Abstract
Possible effects of large-scale magnetic fields on the cosmic microwave background (CMB) are reviewed. Depending on the specific branch of the spectrum of plasma excitations, magnetic fields are treated either within a two-fluid plasma description or within an effective (one-fluid) approach. The uniform field approximation is contrasted with the fully inhomogeneous field approximation. It is argued that the interplay between CMB physics and large-scale magnetic fields will represent a rather interesting cross-disciplinary arena over the next few years.

1. Why CMB anisotropies could be magnetized?

Simplified magneto-hydrodynamical estimates imply that the magnetic diffusivity length scale\(^1\) in the interstellar medium is of the order of the astronomical unit. On the other hand, magnetic fields are present over much larger length scales so that there seems to be rather compelling evidence that galaxies, clusters and possibly super-clusters are all magnetized. The question that arises naturally in this context concerns the possible effects of large-scale magnetic fields on the cosmic microwave background (CMB). In the last 50 years, various cosmological mechanisms for the origin of large-scale magnetic fields have been proposed. While different mechanisms rely on diverse physical assumptions some general features can be identified:

• the majority of the cosmological mechanisms imply the existence of large-scale magnetic fields after equality (but before decoupling);

\(^1\) The magnetic diffusivity length is the typical scale below which magnetic fields are diffused because of the finite value of the conductivity of the (interstellar) medium.
• the magnetic field present after equality is, according to the mentioned mechanisms, fully inhomogeneous;
• the typical amplitudes and length scales of the magnetic field are characteristic of the given model.

The first possibility we can think of implies that magnetic fields are produced, at a given epoch in the life of the Universe, inside the Hubble radius, for instance by a phase transition or by any other phenomenon able to generate a charge separation and, ultimately, an electric current. In this context, the correlation scale of the field is much smaller than the typical scale of the gravitational collapse of the proto-galaxy which is of the order of Mpc. In fact, if the Universe is decelerating and if the correlation scale evolves as the scale factor, the Hubble radius grows much faster than the correlation scale. Of course, one might invoke the possibility that the correlation scale of the magnetic field evolves more rapidly than the scale factor. A well-founded physical rationale for this occurrence is what is normally called inverse cascade, i.e. the possibility that magnetic (as well as kinetic) energy density is transferred from small to large scales. This implies, in real space, that (highly energetic) small scale magnetic domains may coalesce to form magnetic domains of smaller energy but over larger scales. In the best of all possible situations, i.e. when inverse cascade is very effective, it seems rather hard to justify a growth of the correlation scale that would eventually end up in an Mpc scale at the onset of gravitational collapse. In figure 1, we report a schematic illustration of the evolution of the Hubble radius $R_H$ and of the correlation scale of the magnetic field as a function of the scale factor. In figure 1, the horizontal dashed line simply marks the end of the radiation-dominated phase and the onset of the matter-dominated phase: while above the dashed line the Hubble radius evolves as $a^2$ (where $a$ is the scale factor), below the dashed line the Hubble radius evolves as $a^{3/2}$. We consider, for simplicity, a magnetic field whose typical correlation scale is as large as the Hubble radius at the electroweak epoch when the temperature of the plasma was of the
Figure 2. Evolution of the correlation scale if magnetic fields were produced by super-adiabatic amplification during a conventional inflationary phase. The dashed vertical lines denote the evolution of the Hubble radius while the full line denotes the evolution of the correlation scale (typically selected to be smaller than the Hubble radius during inflation).

order of 100 GeV. If the correlation scale evolves as the scale factor, the Hubble radius at the electroweak epoch (roughly 3 cm) projects today over a scale of the order of the astronomical unit. If inverse cascades are invoked, the correlation scale may grow, depending on the specific features of the cascade, up to 100 AU or even up to 100 pc. In both cases the final scale is too small if compared with the typical scale of the gravitational collapse of the protogalaxy. In figure 1, a particular model for the evolution of the correlation scale $\lambda(a)$ has been reported$^2$.

In the context of (conventional or unconventional) inflationary models, in contrast, the correlation scale of the produced magnetic fields may be rather high. The physical picture is that during the inflationary phase the quantum fluctuations of the hypercharge field are amplified either through some coupling to the geometry or through the coupling to some other spectator field. Since during inflation the Hubble radius is roughly constant (see figure 2), the correlation scale evolves much faster than the Hubble radius itself and, therefore, large-scale magnetic domains can naturally be obtained. Note that in figure 2 the (vertical) dashed lines illustrate the evolution of the Hubble radius (that is roughly constant during inflation) while the full line denotes the evolution of the correlation scale. Furthermore, the horizontal (dashed) lines mark, from top to bottom, the end of the inflationary phase and the onset of the matter-dominated phase. This phenomenon can be understood as the gauge counterpart of the super-adiabatic amplification of the scalar and tensor modes of the geometry. The main problem, in such a framework, is to get large amplitudes for scale of the order of Mpc at the onset of gravitational collapse. Models where the gauge couplings are effectively dynamical

$^2$ Note, as will be discussed later, that the inverse cascade lasts, in principle, only down to the time of $e^+e^-$ annihilation (see also the thin dashed horizontal line in figure 1) since for temperatures smaller than $T_{e^+e^-}$ the Reynolds number drops below 1. This is the result of the sudden drop in the number of charged particles that leads to a rather long mean free path for the photons.
(breaking, consequently, the Weyl invariance of the evolution equations of Abelian gauge modes) may provide rather intense magnetic fields.

The two extreme possibilities mentioned above may be sometimes combined. For instance, it can happen that magnetic fields are produced by super-adiabatic amplification of vacuum fluctuations during an inflationary stage of expansion. After exiting the horizon, the gauge modes will re-enter at different moments all along the radiation and matter-dominated epochs. The spectrum of the primordial gauge fields after re-entry will not only be determined by the amplification mechanism but also by the plasma effects. As soon as the magnetic inhomogeneities re-enter, some other physical process, taking place inside the Hubble radius, may be triggered by the presence of large-scale magnetic fields. An example, in this context, is the production of topologically non-trivial configurations of the hypercharge field (hypermagnetic knots) from a stochastic background of hypercharge fields with vanishing helicity.

Since magnetic fields are produced over different length scales, it seems plausible to discuss their effect on the anisotropies of the cosmic microwave background (CMB) radiation. The finite values of the thermal and magnetic diffusivity scales forbid the presence of magnetic fields over length scales that are very small in comparison with the size of the Hubble radius at a given epoch. On the other hand, dissipation is not effective in erasing the magnetic energy density over very large scales comparable with the Hubble radius itself.

Different topics are relevant for the interplay between large-scale magnetic fields and CMB physics. A simplified list of the main effects involving, simultaneously, large-scale magnetic fields and CMB physics must include

• possible distortions of the CMB blackbody spectrum;
• possible induction of primary anisotropies;
• possible effects on the CMB polarization.

To this list it is appropriate to add another important topic that has to do with the subtraction of foregrounds. In fact, to disentangle the signal of the CMB anisotropies one has to usually subtract the emission of the galaxy. The synchrotron emission is indeed one of the foregrounds to be subtracted.

To estimate the effects of large-scale magnetic fields on CMB physics various approximations have been used through the years. Again, for the sake of simplicity, it is useful to divide them into two broad classes:

• uniform field approximation;
• inhomogeneous field approximation.

In the uniform field approximation, the magnetic field is taken to be uniform and pointing along a specific direction in the sky. In this approximation (pioneered by Zeldovich in the 1960s) the magnetic field slightly breaks the spatial isotropy of the background geometry. The break in the spatial isotropy can easily be connected with a difference in the propagation of electromagnetic signals along different spatial directions. This phenomenon is ultimately responsible, in this context, for the anisotropy of the CMB.

In a complementary perspective, fully inhomogeneous large-scale magnetic fields do not break the spatial isotropy of the background geometry. This happens, for instance, when the magnetic field is fully inhomogeneous and characterized by its two-point function. In the uniform field approximation the resulting evolution equations are rather tractable and semi-analytical estimates of various effects can be swiftly obtained. It is, however, problematic to imagine that a uniform magnetic field (oriented along a specific spatial direction) may be generated in the early Universe. The presence of a uniform field could be viewed as a remnant of the initial conditions of the evolution of the Universe.
Conversely, the fully inhomogenous approach is more realistic but also harder to implement analytically. An intermediate approach is to discuss the uniform field case supplemented by the appropriate fluctuations. In this approach, the parameters describing the model are given by the uniform component of the magnetic field and by the two-point function of the fluctuations.

An important point to be borne in mind when discussing the effects of large-scale magnetic fields on CMB anisotropies concerns the suitable set of equations used to model the plasma effects. For the purposes of this review, we will confine ourselves to the two most practical sets of equations normally employed in this type of study, namely,

- a set of two-fluid plasma equations in curved space;
- an effective one-fluid (magnetohydrodynamical) description.

These two systems of equations are not equivalent for all the frequencies of the spectrum of plasma excitations. In particular, if we ought to address phenomena involving the propagation of electromagnetic disturbances in the plasma (as in the case of Faraday) rotation, the two-fluid description (or even a kinetic Vlasov–Landau description) has to be employed. Magnetohydrodynamics (MHD) is a good effective description for sufficiently small frequencies in the spectrum of plasma excitations.

The plan of the present review is the following. In section 2, the uniform field approximation will be reviewed. In section 3, a two-fluid plasma description will be introduced. As an application, the Faraday effect in the uniform field approximation will be discussed. In section 4, after discussing a one-fluid plasma description, fully inhomogeneous magnetic fields will be analysed. Section 5 contains an introduction to the evolution of metric fluctuations in the presence of large-scale magnetic fields. In this context, the problem of initial conditions of CMB anisotropies will be reviewed in the presence of large-scale magnetic fields. The final part of section 5 contains a summary of the numerical results obtained so far in the context of fully inhomogeneous magnetic fields. A brief collection of concluding remarks and future perspectives is presented in section 6.

2. Uniform field approximation

The uniform field approximation has a long history that could be traced back to the work of Zeldovich [1] (see also [2, 3]). Before the formulation of inflationary models the problem of the initial conditions of Friedmann–Robertson–Walker models was debated. Among different options (early dominance of viscous effects, anisotropy in the expansion, etc), a particularly interesting possibility was represented by a uniform background magnetic field oriented along a specific spatial direction. Indeed, close to a big-bang singularity the spatial gradients are sub-leading but the model can well be anisotropic [4–6]. In other words, close to the big bang, the homogeneous (but anisotropic) metric can fall into one of the Bianchi classes [7] and a uniform magnetic field can fit into this scheme. During an inflationary phase the anisotropy decays exponentially and, therefore, we have to imagine that the (uniform) field considered in this section was created, for instance, close to the end of inflation. Since the work of Zeldovich [1, 2], the uniform field approximation has been exploited in various frameworks (see [8–13] and references therein for a tentative list of theoretical studies).

