than antiport (Figure 2; Leroch et al., 2005; Kirchberger et al., 2008).

TRANSPORTERS INVOLVED IN THE ONE-CARBON METABOLISM

Several cellular processes such as the synthesis of amino acids, purines, secondary metabolites, and the photosynthetic pathway depend upon the supply or removal of one-carbon units by tetrahydrofolate (THF) or S-adenosylmethionine (SAM).

Tetrahydrofolate and its derivatives are a family of co-factors that are essential for all cellular one-carbon transfer reactions: they are required for the synthesis of purines, thymidylate, methionine, pantothenate, and the interconversion of serine and glycine (Hanson and Roje, 2001). Folates are tripartite molecules composed of a pterin, a p-aminobenzoic acid (pABA), and a glutamate chain with a variable number of glutamate moieties.

In plants, folate synthesis presents a complex spatial organization, involving three subcellular compartments: the cytosol, the plastid, and the mitochondria.

In Arabidopsis, one member of the MCF was identified as folate carrier of the plastid envelope (Bedhomme et al., 2005). The AtFOLT1 protein is the closest homolog of the human mitochondrial folate transporter. Functional complementation of a glycine auxotroph Chinese hamster ovary (CHO) cell line deficient for the transport of folates into mitochondria could identify the folate carriers both in human and Arabidopsis (Titus and Moran, 2000; Bedhomme et al., 2005). The expression of AtFOLT1 in E. coli confers to the bacteria the ability to uptake exogenous folate, whereas the disruption of the gene did not lead to a deficient folate supply to the plastid, since wild-type levels of folates were detected in the chloroplasts and the enzymatic capacity to catalyze folate-dependent reactions was preserved (Bedhomme et al., 2005). This suggests that alternative routes for folate uptake into plastids are present.

SAM serves as methyl-group donor and it is exclusively synthesized in the plant cytosol. Consequently, it has to be imported into plastids and mitochondria where it acts as substrate for the methyltransferases. The product resulting from the transmethylation reaction, S-adenosylhomocysteine (SAHC) has to be in turn exported to undergo re-methylation in the cytosol. The carrier that catalyzes the counter exchange of SAM for SAHC has been recently identified in Arabidopsis (Bouvier et al., 2006; Palmieri et al., 2006). The SAM transporter (SAMT) exhibits a broad expression in various plant tissues, is localized to the plastid envelope membrane and, interestingly, the complete sequence contains additional information for mitochondrial targeting (Palmieri et al., 2006).

OTHER TRANSPORTERS

THE DICARBOXYLATE TRANSLOCATORS

For plants, nitrogen is available in the form of nitrate, which is sequentially reduced to nitrite in the cytosol and finally to ammonia in the chloroplast stroma. Ammonia is further assimilated into nitrogen compounds via the plastidic glutamine synthetase/glutamate synthetase (GS/GOGAT) cycle. Glutamate serves as a universal organic nitrogen donor for the biosynthesis of a vast variety nitrogen-containing compounds. Assimilation of ammonia in the plastids involves two distinct dicarboxylate translocators (DiTs) with partially overlapping substrate specificities, the 2-oxoglutarate/malate-translocator (DiT1), and the glutamate/malate-translocator (DiT2). DiT1 imports the precursor of ammonia assimilation, 2-oxoglutarate, in exchange with malate; DiT2 exports the end product of ammonia assimilation, glutamate, to the cytosol, importing back the malate (Figure 2; Weber et al., 1995; Weber and Flügge, 2002; Renne et al., 2003). These transporters play also an important role in recycling the ammonia lost during photorespiration by the mitochondrial glycine decarboxylase, as indicated by the photosynthetic phenotype displayed by Arabidopsis plants lacking DiT2 and tobacco DiT1 antisense plants (Renne et al., 2003; Linka and Weber, 2005; Schneiderireit et al., 2006). DiT1 also displays a high affinity for oxaaloacetate (OAA) and has been proposed as the long-sought OAA/malate valve (Tanimuchi et al., 2002). The malate valve functions as redox sink to dissipate excess of electrons and protect the photosynthetic apparatus from photoinhibition by exporting reducing equivalents thus balancing the stromal ATP/NADPH ratio (Heineke et al., 1991; Scheibe, 2004; Scheibe et al., 2005). The role as malate valve for DiT1 was recently proven by mutant
analysis: CO₂-dependent O₂ evolution assays showed that cytosolic oxaloacetate is efficiently transported into chloroplasts mainly by DiT1 and O₂ evolution is not enhanced by addition of OAA in the mutant, supporting the absence of additional oxaloacetate transporters (Kinoshita et al., 2001).