Consider then, as an illustration, the case when the magnetic field is oriented along the \( \hat{x} \) axis. Suppose also, for the sake of simplicity, that the Universe is filled by a perfect barotropic fluid and that the spatial curvature vanishes. In this case, the line element must account for the possibility of a different expansion rate along the \( \hat{x} \) axis or along the \( \{\hat{y}, \hat{z}\} \) plane and may
have the form
\[ ds^2 = dt^2 - a^2(t) dx^2 - b^2(t) (dy^2 + dz^2). \] (2.1)

The metric (2.1) corresponds to a particular case of a Bianchi-type I metric. Uniform magnetic fields can also be introduced in other Bianchi metrics [8, 10–12]. The anisotropy in the expansion and the total expansion rate are, in this case,
\[ \mathcal{A} = \frac{H - F}{\Theta}, \quad \Theta = \frac{H + 2F}{3}, \] (2.2)

where \( H = \dot{a}/a \) and \( F = b/b \) are the expansion rates and the overdot denotes a derivation with respect to the cosmic time coordinate \( t \).

In the model defined by equation (2.1) the propagation of an electromagnetic signal will be different along the \( \hat{x} \) and \( \hat{y} \) axes (see figure 3). Therefore, the temperature anisotropy will depend both on \( \Theta \) and \( \mathcal{A} \):
\[ \frac{\Delta T}{T} = \frac{T_x - T_y}{T_z} \simeq - \int \mathcal{A} \Theta \, dt, \] (2.3)

where we used that \( T_x = T_0/a \) and \( T_y = T_0/b \) together with the identities \( a^{-1} = e^{-\int H \, dt} \) and \( b^{-1} = e^{-\int F \, dt} \).

The quantities appearing in equation (2.3) can be estimated by studying the evolution of the anisotropic expansion and of the total expansion rate along the different stages of the life of the Universe. For this purpose it is practical to phrase Einstein equations directly in terms of \( \mathcal{A} \) and \( \Theta \). The procedure is rather simple since it suffices to write the extrinsic curvature in terms of \( H \) and \( F \). Then, by recalling the definitions of equation (2.2), the full set of Einstein equations and of the continuity equations can be written, respectively, as
\[ \Theta + 3\Theta^2 = \frac{8\pi G}{3} \rho \left[ \frac{2 - 3\epsilon}{2} + q \right], \] (2.4)
\[ \mathcal{A} \Theta + \mathcal{A} (\dot{\Theta} + 3\Theta^2) = -16\pi G \rho q, \] (2.5)
\[ \rho + \Theta (4 + 3\epsilon) \rho = 0, \] (2.6)
\[ \dot{q} = 3q\Theta \epsilon + \frac{4}{3} q \Theta \mathcal{A}. \] (2.7)
where the following conventions have been adopted:

\[ w = \epsilon + \frac{1}{3}, \quad q = \frac{\rho_B}{\rho}, \quad (2.8) \]

In equation (2.8), \( w \) is the barotropic index of the fluid background and \( \rho_B = \frac{B^2}{8\pi} \).

\[ \dot{\rho}_B + 4F\rho_B = 0. \quad (2.9) \]

In the case \( \epsilon = 0 \), the barotropic index is exactly that of radiation and equations (2.4)–(2.7) admit a solution where \( \dot{A} \simeq 0 \) and \( \Theta \simeq (2t)^{-1} \). Inserting then equation (2.5) into equation (2.7) (and recalling that \( \dot{\Theta} = -2\Theta^2 \)) it is easy to obtain the evolution of \( q(t) \), i.e.

\[ q(t) = q_1 \frac{1}{1 + 4q_1 \ln \left( \frac{t}{t_1} \right)}, \quad t \geq t_1. \quad (2.10) \]

This means that in the case of a radiation background the anisotropy in the expansion is conserved and the ratio between radiation and magnetic energy densities is roughly constant (up to logarithmic corrections). For generalization of this analysis to more complicated situations involving different equations of state or various fluids and fields see, for instance, [8, 10, 13].

The property expressed by equation (2.10) is a consequence of the fact that both energy–momentum tensors (i.e. the one of the background fluid and the other of the magnetic field) are traceless. Therefore, the evolution of \( q(t) \) will be different if the background fluid is dominated by dusty sources. In the case of dusty matter equation (2.8) implies that \( \epsilon = -1/3 \). Therefore, an approximate solution of the system in this case is given by

\[ \Theta(t) \simeq \frac{2}{3t}, \quad A(t) \simeq -12q_{eq} \left( \frac{a_{eq}}{a} \right), \quad q(t) = q_{eq} \left( \frac{a}{a_{eq}} \right). \quad (2.11) \]

By following the evolution of the system through equality up to decoupling the value of the anisotropy can then be roughly calculated to be

\[ \frac{\Delta T}{T} \simeq \frac{B^2}{16\pi\rho_y} z_{dec}. \quad (2.12) \]

By requiring that the temperature anisotropy is smaller than \( 10^{-5} \) we get in the case of \( \Omega_{tot} = 1 \),

\[ B_0 \leq 2 \times 10^{-9} \text{ G}, \quad (2.13) \]

where \( B_0 \) refers to the value of the field at the present time. The logic leading to the limit reported in equation (2.13) has been followed, for instance, in [9].

A complementary way of describing the effect of a uniform magnetic field on the temperature anisotropies relies on the observation that, thanks to the breaking of spatial isotropy, the angular power spectrum will depend not only on the polar angle but also on the azimuthal angle. In fact, if spatial isotropy is \emph{unbroken}, the angular power spectrum is customarily defined as

\[ C(\hat{\theta}) = \langle \Delta_1(\hat{\theta}_1, \tau_0) \Delta_1(\hat{\theta}_2, \tau_0) \rangle, \quad (2.14) \]

where \( \Delta_1 \) is the brightness perturbation in the intensity of the radiation field whose expansion in terms of spherical harmonics is

\[ \Delta_1(\hat{n}, \tau_0) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} a_{\ell m} Y_{\ell m}(\hat{n}). \quad (2.15) \]
If the background space is isotropic, the ensemble average of $a_{\ell m}$ only depends upon $\ell$, not upon $m$, i.e.

$$\langle a_{\ell m} a_{\ell' m'}^{*} \rangle = C_\ell \delta_{\ell \ell'} \delta_{m m'}.$$  
(2.16)

Therefore, inserting equation (2.15) into equation (2.14), the addition theorem of spherical harmonics, i.e.

$$P_\ell (\hat{n}_1 \cdot \hat{n}_2) = \frac{4\pi}{2 \ell + 1} \sum_{m=-\ell}^{\ell} Y^*_{\ell m} (\hat{n}_1) Y_{\ell m} (\hat{n}_2),$$  
(2.17)

leads to the usual form of the angular power spectrum,

$$C(\theta) = \langle \Delta_1 (\hat{n}_1, \tau_0) \Delta_1 (\hat{n}_2, \tau_0) \rangle \equiv \frac{1}{4\pi} \sum_\ell (2\ell + 1) C_\ell P_\ell (\theta),$$  
(2.18)

where $\theta = \hat{n}_1 \cdot \hat{n}_2$.

If spatial isotropy is slightly broken (as in the case when a uniform magnetic field is present), equation (2.16) is not justified since the ensemble average of $a_{\ell m}$ should depend not only on $\ell$ but also on $m$. Indeed, it can be shown that when a uniform magnetic field is present, the average of temperature fluctuations in two directions of the sky can be expressed as

$$\langle \Delta_1 (\hat{n}_1, \tau_0) \Delta_1 (\hat{n}_2, \tau_0) \rangle = \sum_{\ell, m} C_{\ell} (m) Y_{\ell, m} (\hat{n}_1) Y_{\ell, m}^{*} (\hat{n}_2) + \sum_{\ell, m} D_{\ell} (m) [Y_{\ell+1, m} (\hat{n}_1) Y_{\ell-1, m}^{*} (\hat{n}_2) + Y_{\ell-1, m} (\hat{n}_1) Y_{\ell+1, m}^{*} (\hat{n}_2)],$$  
(2.19)

where both $C_{\ell} (m)$ and $D_{\ell} (m)$ depend upon the (uniform) magnetic field intensity. From equation (2.19) it is apparent that the presence of a magnetic field with uniform component induces off-diagonal correlations in multipole space between a given $\ell$ and multipoles $\ell \pm 2$.

The breaking of spatial isotropy in the CMB maps can be constrained, for instance, from WMAP data.

This analysis has been recently performed in [14] (see also [15]). The constraints on the off-diagonal correlations in multipole space imply a bound on the (present) uniform component of the magnetic field intensity:

$$B_0 \leq 1.7 \times 10^{-9} \text{ G}.$$  
(2.20)

It should be mentioned that the bound of equation (2.20) has been derived by taking into account also the fluctuations of the magnetic field around the uniform configuration. The presence of the fluctuations of a uniform configuration introduces extra parameters (such as the spectral index of the fluctuations) that make the allowed region in the parameter space effectively two dimensional. Various studies assume a (uniform) background field and consider the possible fluctuations of such a configuration (see for instance [16–18] and references therein). In particular, in [17] the magnetic field has been parametrized in terms of a uniform component directed along a specific axis and a tangled component. The Alfvén-wave modes associated with this configuration may induce a small rotational perturbation in the last scattering surface.

In [19], this analysis has been performed in a non-relativistic approximation where the scalar perturbations of the geometry obey linearized Newtonian equations of motion. The magnetic field has been assumed to be uniform (but supplemented with the appropriate fluctuations). In this framework, it has been argued that the effect of the presence of the (uniform) magnetic field can be phrased into an effective renormalization of the speed of sound of the baryons (see also [20]).
3. Two-fluid plasma description and CMB polarization

Right before decoupling the value of the Debye screening length is much larger than the electron and photon mean free paths. In fact, the Debye length scale can be written as

$$\lambda_D = \sqrt{\frac{T_{ei}}{8\pi e^2 n_0}} \approx 10 \left( \frac{n_0}{10^3 \text{ cm}^{-3}} \right)^{-1/2} \left( \frac{T_{ei}}{0.3 \text{ eV}} \right)^{1/2} \text{ cm},$$  \hspace{1cm} (3.1)

where $n_0 \simeq n_e \simeq n_i$ is the mean electron–ion density and $T_{ei}$ is the electron–ion temperature. For length scales larger than $\lambda_D$, the plasma is globally neutral. For typical values of the parameters in equation (3.1), $\lambda_D$ is of the order of 10 cm around recombination while the electron and photon mean free paths are much larger, i.e.

$$\ell_e \simeq 5.7 \times 10^7 \text{ cm}, \quad \ell_\gamma \simeq 10^4 (1 + z)^{-2} (\Omega_b h_0^2)^{-1} \text{ Mpc},$$  \hspace{1cm} (3.2)

where $z = a_0/a - 1$ is the redshift, $\Omega_b$ is the baryon fraction of the critical energy density and $h_0$ is the indetermination in the Hubble parameter.