Dicarboxylate translocators belong to the Divalent Anion:Na⁺ Symporter (DASS) Family (TC 2.A.47) which transport organic di- and tri-carboxylates of the Krebs Cycle as well as dicarboxylate amino acid, inorganic sulfate, and phosphate. These proteins are found in Gram-negative bacteria, cyanobacteria, archaea, plant chloroplasts, yeast, and animals. DiTIs are present only in the green lineage of plants and in bacteria, but not in red algae or glaucophytes. Phylogenetic surveys indicate that the dicarboxylate transporters are of chlamydial origin, reinforcing the hypothesis on the importance these intracellular parasites had in the establishment of endosymbiosis (Tyra et al., 2007). In isolated C. paradoxa muroplasts, transport activities for glutamine and 2-oxoglutarate could be measured (Kloos et al., 1993). In uptake experiments with isolated cyanelles by silicone oil filtering it could be shown that glutamate poorly penetrated into cyanelles, whereas glutamine was enriched in the plastid fraction by 1.7 fold within 10 min. Glutamine uptake proceeded in two phases and was stimulated by 2-oxoglutarate (Kloos et al., 1993). Ammonia formed by nitrite reduction inside the cyanelles is incorporated by GS into glutamine and then exported jointly with oxoglutarate (Kloos et al., 1993). The export of glutamine appears to be the route for providing the host cell with fixed nitrogen, a situation that encounters a parallel in the nitrogen-fixing filamentous cyanobacteria. In cyanobacteria however, the transporter seems not to discriminate between glutamine and glutamate, indicating that the glutamine export route is unique to C. paradoxa (Chapman and Meeks, 1983; Flores and Muropastor, 1988; Kloos et al., 1993).

THE MALTOSE TRANSPORTER

In the dark, the starch which has accumulated during the day is degraded to supply sucrose biosynthesis. Maltose and glucose are the main products of starch degradation, with maltose being the most prominent sugar exported to the cytosol at night or during increased sink demand (Figure 2; Weise et al., 2004). The maltose transporter was identified by a screening of Arabidopsis mutants displaying a maltose excess (MEX) phenotype (Niityla et al., 2004). MEX is unrelated to any other membrane transporter and belongs to a family represented solely by the Arabidopsis member (TC 2.A.84). The maltose exporter is found only in the genomes of chloroplastida and is absent in red algae, glaucophytes, and photosynthetic organisms derived by secondary endosymbiosis. The presence of MEX orthologs in the dinoflagellate Karlodinium micrum and in Synecococcus likely is the result of independent horizontal gene transfers (Figure 6; Tyra et al., 2007). The pathway of starch synthesis and degradation is presumed to have been cytosolic in the common ancestor of the three Archaeplastida lineages (Deschamps et al., 2008a). MEX appears therefore to be a plant-specific transporter, evolved as a consequence of the relocation of the starch metabolism to the stroma of the green algal ancestor (Tyra et al., 2007; Deschamps et al., 2008a).

THE PLASTIDIC GLUCOSE TRANSPORTER

Starch breakdown initiates by the action of the phosphorylating enzymes glucan, water dikinase (GWD) and phosphoglucan, water dikinase (PDW) and, after involvement of a debranching enzyme, results in the release linear glucans (Smith et al., 2005). β-amyloses catalyze the production of maltose from linear glucans, and, to a lesser extent, maltotriose which is further metabolized to glucose by the disproportionating enzyme DPE1 (Critchley et al., 2001; Smith et al., 2005). A transporter involved in carbon mobilization mediating glucose export has been initially characterized and two decades later cloned and identified (Schafer et al., 1977; Weber et al., 2000). The glucose transporter (pGlcT) mediates the export of glucose released during the onset of starch degradation and has additional and still unknown roles suggested by its expression in some heterotrophic tissues that do not contain starch (Butowt et al., 2003). pGlcT contributes to the export of photosimulates from chloroplasts, even though it is not the major route for the export of starch degradation products (Figure 2). The pgketl-1mxcl double knock-out Arabidopsis line displays a severe growth retardation phenotype suggesting that the effects of pGlcT loss on photoassimilate partitioning and plant growth are observable when the major route for exporting starch degradation products is blocked (Hahn et al., 2011). pGlcT belongs to the (MFS, TC 2.A.1) a very old, large and diverse superfamily whose members catalyse uniport, solute:cation symport and/or solute:H⁺ or solute:solute antiport (Law et al., 2008). This superfamily is ubiquitous in all kingdoms of life, however, close relatives of pGlcT are found only within the Chloroplastida and, as for the maltose exporter, it reflects an acquisition by the green lineage imposed by the compartmentalization of the starch metabolism within the chloroplast (Tyra et al., 2007).

THE PLASTIDIC BILE ACID:Na⁺ SYMPORTER

Glucosinolates (GSLs) are sulfur- and nitrogen-containing plant secondary metabolites derived from amino acids and sugar. They are mainly present in the Brassicaceae family, including Arabidopsis, and have repellent activity against herbivore insects and pathogens (Fahey et al., 2001).

The biosynthesis of methionine-derived glucosinolates involves both the chloroplast and the cytosolic compartments and starts in the cytosol where Met is transaminated by the aminotransferase BCA4. The resulting 2-keto acid, 4-methylthio-2-oxobutanoate (MTOB) is imported into the chloroplast where it undergoes repeated condensations with acetyl-CoA and subsequent decarboxylations to the corresponding α-keto acid. The chain-elongated keto acid is aminated to the amino acid and transported back to the cytosol for the following core structure synthesis (Fahey et al., 2001; Knill et al., 2008; Nour-Eldin and Halkier, 2009). Thus, the methionine derivatives must be transported at least twice across the chloroplast membranes. The first transporter involved in the biosynthesis of Met-derived glucosinolates was recently identified as member of the Bile Acid:Na Symporter (BASS) Family (TC 2.A.28) due to significant sequence similarities to mammalian sodium-coupled bile acid transporters (Gigolashvili et al., 2009; Sawada et al., 2009). The BAT5 protein localizes to the plastid and loss-of-function mutants defective in BAT5 function contained strongly reduced levels of aliphatic glucosinolates. Feeding
FIGURE 6 | Molecular phylogenetic analysis of the MEX1 proteins. The evolutionary history was inferred by using the maximum likelihood method based on the WAG model (Whelan and Goldman, 2001). Sequence alignment was performed with MUSCLE included in MEGA5 (Tamura et al., 2011). Alignment quality was assessed by GUIDANCE giving an alignment score of 0.783. The bootstrap consensus tree inferred from 500 replicates is taken to represent the evolutionary history of the taxa analyzed. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (500 replicates) are shown next to the branches. A discrete gamma distribution was used to model evolutionary rate differences among sites (five categories, +G, parameter = 3.3094). The rate variation model allowed for some sites to be evolutionarily invariable (+I, 5.4532% sites). The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 14 amino acid sequences. All positions containing gaps and missing data were eliminated. There were a total of 173 positions in the final dataset. Evolutionary analyses were conducted in MEGA5 (Tamura et al., 2011).

experiments suggest that BAT5 transports MTOB and chain-elongated 2-keto acids across the chloroplast envelope membrane, indicating a role for BAT5 in the transport of GS intermediates (Gigolashvili et al., 2009; Sawada et al., 2009).