The other set of quantities relevant for the determination of the appropriate system of equations is given by the plasma and Larmor frequencies of electrons and ions, i.e.

$$\omega_{pe} \simeq 2 \left( \frac{n_e}{10^3 \text{ cm}^{-3}} \right)^{1/2} \text{ MHz}, \quad \omega_{Be} \simeq 18.08 \left( \frac{B}{10^{-3} \text{ G}} \right) \text{ kHz},$$  \hspace{1cm} (3.3)

$$\omega_{pi} \simeq 40 \left( \frac{n_e}{10^3 \text{ cm}^{-3}} \right)^{1/2} \text{ kHz}, \quad \omega_{Bi} \simeq 9.66 \left( \frac{B}{10^{-3} \text{ G}} \right) \text{ Hz}.$$  \hspace{1cm} (3.4)

Note that the typical value of $B$ around decoupling reported in equations (3.3) and (3.4) corresponds, today, to a magnetic field of the order of $10^{-9} - 10^{-10}$ G.

If we are now interested in the propagation of electromagnetic disturbances with frequencies larger than the plasma and Larmor frequencies, then it is clear that a two-fluid plasma description should be adopted. For some classes of problems, it will also be useful to employ directly a kinetic (Vlasov–Landau [21–23]) description. If, in contrast, we were interested in the spectrum of plasma excitations for $\omega < \omega_p$, then effective (one-fluid) descriptions (such as MHD [24]) can be usefully employed. This second regime will be addressed in section 4.

The two-fluid plasma equations in curved spacetime will now be discussed and treated in analogy with the well-known flat-space case [25]. Let us consider, for simplicity, a conformally flat geometry of Friedmann–Robertson–Walker (FRW) type

$$\text{d}s^2 = a^2(\tau) \left[ \text{d}\tau^2 - \text{d}\vec{x}^2 \right].$$  \hspace{1cm} (3.5)

The following two equations account for the continuity of electron and ion charge densities:

$$n_e' + 3 w_e H n_e + (w_e + 1) \vec{V} \cdot (n_e \vec{v}_e) = 0,$$  \hspace{1cm} (3.6)

$$n_i' + 3 w_i H n_i + (w_i + 1) \vec{V} \cdot (n_i \vec{v}_i) = 0,$$  \hspace{1cm} (3.7)

where the prime denotes a derivation with respect to the conformal time coordinate $\tau$ while the other quantities appearing in equations (3.6) and (3.7) are

$$H = a'/a, \quad n_e = a^3 \tilde{n}_e, \quad n_i = a^3 \tilde{n}_i.$$  \hspace{1cm} (3.8)

In equations (3.6) and (3.7) $w_e$ and $w_i$ are the barotropic indices for the electron and ion fluids. Both electrons and ions are non-relativistic (for the ion mass, in the numerical estimates, we take $m_i \simeq m_p$ where $m_p$ denotes the proton mass). Hence the barotropic indices $w_e$ and $w_i$...
will be close to zero. In fact, the energy and pressure densities of an ideal electronic gas are given by
\[
\rho_e = n_e (m_e + \frac{1}{2} T_e), \quad \rho_c = n_c T_e,
\] (3.9)
and since \( w_{e,i} = T_{e,i} / m_{e,i} \), we will also have \( w_{e,i} \ll 1 \) as far as \( T_{e,i} \ll m_{e,i} \). Recalling that \( \rho_e = m_e n_e \) and \( \rho_i = m_i n_i \), the momentum conservation equations are
\[
\rho_e [\vec{v}_e' + \eta \vec{v}_e + (\vec{v}_e \cdot \vec{\nabla}) \vec{v}_e] = -n_e e \left( \vec{E} + \frac{\vec{v}_e}{c} \times \vec{B} \right), \quad (3.10)
\]
\[
\rho_i [\vec{v}_i' + \eta \vec{v}_i + (\vec{v}_i \cdot \vec{\nabla}) \vec{v}_i] = n_i e \left( \vec{E} + \frac{\vec{v}_i}{c} \times \vec{B} \right), \quad (3.11)
\]
where \( \vec{E} = a^2 \vec{E} \) and \( \vec{B} = a^2 \vec{B} \) are the conformally rescaled electromagnetic fields obeying the following set of equations:
\[
\vec{\nabla} \cdot \vec{E} = 4\pi e (n_i - n_e), \quad (3.12)
\]
\[
\vec{\nabla} \cdot \vec{B} = 0, \quad \vec{\nabla} \times \vec{E} = -\frac{1}{c} \vec{B}', \quad (3.13)
\]
\[
\vec{\nabla} \times \vec{B} = \frac{1}{c} \vec{E}' + \frac{4\pi e}{c} (n_i \vec{v}_i - n_e \vec{v}_e). \quad (3.14)
\]
The dispersion relations relevant for the propagation of electromagnetic waves with \( \omega > \omega_p \) can be found, after some algebra, in the case of a uniform magnetic field directed, for instance, along the \( \hat{z} \) axis\(^3\).

Equations (3.6) and (3.7) can be first linearized around a globally neutral configuration, i.e.
\[
n_e (\tau, \vec{x}) = n_0 + \delta n_e (\tau, \vec{x}), \quad n_i (\tau, \vec{x}) = n_0 + \delta n_i (\tau, \vec{x}), \quad (3.15)
\]
where \( n_0 \) is the common electron and ion density. The remaining equations can also be linearized around the uniformly magnetized configuration:
\[
\vec{B}(\eta, \vec{x}) = \vec{B}_0 + \delta \vec{B}(\eta, \vec{x}), \quad \vec{v}_{e,i}(\eta, \vec{x}) = \delta \vec{v}_{e,i}(\eta, \vec{x}), \quad \vec{E}(\eta, \vec{x}) = \delta \vec{E}(\eta, \vec{x}). \quad (3.16)
\]
The linearized equations around the uniformly magnetized background can be solved [26]. The dielectric tensor can then be obtained and it has the following general form [26]:
\[
\epsilon(\omega, \alpha) = \begin{pmatrix}
\epsilon_1(\omega, \alpha) & i \epsilon_2(\omega, \alpha) & 0 \\
-i \epsilon_2(\omega, \alpha) & \epsilon_1(\omega, \alpha) & 0 \\
0 & 0 & \epsilon_\parallel(\omega, \alpha)
\end{pmatrix}, \quad (3.17)
\]
where
\[
\epsilon_1(\omega, \alpha) = 1 - \frac{\omega_p^2}{\omega^2 (1 + \alpha)} - \frac{\omega_e^2}{\omega^2 (1 + \alpha)} \quad (3.18)
\]
\[
\epsilon_\parallel(\omega, \alpha) = 1 - \frac{\omega_p^2 (\alpha + 1)}{\omega^2 (\alpha + 1)^2} - \frac{\omega_e^2 (\alpha + 1)}{\omega^2 (\alpha + 1)^2} - \omega_{pe}^2, \quad (3.19)
\]
\(^3\) In principle we should allow a different expansion rate along the \( (\hat{x}, \hat{y}) \) plane and along the \( \hat{z} \) axis, as discussed in the previous section (see, for instance, equation (2.1)). This is not strictly necessary for the derivation of the dispersion relations. While the anisotropic expansion caused by a uniform magnetic field affects the primary anisotropies, the dispersion relations are weakly affected by the curved space corrections. This statement will explicitly be verifed in our case.
The quantity \( \epsilon_2(\omega, \alpha) \) denotes the dielectric constant parallel to the direction of the uniform component of the magnetic field intensity while \( \epsilon_1(\omega, \alpha) \) and \( \epsilon_2(\omega, \alpha) \) denote the dielectric constants determined by the motion of charged particles orthogonal to the direction of the uniform magnetic field. If the uniform magnetic field vanishes, we can obtain the dielectric tensor of the cold plasma by formally taking the limits \( \epsilon_2(\omega, \alpha) \to 0 \) and \( \epsilon_1(\omega, \alpha) \to \epsilon_1(\omega, \alpha) \).

It is then clear that in the absence of magnetic field the only scales entering the dispersion relations are the plasma frequencies of electrons and ions. The quantity \( \alpha \) appearing in the dielectric tensor is defined as \( \alpha = i\hbar/\omega \) and is the lowest order correction arising in curved space. This correction is negligible for the present purposes since it is of the order of the ratio between the Hubble radius at the decoupling and the inverse of the frequency of propagation. Recalling that \( H_{\text{dec}} \simeq 5.6 \times 10^{12} (\Omega_0 h_0^2)^{-1/2} \) s and that \( \omega \gg 100 \) MHz, we have that \( |\alpha| < 10^{-22} \).

To derive the dispersion relations it is appropriate to fix the coordinate system: for instance, we can set \( k_\parallel = 0, k_\perp = k \sin \theta \) and \( k_z = k \cos \theta \) with the magnetic field oriented along the \( \hat{z} \) direction. Introducing the refraction index \( n \) and recalling that \( k = \omega/v = n \omega/c \) (where \( v \) is the phase velocity) the dispersion relations are determined from the solution of the following equation:

\[
s^2(\theta) \left( \frac{1}{\epsilon_\parallel} - \frac{1}{n^2} \right) \left[ \frac{1}{n^2} - \frac{\omega^2_{\text{pe}}}{\omega^2 - \omega^2(\alpha + 1)^2} \right] - c^2(\theta) \left( \frac{1}{n^2} - \frac{1}{\epsilon_\parallel} \right) \left( \frac{1}{n^2} - \frac{1}{\epsilon_\perp} \right) = 0,
\]

where \( c(\theta) = \cos \theta \) and \( s(\theta) = \sin \theta \). In equation (3.21) the following linear combinations have also been introduced:

\[
\epsilon_\parallel = \epsilon_1 + \epsilon_2 = 1 - \frac{\omega_{\text{pe}}^2}{\omega[\omega(\alpha + 1) - \omega_{\text{Be}}]}, \quad \epsilon_\perp = \epsilon_1 - \epsilon_2 = 1 - \frac{\omega_{\text{pe}}^2}{\omega[\omega(\alpha + 1) + \omega_{\text{Be}}]},
\]

(3.22)

The quantities \( \epsilon_\parallel \) and \( \epsilon_\perp \) are the dielectric constants appropriate for the propagation of the two (left and right) circular polarizations. The dispersion relations for the propagation of electromagnetic disturbances parallel (i.e. \( \theta = 0 \)) and orthogonal (i.e. \( \theta = \pi/2 \)) to the uniform component of the magnetic field can then be obtained from equation (3.21):

\[
(n^2 - \epsilon_\parallel)(n^2 - \epsilon_\perp) = 0, \quad \theta = 0,
\]

(3.24)

\[
(n^2 - \epsilon_\parallel)(n^2(\epsilon_\perp + \epsilon_\parallel) - 2\epsilon_\perp \epsilon_\parallel) = 0, \quad \theta = \frac{\pi}{2}.
\]

Equation (3.24) gives the usual dispersion relations for the two circular polarizations of the electromagnetic wave, i.e. \( n^2 = \epsilon_\parallel \) and \( n^2 = \epsilon_\perp \), while equation (3.25) gives those for the ‘ordinary’ (i.e. \( n^2 = \epsilon_\parallel \)) and ‘extraordinary’ (i.e. \( n^2 = 2\epsilon_\parallel \epsilon_\perp / (\epsilon_\parallel + \epsilon_\perp) \)) plasma waves.

Consider now an electromagnetic wave that is linearly polarized. A linearly polarized electromagnetic wave can always be seen as the sum of two circularly polarized waves. Now the left and right polarizations have different phase velocities and, therefore, after the waves have travelled a distance \( \Delta z \) in a (cold) magnetized plasma the resulting phase difference will be

\[
\Delta \Phi = \frac{\omega}{2c} [\sqrt{\epsilon_\parallel} - \sqrt{\epsilon_\perp}] \Delta z.
\]

(3.26)
Equation (3.26) has been derived using two physical assumptions:
- the plasma is cold, i.e. the temperature of the electrons does not enter the dispersion relations;
- there are no other sources leading to a rotation of linearly polarized radiation.

Let us now see what happens by relaxing these two assumptions. The adoption of a cold (as opposed to warm) plasma description means that the temperature of the electrons has been taken to be effectively zero. The effects arising from the finite temperature of the electrons do not modify the leading result obtained in the context of the cold plasma theory. The derivation of the dispersion relations in the case of a warm plasma can be performed, for instance, within a kinetic approach where it can be shown, following the same calculation discussed in the flat space case [27], that the first correction to the leading cold plasma calculation can be recast in an effective redefinition of the plasma frequency for the electrons, namely, $\omega_{pe} \rightarrow \frac{4\pi n e^2}{m_e \gamma}$, where $\gamma = (1 - \langle v^2 \rangle)^{-1/2}$ and $\langle v^2 \rangle$ is the thermal average of the electron velocity.

Equation (3.26) has been derived under the assumption that the only source of birefringence is represented by a uniform magnetic field. This is certainly legitimate in a standard electromagnetic context. There could be however other sources of cosmological birefringence leading to a generalized expression of Faraday rotation. In particular let us consider the case when, in the plasma, a dynamical pseudo-scalar field is present together with a magnetic field. This situation may easily arise in the case of a quintessential background with pseudo-scalar coupling to electromagnetism described by an action

$$S_{\sigma} = \int d^4 x \sqrt{-g} \left[ \frac{1}{2} g^{\alpha\beta} \partial_\alpha \sigma \partial_\beta \sigma - W(\sigma) + \frac{\beta}{4M} F_{\alpha\beta} \tilde{F}^{\alpha\beta} \right], \quad (3.27)$$

where $F_{\alpha\beta}$ and $\tilde{F}_{\alpha\beta}$ are the Maxwell field strength and its dual. The coupling of electromagnetism to the field $\sigma$ changes the form of equations (3.12), (3.13) and (3.14). The resulting system of equations can be discussed in the presence both of a uniform magnetic field and of a cold (or warm) plasma. This calculation has been performed in [26]. While equations (3.13) do not change, the generalization of equations (3.12) and (3.14) becomes

$$\vec{\nabla} \cdot \vec{E} = 4\pi e (n_i - n_e) + \frac{\beta}{M} \vec{\nabla} \sigma \cdot \vec{B}, \quad (3.28)$$

$$\vec{\nabla} \times \vec{B} = \frac{1}{c} \vec{E} - \frac{\beta}{M} \left[ \sigma \vec{B} + \vec{\nabla} \sigma \times \vec{E} \right] + \frac{4\pi e}{c} (n_i \vec{v}_i - n_e \vec{v}_e). \quad (3.29)$$

To understand the rationale of the physical difference induced by the presence of $\sigma$ consider, indeed, the case when $\nabla \sigma = 0$ and the charge and current densities are vanishing. In this case, taking the curl of equation (3.29) and using the second of equations (3.13) we obtain the following equation:

$$\vec{B}'' - c^2 \nabla^2 \vec{B} + \frac{\beta}{M} \sigma \vec{\nabla} \times \vec{B} = 0. \quad (3.30)$$

Equation (3.30) implies that the two polarizations of the magnetic field are mixed as a consequence of the time dependence of $\sigma$. If the plasma contribution is included, equation (3.21) is modified [26]. Consequently, the dispersion relations given in equations (3.24) and (3.25) are also modified:

$$(n^2 - \frac{\omega_{pe}}{\omega} n - \epsilon_R) \left( n^2 + \frac{\omega_{pe}}{\omega} n - \epsilon_L \right) = 0, \quad \theta = 0, \quad (3.31)$$

$$n^4 = \frac{2 \epsilon_L \epsilon_R}{\epsilon_L + \epsilon_R} + \epsilon_\parallel + \left( \frac{\omega_{pe}}{\omega} \right)^2 \left[ n^2 + 2 \frac{\epsilon_L \epsilon_R}{\epsilon_R + \epsilon_L} = 0, \quad \theta = \pi \frac{2}{3}. \quad (3.32)$$
The presence of the quintessence field introduces a further frequency scale into the problem, namely $\omega_\sigma = c(\beta/M)\sigma'$. If the quintessence field dominates today (or between redshifts 0 and 3), $\sigma(t_0) \sim \Lambda^2/m$ where, typically, $\Lambda \sim 10^{-3}$ eV, and $m \sim 10^{-33}$ eV. The value of $\dot{\sigma}$ can be estimated, and it is, today, $\dot{\sigma}(t_0) \sim \Lambda_1^2/m$ where, typically, $\Lambda_1 \sim 10^{-3}$ eV, and $m \sim 10^{-33}$ eV.

Hence, recalling that prior to quintessential dominance, $\dot{\sigma}$ scales as $a^{-3}$, from the previous expressions

$$\dot{\sigma}_{\text{dec}} \simeq \left( \frac{H_{\text{dec}}}{H_0} \right)^2 \frac{m \Lambda^2}{H_0^2}, \quad \omega_\sigma = \beta \left( \frac{M}{M_P} \right) \times 10^{-6} \text{ Hz},$$

(3.33)

where the values of $\Lambda$ and $m$ are those discussed above with $M \simeq M_P$. The value of $\beta$ is rather uncertain and a conservative limit from radio-astronomical analyses would imply $\beta \lesssim 10^{-3}$ for $0 \lesssim z \lesssim 1$ [28, 29]. Note that action (3.27) can also be relevant in a class of baryogenesis models [30, 31] (see also [32]).

From equation (3.31), the generalized Faraday rotation experienced by the linearly polarized CMB travelling parallel to the magnetic field direction can be obtained as

$$\Delta \Phi = \frac{\omega}{2c} \left[ \frac{\omega_\sigma}{\omega} + \sqrt{\frac{1}{2} \left( \frac{\omega_\sigma}{\omega} \right)^2 + \epsilon_R} - \sqrt{\frac{1}{2} \left( \frac{\omega_\sigma}{\omega} \right)^2 + \epsilon_L} \right] \Delta z.$$

(3.34)

This expression includes, simultaneously, the birefringence produced by the evolution of the pseudo-scalar field $\sigma$ and the rotation induced by the finite value of the magnetic field intensity. In [34], the effect of parity-violating interactions on CMB polarization has been recently discussed in the absence of a magnetic field. A similar analysis was presented in [35] (see also [36]). In the absence of magnetic field, equation (3.34) leads to a $\Delta \Phi$ that is frequency independent. In contrast, if the contribution of the pseudo-scalar field $\sigma$ is negligible, then $\Delta \Phi$ decreases at high frequencies as $1/\omega^2$. In the intermediate situation more complicated dependences of $\Delta \Phi$ upon the frequency may be envisaged. This aspect answers the second question raised after equation (3.26): on top of the magnetic fields there are different sources affecting $\Delta \Phi$. However, the characteristic frequency dependence of the different signals may allow us, at least in principle, to disentangle different sources of birefringence.

### 3.1. Magnetized Faraday effect at decoupling

Let us now assume, for simplicity, that the only source for $\Delta \Phi$ is represented by a uniform magnetic field. Then, recalling the hierarchy between the plasma, Larmor and propagation frequencies, i.e. equations (3.3) and (3.4), equation (3.26) can be expanded for

$$|\omega_{p,e,i}/\omega| \ll 1, \quad |\omega_{B,e,i}/\omega| \ll 1.$$  

(3.35)

Thus, from equation (3.26), we will have

$$\Delta \Phi \simeq \frac{\omega}{2c} \left[ \sqrt{1 - \left( \frac{\omega_{p,e}}{\omega} \right)^2 \left( \frac{\omega_{p,e}}{\omega} \right)^2} - \sqrt{1 - \left( \frac{\omega_{B,e}}{\omega} \right)^2 \left( \frac{\omega_{B,e}}{\omega} \right)^2} \right] \Delta z,$$

(3.36)

where, by virtue of equations (3.3) and (3.4), the sub-leading contribution of the ions has been neglected. In some simplified treatments, this approximation is made from the very beginning by defining two generalized refraction indices $n_R$ and $n_L$:

$$n_{R,L} = \sqrt{\epsilon_{R,L}} = 1 - \frac{\omega_{p,e}^2}{\omega(\omega \pm \omega_{B,e})},$$

(3.37)

(4) Recalling that $\omega = kc/n_{R,L}$, by computing $\partial\omega/\partial k$ we can easily get, from equation (3.37), an approximate expression of the group velocity.
A last expansion for $|\omega_B/e/\omega| \ll 1$ and for $|\omega_p/e/\omega| \ll 1$ brings equation (3.36) to the standard form, i.e.

$$\Delta \Phi = \frac{1}{2c} \left( \frac{\omega_p e}{\omega} \right)^2 \omega_B, e/\omega \ll 1.$$  (3.38)

From equation (3.38), by choosing a generic propagation direction, we can also derive the Faraday rotation rate, i.e.

$$\frac{d\Phi}{dt} = \frac{e^3 x_e n_0}{2 \pi cm^2 \nu^2} \vec{B} \cdot \hat{n},$$  (3.39)

where the ionization fraction $x_e$ has been introduced by replacing $n_0 \rightarrow x_e n_0$ and where we used, from equation (3.38), that $dz = c dt$. In equation (3.39), $\vec{B} \cdot \hat{n}$ denotes the projection of the (uniform) magnetic field intensity along the direction of propagation of the linearly polarized radiation with frequency $\nu = \omega / 2\pi$; $t$ is, as usual, the cosmic time coordinate related to the conformal time coordinate $\tau$ as $a(\tau) d\tau = dt$.