Homologs of the sodium-coupled bile acid transporters are also found in the algal genomes, however no data about their localization or function are to date available.

THE PLASTIDIC FOLATE CARRIER
In addition to the plastidic folate carrier belonging to the MCF, a second folate carrier was identified which belongs to the folate-biopterin transporter (FBT) Family (TC 2.A.71). The FBT family includes functionally characterized members from protozoa and homologs are found in cyanobacteria (Synechocystis) and plants (A. thaliana). The Synechocystis and Arabidopsis FBTs were identified based on their homology to the folate transporter of the trypanosomatid protozoa Leishmania (Klaus et al., 2005). These transporters are able to complement E. coli mutants impaired in folate uptake or production; in particular they are capable of transporting the monoglutamyl form of folate (Klaus et al., 2005). The plant FBT likely originated by endosymbiotic gene transfer (EGT) from the captured cyanobacterium and contributes to a redundant folate uptake system involving also the abovementioned host-derived FOLT1 transporter (Tyra et al., 2007).

THE PYRUVATE CARRIER
Plants that perform C4 photosynthesis require a massive flux of metabolites across the membranes of their MC and bundle sheat cells (BSC). In particular, pyruvate is formed in the chloroplasts of the BSC by decarboxylation of the C4 acid malate and has to be transported back to the MC chloroplasts to regenerate the CO2 acceptor PEP (Bräutigam and Weber, 2011). Pyruvate transport in C4 plants has been shown to occur either in a proton- or sodium-dependent manner (Ohnishi and Kanai, 1987, 1990). Accordingly, a putative plastidic proton:sodium symporter (NHD1) is 16-fold up-regulated in the C4 species Cleome gynandra with respect to the C3 relative Cleome spinosa (Bräutigam et al., 2011). It is proposed that NDH1 functions in exporting sodium out of the chloroplast to sustain a gradient necessary for pyruvate import. In addition, a strong up-regulation of a bile acid:sodium cotransporter was observed in C. gynandra (Bräutigam et al., 2011) and in C4 Flaviera species (Gowik et al., 2011). This cotransporter is a member...
of the BASS Family (TC 2.A.28) and is not found in maize, which is a species which displays a proton-dependent transport of pyruvate (Bräutigam et al., 2008). The biochemical function NDH1 and BASS2 was recently demonstrated by expression in an heterologous system of BASS2 alone and in presence of NDH1 (Furumoto et al., 2011). Indeed, these proteins represent a two-translocator system, consisting of the sodium:pyruvate cotransporter BASS2 and the sodium:proton antiporter NHD1 (Figure 7; Furumoto et al., 2011).

CONCLUSION

The transport of organic compounds across the cyanobacterial membrane was of crucial importance for establishing endosymbiosis and insertion of protein translocators into the envelope was necessary to take full advantage of the newly acquired metabolic entity. The PPTs were most likely pioneers in settling a connection between the host and the cyanobiont in order to tap the photosynthates, as suggested by their ubiquitous distribution among the plastid-bearing organisms. The majority of the plastid translocators, including the PPTs, are of host origin, indicating that establishment of the plastid was a host-driven process. However, evidence is accumulating which implies a small but substantial contribution from the intracellular parasite Chlamydia. The requirement of three organisms in the early steps of endosymbiosis could explain why this event occurred only once during evolution. Understanding the metabolic connection between plastid and cytosol is also crucial for future attempts to generate synthetic organelles, such as synthetic plastids that harbor tailor-made metabolic capacities and that are introduced into plastid-free recipient cells (Weber and Osteryoung, 2010).