For some applications, it is sometimes useful to write equation (3.39) in apparently different forms. Recalling the definition of differential optical depth

$$\epsilon' = x_e n_0 \sigma_T \frac{a}{a_0} = \frac{x_e n_0 \sigma_T}{z + 1},$$  (3.40)

Defining with $\tau_0$ the conformal time at which the signal is received, the optical depth will then be

$$\epsilon(\tau, \tau_0) = \int_{\tau}^{\tau_0} x_e n_0 \sigma_T \frac{a}{a_0} d\tau$$  (3.41)

while the visibility function\(^5\) is

$$K(\tau) = \epsilon' e^{-\epsilon(\tau, \tau_0)}.$$  (3.42)

Equation (3.42) gives the probability that a CMB photon was last scattered between $\tau$ and $\tau + d\tau$ (usually in the literature $K(\tau)$ is denoted by $g(\tau)$).

Using equation (3.41), equation (3.39) can be written as

$$\Omega_\phi = \Phi' = \frac{d\Phi}{d\tau} = \frac{3 e^3 \epsilon'}{16 \pi^2 \epsilon} \vec{B} \cdot \hat{n},$$  (3.43)

where the explicit expression of the Thompson cross section in terms of the classical radius of the electron has been used, i.e.

$$\sigma_T = \frac{8 \pi}{3} r_0^2, \quad r_0 = \frac{e^2}{mc^2}.$$  (3.44)

Equation (3.43) can also be written in terms of the typical values of the magnetic field intensity and of the frequency of emission. Denoting by $\tilde{\nu}$ the physical frequency, i.e. $\tilde{\nu} = \nu / a$, it is clear that $\vec{B} / \nu^2 = \vec{B} / \tilde{\nu}^2$ since the quantities in the numerator and in the denominator redshift in the same way. Thus equation (3.43) becomes

$$\Omega_\epsilon = \frac{d\Phi}{d\epsilon} = 3.56 \times 10^{-3} \left( \frac{B}{10^{-9} \text{ G}} \right) \left( \frac{100 \text{ GHz}}{\tilde{\nu}} \right)^2.$$  (3.45)

The typical quantities reported in equation (3.45) refer to the present time. It is also conventional to use the same quantities but evaluated at the decoupling epoch. In this case, the magnetic field will be of the order of mG while the physical frequency (at the decoupling time) will be of the order of 100 THz.

\(^5\) Recently the possible modifications induced by large-scale magnetic fields on the thermal history of the Universe during the ‘dark age’ between $z \sim 1000$ and $z \sim 10$ have been studied in [33].
3.2. The Faraday effect and radiative transfer equations

The Faraday rotation rate derived in equation (3.43) directly enters the radiative transfer equations. From equation (3.39), it is possible to give an order of magnitude estimate of \( \Phi \) itself. Indeed, by integrating equation (3.39) with respect to \( t \), we can obtain that

\[
\Phi = \frac{e^3}{2\pi c m_e^2 v^2} \bar{B} \cdot \hat{n} \int x_e n_0 \, dt. \tag{3.46}
\]

Recalling that \( a(\tau) \, d\tau = dt \), the integral appearing in equation (3.46) can be easily estimated using equation (3.41); the result will be

\[
\int x_e n_0 \, dt = \frac{\epsilon(\tau, \tau_0)}{\sigma_T}. \tag{3.47}
\]

For orders of magnitude estimates, one can safely assume that the optical depth, i.e. \( \epsilon(\tau, \tau_0) \), is of order unity out to redshift of decoupling, when the polarization is generated \([37-39]\). Therefore, after averaging over the polarizations of the magnetic field, the final result can be expressed in terms of \( \sqrt{\langle \Phi^2 \rangle} \):

\[
\sqrt{\langle \Phi^2 \rangle} = 1.6 \left( \frac{B}{10^{-9} \text{ G}} \right)^2 \left( \frac{30 \text{ GHz}}{\nu} \right)^2 \text{ deg}. \tag{3.48}
\]

To obtain more accurate estimates of the Faraday rotation rate, the relevant radiative transfer equations must be integrated \([37]\) (see also \([40]\) for an introduction to the radiative transfer equations in CMB physics). As is well known, the polarization of the CMB is a higher order effect with respect to the temperature anisotropies and it depends crucially upon the properties of the photon phase-space distribution that should have a non-vanishing quadrupole moment. Indeed, to zeroth order in the tight-coupling expansion photons and baryons are synchronized so well that the CMB is not polarized. This means, technically, that the brightness perturbation associated with the Q Stokes parameter (i.e. \( \Delta_1 Q \)) is zero to zeroth order in the tight-coupling expansion. To first order in the tight-coupling expansion a small amount of linear polarization is generated and it is proportional to the expansion parameter, i.e. \( 1/\epsilon' \), and to the (zeroth-order) dipole.

This argument disregards the important fact that the Q and U Stokes parameters (and their associated brightness fluctuations \( \Delta_Q \) and \( \Delta_U \)) are not invariant under rotations. It is possible to take into account this aspect by defining a generalized degree of polarization that is proportional to \( (\Delta_U^2 + \Delta_Q^2) \).

The presence of a magnetic field introduces then further terms in the radiative transfer equations. These terms couple directly the evolution of \( \Delta_Q \) to the evolution of \( \Delta_U \) and the strength of the coupling is given by the Faraday rotation rate \( \omega/\Phi \) introduced in equation (3.45). Therefore, the relevant radiative transfer equations can be written as

\[
\Delta'_Q + (ik\mu + \epsilon') \Delta_Q = \frac{\epsilon'}{2} [1 - P_2(\mu)] S_Q + 2 \Omega_\Phi \Delta_U, \tag{3.49}
\]

\[
\Delta'_U + (ik\mu + \epsilon') \Delta_U = -2 \Omega_\Phi \Delta_Q, \tag{3.50}
\]

where

\[
S_Q = \Delta_{Q2} + \Delta_{Q0} + \Delta_{Q2}. \tag{3.51}
\]

Here we are only discussing the Faraday effect induced on the polarization in the case of scalar fluctuations of the geometry.
Equations (3.49) and (3.50) are derived by using the following expansions for the brightness perturbations:

$$\Delta_Q(\vec{k}, \hat{n}, \tau) = \sum_{\ell} (-i)^{\ell} (2\ell + 1) \Delta_{Q\ell}(\vec{k}, \tau) P_{\ell}(\vec{k} \cdot \hat{n}),$$  \hspace{1cm} (3.52)

$$\Delta_U(\vec{k}, \hat{n}, \tau) = \sum_{\ell} (-i)^{\ell} (2\ell + 1) \Delta_{U\ell}(\vec{k}, \tau) P_{\ell}(\vec{k} \cdot \hat{n}),$$  \hspace{1cm} (3.53)

where $\vec{k}$ is the momentum of the Fourier expansion, $\hat{k}$ its direction; $\hat{n}$ is the direction of the photon momentum and $\mu = \vec{k} \cdot \hat{n}$. Consequently, in equation (3.51), $\Delta_{Q\ell}$ denotes the quadrupole moments of the brightness fluctuation associated with the 1 Stokes parameter, while $\Delta_{Q0}$ and $\Delta_{Q2}$ denote, respectively, the monopole and quadrupole moment of $\Delta_Q$. For completeness, and to anticipate further considerations on the cross power spectra, we also introduce the expansion for the brightness perturbation associated with the intensity of the radiation field:

$$\Delta_I(\vec{k}, \hat{n}, \tau) = \sum_{\ell} (-i)^{\ell} (2\ell + 1) \Delta_{I\ell}(\vec{k}, \tau) P_{\ell}(\vec{k} \cdot \hat{n}).$$  \hspace{1cm} (3.54)

An important remark concerns here the symmetry of the radiative transfer equations. In equations (3.49) and (3.50) $\mu$ denotes the projection of the Fourier mode along the direction of the photon momentum, i.e. $\mu = \vec{k} \cdot \hat{n}$. In equations (3.49) and (3.50), the magnetic field may introduce an extra preferred direction, so that the evolution equations will depend, ultimately, not only upon $\mu$ but also upon $\vec{B} \cdot \hat{n}$ (see equation (3.43)). Furthermore, the analysis may become even more cumbersome if the magnetic field is allowed not to be uniform (as assumed in the present and the previous sections). To make equations (3.49) and (3.50) more tractable the direction of the magnetic field intensity is taken to lie along the direction of the Fourier mode. Instead of working with $\Delta_Q$ and $\Delta_U$, it is useful to write down equations (3.49) and (3.50) directly in terms of the two associated complex conjugate combinations, i.e.

$$\mathcal{M}_{\pm} = \Delta_Q \pm i\Delta_U.$$  \hspace{1cm} (3.55)

Using equation (3.55), equations (3.49) and (3.50) give, after some simple algebra,

$$\mathcal{M}_{\pm} + (ik\mu + \epsilon' \pm 2i\Omega_\phi)\mathcal{M}_{\pm} = \frac{3}{4} \epsilon'(1 - \mu^2)S_Q.$$  \hspace{1cm} (3.56)

Using the definitions given in equations (3.41) and (3.42), equation (3.56) can be integrated easily and the result of the integration is

$$\mathcal{M}_{\pm}(\vec{k}, \tau_0) = \frac{3}{4} (1 - \mu^2) \int_0^{\tau_0} K(\tau) e^{ik(\tau - \tau_0)} e^{\epsilon(\tau, \tau_0)\Omega_\phi(\vec{B} \cdot \hat{n})} S_Q(\tau) d\tau,$$  \hspace{1cm} (3.57)

where $\Omega_\phi$ is given by equation (3.45). This equation can be used for semi-analytical estimates of the mixing between $\Delta_Q$ and $\Delta_U$ to corroborate numerical estimates of the same effect.

The analysis performed in terms of $\Delta_Q$ and $\Delta_U$ can also be expressed in terms of the E- and B-modes. In the latter language, the mixing between $\Delta_Q$ and $\Delta_U$ translates into a mixing between E- and B-modes.

Recalling, in fact, that under clockwise rotations of $\varphi$, $\mathcal{M}_{\pm}$ transform as

$$\mathcal{M}_{\pm} = e^{\mp 2\varphi} \mathcal{M}_{\pm},$$  \hspace{1cm} (3.58)

the combinations

$$\mathcal{M}_{\pm}(\hat{n}) = \sum_{\ell m} a_{\pm 2, \ell m} \pm 2 Y_{\ell m}(\hat{n})$$  \hspace{1cm} (3.59)

$^7$ It should be clear that the E- and B-modes discussed here are not necessarily related to physical electric and magnetic fields.
can be expanded in terms of the spin-2 spherical harmonics, i.e. \( \pm 2 Y^m_\ell(\hat{n}) \), with
\[
  a_{\pm 2, \ell m} = \int d\hat{n} (\pm 2 Y^m_\ell(\hat{n}))(\Delta_Q \pm i \Delta_T)(\hat{n}).
\]  
(3.60)

The ‘electric’ and ‘magnetic’ components of polarization are eigenstates of parity and may be defined as
\[
  a^E_{\ell m} = -\frac{1}{2}(a_{2, \ell m} + a_{-2, \ell m}), \quad a^B_{\ell m} = \frac{i}{2}(a_{2, \ell m} - a_{-2, \ell m}).
\]  
(3.61)

These newly defined variables are expanded in terms of ordinary spherical harmonics, \( Y_{\ell m}(\hat{n}) \),
\[
  E(\hat{n}) = \sum_{\ell m} a^E_{\ell m} Y_{\ell m}(\hat{n}), \quad B(\hat{n}) = \sum_{\ell m} a^B_{\ell m} Y_{\ell m}(\hat{n}).
\]  
(3.62)

In connection with the spin-2 spherical harmonics appearing in equations (3.59) and (3.60) it is relevant to mention here that a generic spin-s spherical harmonic is a known concept in the quantum mechanical theory of angular momentum (see, for instance, [41]). A typical quantum mechanical problem is to look for the representations of the operator specifying three-dimensional rotations, i.e. \( \hat{R} \); this problem is usually approached within the so-called Wigner matrix elements, i.e. \( D^{\ell}_{j m}(R) = (j, m' | \hat{R} | j, m) \), where \( j \) denotes the eigenvalue of \( J^2 \) and \( m \) denotes the eigenvalue of \( J_z \). Now, if we replace \( m' \rightarrow -s, \ j \rightarrow \ell \), we have the definition of spin-s spherical harmonics in terms of \( D^{(\ell)}_{-s, m}(\alpha, \beta, 0) \), i.e.
\[
  s Y_{\ell m}(\alpha, \beta) = \sqrt{\frac{2\ell + 1}{4\pi}} D^{(\ell)}_{s, -m}(\alpha, \beta, 0),
\]  
(3.63)

where \( \alpha, \beta \) and \( \gamma \) (set to zero in the above definition) are the Euler angles defined as in [41]. If \( s = 0 \), \( D^{(0)}_{0 m}(\alpha, \beta, 0) = \sqrt{(2\ell + 1)/4\pi} Y_{\ell m}(\alpha, \beta) \), where \( Y_{\ell m}(\alpha, \beta) \) are the ordinary spherical harmonics.

To define properly the cross power spectra we also recall the expansion of the intensity fluctuations of the radiation field (defined in equation (3.54)), in terms of spherical harmonics:
\[
  \Delta_1(\hat{n}) = \sum_{\ell m} a^T_{\ell m} Y_{\ell m}(\hat{n}),
\]  
(3.64)

where we wrote explicitly \( a^T_{\ell m} \) since the fluctuations in the intensity of the radiation field, i.e. \( \Delta_1 \), are nothing but the fluctuations in the CMB temperature.

Under parity inversion, the components appearing in equations (3.62) and (3.64) transform as
\[
  a^E_{\ell m} \rightarrow (-1)^\ell a^E_{\ell m}, \quad a^B_{\ell m} \rightarrow (-1)^{\ell + 1} a^B_{\ell m}, \quad a^T_{\ell m} \rightarrow (-1)^\ell a^T_{\ell m}.
\]  
(3.65)

Therefore, the E-modes have the same parity as the T-modes which have, in turn, the same parity of spherical harmonics, i.e. \((-1)^\ell\). In contrast, the B-modes have \((-1)^{\ell + 1}\) parity.

The existence of linear polarization allows for six different cross power spectra to be determined, in principle, from data that measure the full temperature and polarization anisotropy information. The cross power spectra can be defined in terms of the spectral functions \( C^{X,Y}_{\ell} \) where \( X \) and \( Y \) stand for E, B or T depending on the cross correlation one is interested in
\[
  C^{X,Y}_{\ell} = \frac{1}{2\pi} \int k^2 dk \sum_{m=-\ell}^\ell \frac{(a^X_{\ell m})^* a^Y_{\ell m}}{(2\ell + 1)}.
\]  
(3.66)

Therefore, if we are interested in the TE correlations we just have to set \( X = T \) and \( Y = E \) and use the relevant expansions given above. In the following, we will denote the correlations as TT, EE, BB, TB and so on. This notation refers to the definition given in equation (3.66).
Let us now see how definition (3.66) works. Suppose we are interested in the TT correlations, i.e. the usual and well-known temperature correlations. From equation (3.66) we will have

\[ C_{\ell}^{TT} = \frac{1}{2\pi^2} \int k^2 \, dk \, \sum_{m=-\ell}^{\ell} \frac{[a_{\ell m}(k)]^* a_{\ell m}(k)}{(2\ell + 1)}. \]  

(3.67)

Now, from equation (3.64), using the orthogonality of spherical harmonics, we have that

\[ a_{\ell m}(k) = \int d\hat{n} \, Y_{\ell m}(\hat{n}) \Delta_1(\tilde{k}, \hat{n}). \]  

(3.68)

Inserting equation (3.68) into equation (3.67) and recalling the expansion of \( \Delta_1(\tilde{k}, \hat{n}) \) in terms of Legendre polynomials we get

\[ C_{\ell}^{TT} = \frac{2}{\pi} \int d\mathbf{k} \, k^2 |\Delta_1|^2. \]  

(3.69)

To get equation (3.69), the following two identities have been used, i.e.

\[ \int d\hat{n} \, P_{\ell}(\mathbf{k} \cdot \hat{n}) Y_{\ell m}(\hat{n}) = \frac{4\pi}{(2\ell + 1)} \delta_{\ell \ell'}, \]

\[ \sum_{m=-\ell}^{\ell} Y_{\ell m}^*(\hat{k}) Y_{\ell m}(\hat{n}) = \frac{2\ell + 1}{4\pi} P_{\ell}(\hat{k} \cdot \hat{n}). \]  

(3.70)

The second identity in equation (3.70) has already been exploited in equation (2.17).

In similar ways, different expressions for the other correlations may be obtained. Note that equation (3.69) is a consequence of the specific conventions adopted in equation (3.54). In particular note that the factor \((2\ell + 1)\) is included in the expansion. It must be clearly said that this is a matter of convention. For instance, in [40, 42] the factors \((2\ell + 1)\) and \(\left(-i\right)\ell\) are included in the expansion\(^8\). In contrast, in [43], the authors did not include the factor \((2\ell + 1)\) in the expansions for the brightness perturbations that we defined in equations (3.52), (3.53) and (3.54). Consequently, the cross correlations will inherit extra terms that are simply a consequence of the different conventions adopted. So, for instance, in equation (3.69), and in the conventions of [43], a factor \((2\ell + 1)^2\) typically appears in the denominator.

Recalling the connection between the Wigner matrix elements and the spin-s spherical harmonics, i.e. equation (3.63), it is possible to show that, under complex conjugation,

\[ a_{\ell m}^{T.E.B} = (-1)^m a_{\ell m}^{T.E.B}, \]  

(3.71)

where the second equality follows from the first one by using equation (3.61). It is then possible to show that while the TB and EB correlators are parity-odd, all the other correlators (i.e. TT, BB, EE, TE) are parity-even.

3.3. Limits on uniform magnetic fields from the Faraday effect

In the absence of magnetic fields, the scalar fluctuations of the geometry only generate E-modes. The presence of a magnetic field induces, however, a mixing between E-modes and B-modes. Consequently, if we have an initial E-mode generated by scalar metric perturbations, the presence of a magnetic field induces a non-vanishing B-mode. In the case of scalar fluctuations, a non-vanishing TE power spectrum arises directly as a result of the CMB polarization as can be verified by studying the first-order tight-coupling expansion. Recently,\(^8\) Note that the authors of [39] do not include the factor \(\left(-i\right)\ell\) but do include the factor \((2\ell + 1)\) in the expansion of the various brightness perturbations.
the WMAP collaboration [44, 45] measured the TE correlations. As discussed in [46],
the induced TB angular power spectrum is, roughly, $\Omega_e$ times smaller than the initial TE
correlations. From the WMAP measurement, the measured value of the TE correlation and
the absence of the TB correlations allows a limit to be set on $\Omega_e$. At a given frequency, the
limit on $\Omega_e$ can be translated into a bound on the magnetic field intensity, i.e.

$$B_0 < 10^{-8} \text{G}$$  \hspace{1cm} (3.72)

at a typical (present) frequency of 30 GHz [46]. The values of the TE and EE correlations
induced by the presence of a magnetic field are $\Omega_e^2$ times smaller than their values in the
absence of the magnetic fields. In figure 4, the autocorrelation of the B-modes of CMB
polarization is reported in the case of a uniform magnetic field (recall that $\Omega_e$ is defined in
equation (3.45)). Note that when $2\Omega_e \simeq 1$ the TE (as well as the other correlations) is strongly
damped and the differential Faraday rotation has a net depolarizing effect [39].

We conclude this section by remarking that the Faraday rotation is not the only way to
generate B-modes. In fact,

- B-modes can be generated directly by fully inhomogeneous magnetic fields (see following
  sections);
- B-modes can be generated by gravitational waves (in figure 4, the GW contribution is
  reported for a value of the tensor-to-scalar ratio compatible with the present WMAP data);
- B-modes can be generated by weak lensing.

To this list one should also add the possibility that some other form of birefringence is allowed
(as elaborated in the derivation of equation (3.34)). In connection with the GW contribution,
it should be noted that $r$ (denoting the ratio between the tensor and scalar (primordial) power
spectra) is limited from above, by current experimental data, i.e. $r < 0.53$. In figure 4, the
contribution of the B-mode induced by GW is illustrated in the case $r = 0.01$.

The peculiar feature of the Faraday rotation signal induced by a uniform magnetic field
is the frequency dependence. In fact, by going to higher frequencies, the signal gets reduced
as $\nu^{-2}$. In contrast, the B-modes induced by gravitational waves do not depend upon the
frequency. The birefringence induced by a dynamical quintessence (pseudo-scalar) field is
also independent of the frequency. The need for multifrequency determination of the Faraday rotation is then clear and this point has also been correctly emphasized in [47, 48]. In [47], a scheme for the treatment of the Faraday rotation in the case of fully inhomogeneous magnetic fields has been studied and along a similar line another analysis has also been presented in [49].

In the coming years, on the CMB side the Planck mission [50] will give us, hopefully, important clues concerning CMB polarization. For the purposes of the present subject it is appropriate to recall that the Planck mission will operate in nine frequency channels ranging from 30 to 857 GHz. Multifrequency Faraday rotation measurements may become possible. Unfortunately, owing to the fact that the nominal Planck sensitivity to polarization is larger at higher frequencies, these measurements may also be difficult. In fact, Faraday rotation signals are suppressed by the square of the frequency and are therefore smaller at high frequencies. Other instruments dedicated to the analysis of CMB polarization may also give important clues. These experiments include polarization-sensitive balloon borne experiments (such as the polarization-sensitive version of Boomerang [51, 52] and its possible improvements) as well as ground-based arrays like the promising QUIET (Q/UImagingExperimenT) [53]. On the radio-astronomical side, the very ambitious SKA (square kilometre array) project will be able to give us precious full-sky surveys of Faraday rotation measurements [54] (see also [55, 56]). The SKA experiment should cover a frequency range between 0.1 and 20 GHz.

4. One-fluid plasma description

Since a fully inhomogeneous magnetic field acts as a source term in the evolution equations of the gravitational perturbations, the CMB observables may be affected. To investigate this situation, the relevant system of equations describing the large-scale magnetic fields is slightly different from that introduced in equations (3.12), (3.13) and (3.14) (where, however, the displacement current may be neglected). In fact, we are here interested in the dynamics taking place for typical frequencies much smaller than $\omega_p, e$ and $\omega_p, i$. In this situation, from the two-fluid equations of equations (3.12), (3.13) and (3.14) it is possible to derive various one-fluid plasma descriptions by defining a set of appropriate one-fluid variables such as the total current [24, 57]

$$\vec{J} = e(n_i\vec{v}_i - n_e\vec{v}_e), \quad (4.1)$$

the centre-of-mass velocity

$$\vec{v} = \frac{m_i\vec{v}_i + m_e\vec{v}_e}{m_e + m_i}, \quad (4.2)$$

and so on. Among the one-fluid descriptions, a particularly simple possibility is provided by magnetohydrodynamics (MHD) that can be characterized by the following set of conditions:

$$\vec{\nabla} \cdot \vec{E} = 0, \quad \vec{\nabla} \cdot \vec{B} = 0, \quad \vec{\nabla} \cdot \vec{J} = 0. \quad (4.3)$$

As mentioned above, the derivative of the electric field is neglected in the MHD analogue of equation (3.14). Moreover, since the current is solenoidal, as the magnetic field intensity, it follows, from Maxwell’s equations, that

$$\vec{J} = \frac{1}{4\pi} \vec{\nabla} \times \vec{B}. \quad (4.4)$$

The induced (ohmic) electric field is therefore given, in the absence of Hall and thermoelectric terms, by

$$\vec{E} + \vec{v} \times \vec{B} = \frac{1}{4\pi \sigma} \vec{\nabla} \times \vec{B}, \quad (4.5)$$
where $\sigma$ is the conductivity and where we used units where the speed of light is equal to 1. In a relativistic plasma $\sigma \simeq T/\alpha_{em}$ while in a non-relativistic plasma $\sigma \simeq (T/\alpha_{em})(T/m_e)^{1/2}$. Since the conductivity increases as we go back in time, in the early Universe the condition $\vec{E} + \vec{v} \times \vec{B}/c \simeq 0$ is approximately verified. Under these conditions, two (approximate) conservation laws may be derived, namely, the magnetic flux conservation

$$\frac{d}{d\tau} \int_{\Sigma} \vec{B} \cdot d\Sigma = -\frac{1}{4\pi\sigma} \int_{\Sigma} \vec{\nabla} \times \vec{v} \times \vec{B} \cdot d\Sigma,$$  

and the magnetic helicity conservation

$$\frac{d}{d\tau} \left( \int_{V} d^3x \vec{A} \cdot \vec{B} \right) = -\frac{1}{4\pi\sigma} \int_{V} d^3x \vec{B} \cdot \vec{\nabla} \times \vec{B}.$$  

In equation (4.6), $\Sigma$ is an arbitrary closed surface that moves with the plasma. According to equation (4.6), in MHD the magnetic field has to be always solenoidal (i.e. $\vec{\nabla} \cdot \vec{B} = 0$). Thus, the magnetic flux conservation implies that, in the superconducting limit (i.e. $\sigma \rightarrow \infty$), the magnetic flux lines, closed because of the transverse nature of the field, evolve always glued together with the plasma element. In this approximation, as far as the magnetic field evolution is concerned, the plasma is a collection of (closed) flux tubes. The theorem of flux conservation states then that the energetic properties of large-scale magnetic fields are conserved throughout the plasma evolution.

While the flux conservation concerns the energetic properties of the magnetic flux lines, the magnetic helicity, i.e. equation (4.7), concerns chiefly the topological properties of the magnetic flux lines. In the simplest situation, the magnetic flux lines will be closed loops evolving independently in the plasma and the helicity will vanish. There could be, however, more complicated topological situations [102] where a single magnetic loop is twisted (such as some kind of Möbius strip) or the case where the magnetic loops are connected like the rings of a chain: now the non-vanishing magnetic helicity measures, essentially, the number of links and twists in the magnetic flux lines [24]. Furthermore, in the superconducting limit, the helicity will not change throughout the time evolution. The conservation of the magnetic flux and of the magnetic helicity is a consequence of the fact that, in ideal MHD, the ohmic electric field is always orthogonal both to the bulk velocity field and to the magnetic field. In the resistive MHD approximation this conclusion may not apply.

The quantity on the right-hand side of equation (4.7), i.e. $\vec{B} \cdot \vec{\nabla} \times \vec{B}$, is called magnetic gyrotropy and it is a gauge-invariant measure of the number of contact points in the magnetic flux lines. The magnetic helicity (or the magnetic gyrotropy) and the Lorentz force can be used to give a general classification of the possible inhomogeneous magnetic field configurations that are relevant in a MHD context. Since the current density is solenoidal, we have that, in MHD,

$$\vec{F}_B = \vec{J} \times \vec{B} \simeq \frac{1}{4\pi} (\vec{\nabla} \times \vec{B}) \times \vec{B}.$$  

Looking at the expressions of the magnetic gyrotropy and the Lorentz force, there are, in principle, two extreme situations that may arise:

- in the first case $\vec{\nabla} \times \vec{B} \times \vec{B} = 0$ and the magnetic gyrotropy, i.e. $\vec{B} \cdot \vec{\nabla} \times \vec{B}$, is maximal;
- in the second case, the Lorentz force is maximal and the magnetic gyrotropy vanishes.

The presence (or absence) of magnetic helicity plays an important role for the possibility of inverse cascades in the pre-recombination plasma. In particular, one of the evolutions of the correlation scale presented in figure 1 refers to the case where the magnetic field is helical [58].
In the case when the Lorentz force term vanishes, the configuration is said to be force free. In this limit, the MHD equations (coupled with the Navier–Stokes equation) become particularly simple and appropriate for the deduction of useful scaling laws [24, 59–61]. Fully inhomogeneous magnetic field configurations may then gravitate and affect the evolution equations of the tensor, vector and scalar modes of the geometry. Therefore, in the following section, the evolution equations of metric fluctuations will be investigated in the presence of fully inhomogeneous magnetic fields. MHD equations in curved spacetimes are also relevant for a number of different problems arising in the physics of large-scale magnetic field. Concerning the various aspects of this subject see, for instance, [62–64] and references therein.

As a last comment, we would like to stress that the magnetic helicity as well as the magnetic gyrotropy are parity-odd quantities. Therefore, recalling the considerations related to equation (3.71), if sources of gyrotropy and helicity are present after equality the BE and TB correlators may not be zero. This point has been discussed in [65] (see, however, also [47]).

### 4.1. Fully inhomogeneous magnetic correlators

Nearly all mechanisms able to generate large-scale magnetic fields imply the existence of a stochastic background of magnetic disturbances that could be written, in the Fourier space, as

\[
\langle B_i(\vec{k}, \tau) B_j^*(\vec{p}, \tau) \rangle = (2\pi)^3 P_{ij}(k) \delta^{(3)}(\vec{k} - \vec{p}),
\]

(4.9)

where

\[
P_{ij}(k) = Q(k) \left( \delta_{ij} - \frac{k_i k_j}{k^2} \right), \quad Q(k) = Q_0 k^m.
\]

(4.10)

From equation (4.10), the magnetic field configuration of equation (4.9) depends on the amplitude of the field \(Q_0\) and on the spectral index \(m\).

It is easy to check that, in the case of configuration (4.9), the magnetic gyrotropy is vanishing, i.e.

\[
\langle \vec{B} \cdot \nabla \times \vec{B} \rangle = 0, \quad \langle (\vec{B} \cdot \nabla \times \vec{B})^2 \rangle = 0,
\]

(4.11)

where the second expression denotes, for short, the two-point function of the magnetic gyrotropy. In contrast, it should also be clear that, from equation (4.9), \(\langle \nabla \cdot [\nabla \times \vec{B}] \times \vec{B} \rangle \neq 0\).

There are situations where magnetic fields are produced in a state with non-vanishing gyrotropy (or helicity) [65–68]. In this case, the two-point function can be written in the same form given in equation (4.9),

\[
\langle B_i(\vec{k}, \tau) B_j^*(\vec{p}, \tau) \rangle = (2\pi)^3 \tilde{P}_{ij}(k) \delta^{(3)}(\vec{k} - \vec{p}),
\]

(4.12)

but where now

\[
\tilde{P}_{ij}(k) = Q(k) \left( \delta_{ij} - \frac{k_i k_j}{k^2} \right) + i \tilde{Q}(k) \epsilon_{ij\ell} \frac{k^\ell}{k}, \quad \tilde{Q}(k) = \tilde{Q}_0 k^m.
\]

(4.13)

From equation (4.13), we can appreciate that, on top of the parity-invariant contribution (already defined in equations (4.9) and (4.10)), there is a second term proportional to the Levi-Civita \(\epsilon_{ij\ell}\). In Fourier space, the introduction of gyrotropic configurations also implies the presence of a second function of the momentum \(\tilde{Q}(k)\).

---

\(^{10}\)For the Fourier transforms we use the following conventions: \(B_i(\vec{x}) = (2\pi)^{-3} \int d^3 k e^{-i \vec{k} \cdot \vec{x}} B_i(\vec{k})\) and, conversely, \(B_i(\vec{k}) = \int d^3 x e^{i \vec{k} \cdot \vec{x}} B_i(\vec{x})\).
As will become more plausible from the considerations reported in section 5, the two-point function determines, eventually, the higher order correlation functions. Since the contribution of fully inhomogeneous magnetic fields to the energy–momentum tensor is quadratic, it is rather frequent, in various calculations, to evaluate four-point correlation functions. Fourier space is not always the best framework for the evaluation of higher order correlation functions. Indeed, a swifter derivation of various results can be achieved, in some cases, by staying in real space (and by eventually Fourier transforming the final result). Let us therefore elaborate on the real space correlators associated with the configurations discussed in equations (4.9) and (4.12).

The real space two-point function can be written, for instance, as

\[ G_{ij}(r) = (B_i(\vec{x} + \vec{r})B_j(\vec{x})) = F_1(r)\delta_{ij} + F_2(r)r_ir_j + F_3(r)\epsilon_{ijk}r_k. \]  

(4.14)

If \( F_3(r) = 0 \), then we are in the situation described by equation (4.9). If \( F_3(r) \neq 0 \), the framework is that defined by equation (4.12).

Consider, for instance, the case \( F_3(r) = 0 \). Then, using the parametrization (4.14), equations (4.9) and (4.10) lead to

\[ G_{ij}(r) = G_{\perp}(r)\delta_{ij} + [G_{\parallel}(r) - G_{\perp}(r)]\frac{r_ir_j}{r^2}, \]  

(4.15)

where

\[ G_{\perp}(r) = \frac{4}{(2\pi)^2} \int d^2 k \, Q(k) \left[ j_0(kr) - j_1(kr) \frac{kr}{kr} \right], \]

\[ G_{\parallel}(r) = \frac{8}{(2\pi)^2} \int d^2 k \, Q(k) \frac{j_1(kr)}{kr}, \]  

(4.16)

where \( j_0(kr) \) and \( j_1(kr) \) are the usual spherical Bessel functions [69, 70]:

\[ j_0(kr) = \frac{\sin kr}{kr}, \quad j_1(kr) = \frac{\sin kr}{kr} - \frac{\cos kr}{kr}. \]  

(4.17)

Another useful parametrization of the real space correlators is that where the functions \( F_1(r) \) and \( F_2(r) \) are written as derivatives of a function \( f(r^2) \) whose asymptotic behaviour can be determined from the trace of the two-point function [66]. More precisely, in the case \( F_3(r) = 0 \), the functions appearing in equation (4.14) can be written as

\[ F_1(r) = \frac{\partial}{\partial r^2}[r^2 f(r^2)], \quad F_2(r) = -\frac{\partial}{\partial r^2}[f(r^2)]. \]  

(4.18)

With definitions (4.18), equation (4.14) is clearly transverse (i.e. \( \partial^iG_{ij} = 0 \)). Moreover, defining \( \tilde{G}(r) = \text{Tr}[G_{ij}] \), we also have

\[ r\tilde{G}(r) = 2\frac{\partial}{\partial r^2}[r^3 f(r^2)]. \]  

(4.19)

It is often useful, in practical estimates, to regularize the two-point function by using an appropriate ‘windowing’ [71]. Two popular windows are, respectively, the Gaussian and the top-hat functions, i.e.

\[ W_g(k, L) = e^{-\frac{k^2 L^2}{2}}, \quad W_{\text{th}}(k, L) = \frac{3}{kL}j_1(kL). \]  

(4.20)

For instance, the regularized trace of \( G_{ij}(r) \) with Gaussian filter can be obtained from the previous expressions by shifting \( Q(k) \rightarrow \tilde{Q}(k)W_g(k, L) \). The result is

\[ \tilde{G}(r) = \frac{2Q_0}{(2\pi)^2} L^{3m} \frac{1}{L^{3m}} F \left( m + 3, \frac{3}{2}, \frac{r^2}{4L^2} \right), \]  

(4.21)
where $F(a, b, x) \equiv \, _1F_1(a, b, x)$ is the confluent hypergeometric function \cite{69, 70}. Note that the integral appearing in the trace converges for $m > -3$. The amplitude of the magnetic power spectrum $Q_0$ can be traded for $\mathcal{G}(0) \equiv B_1^2$ (as suggested, for instance, in \cite{72}). From equation (4.21), we have that $Q_0$ becomes

$$Q_0 = \frac{(2\pi)^{m+5}}{2} \frac{k_{L}^{-3(m)}}{\Gamma\left(\frac{m+5}{2}\right)} B_1^2,$$

(4.22)

where $k_{L} = 2\pi/L$.

In the real space approach, the higher order correlators are reduced to the calculation of derivatives of special functions (depending upon the regularization scheme). For instance, we can compute easily, in general terms, the correlation function for the energy density fluctuations. Defining

$$\delta \rho_{B}(\vec{x}) = \frac{1}{8\pi} B_{k}(\vec{x}) B^{i}(\vec{x}),$$

(4.23)

it is sometimes important to evaluate

$$E(r) = \langle \delta \rho_{B}(\vec{x}) \delta \rho_{B}(\vec{y}) \rangle - \langle \delta \rho_{B}(\vec{x}) \rangle \langle \delta \rho_{B}(\vec{y}) \rangle.$$  

(4.24)

By using decomposition (4.14), we will have (taking for simplicity the case $F_3(r) = 0$)

$$E(r) = \frac{1}{32\pi^{2}} \left[ 3 F_1^2(r) + 2 r^2 F_1(r) F_2(r) + r^4 F_2^2(r) \right] = \frac{1}{32\pi^{2}} \left[ 3 f^2(r^2) + 4 r^2 f(r^2) \frac{\partial f}{\partial r^2} + 2 r^4 \left( \frac{\partial f}{\partial r^2} \right)^2 \right],$$

(4.25)

where the second equality follows from equation (4.18).

With these (or similar techniques) higher order correlation functions magnetic inhomogeneities may be computed for the interesting observables such as the Lorentz force \cite{72}, the magnetic gyrotropy \cite{66} and so on.

It is appropriate to comment here on the parametrizations usually employed in the analysis of the various mechanisms for the magnetic field production in the early Universe. This topic (together with other related subjects) has been reviewed in \cite{63}, and, consequently, that discussion will not be repeated here. For the sake of simplicity consider the mechanisms relying on super-adiabatic amplification of vacuum fluctuations of the gauge fields (see also figure 2). In this context what one is led to compute is the amplification of the magnetic field from some initial (vacuum) state. The precise amount of amplification (as well as the spectral properties of the final configuration) is determined by the features of the pump field that changes from model to model. Therefore, initially (i.e. for $\tau \to -\infty$) the quantum-mechanical operator related to the magnetic field intensity can be decomposed as

$$\hat{B}^{\text{in}}_{l}(\vec{x}, \tau) = \frac{i e_{\alpha \beta}}{(2\pi)^{3}} \sum_{\alpha} e_{\alpha}^{\mu} \int d^{3}k \, k_{\mu} \left[ \hat{a}^{\dagger}_{l,\alpha} f_{k}(\tau) e^{-ik \cdot \vec{x}} + \hat{a}_{l,\alpha} f_{k}^{*}(\tau) e^{ik \cdot \vec{x}} \right].$$

(4.26)

where, within the present conventions, $[\hat{a}_{k,\alpha}, \hat{a}^{\dagger}_{p,\beta}] = (2\pi)^{3} \delta_{\alpha \beta} \delta^{(3)}(\vec{k} - \vec{p})$. For $\tau \to +\infty$

$$\hat{B}^{\text{out}}_{\ell}(\vec{x}, \tau) = \frac{i e_{\alpha \beta \gamma}}{(2\pi)^{3}} \sum_{\alpha} \sum_{\beta} e_{\beta}^{\rho} \int d^{3}k \, k_{\rho} \left[ \hat{b}^{\dagger}_{\ell,\beta \gamma} g_{k}(\tau) e^{-ik \cdot \vec{x}} + \hat{b}_{\ell,\beta \gamma} g_{k}^{*}(\tau) e^{ik \cdot \vec{x}} \right].$$

(4.27)

Since both sets of modes are complete, the old modes can be expressed in terms of the new ones, i.e.

$$f_{k}(\tau) = c_{+}(k) g_{k}(\tau) + c_{-}(k) g_{k}^{*}(\tau).$$

(4.28)
Note that $f_\ell (\tau)$ are normalized, as $\tau \to -\infty$ as $e^{-i k \tau / \sqrt{2k}}$, since we demand that the initial state is the vacuum. Therefore, with this normalization, $c_+ (k)$ for $\tau \to +\infty$ parametrizes the relevant mode-mixing.

Inserting equation (4.28) back into equation (4.26) and imposing the continuity of the operators we also have

$$\hat{b}_{\ell,a} = c_+(k) \hat{a}_{\ell,a} + c_-(k) \hat{a}^\dagger_{\ell,a},$$

(4.29)

$$|c_+(k)|^2 - |c_-(k)|^2 = 1.$$  

(4.30)

The final value of the two-point function can then be obtained as

$$\langle 0 | \hat{B}_i (\vec{x} + \vec{r}) \hat{B}_j (\vec{x}) | 0 \rangle \simeq \frac{1}{(2\pi)^3} \int d^3 k \left( \delta_{ij} - \frac{k_i k_j}{k^2} \right) Q(k) e^{-i \vec{k} \cdot \vec{r}},$$

(4.31)

where now $Q(k) \simeq k |c_-(k)|^2$. In deriving equation (4.31), we used the identity

$$\langle g_k (\tau) \rangle^2 = (1 + 2 |c_-(k)|^2) |f_k (\tau)|^2 - c_-(k) c_+(k) f_k^* (\tau)^2 - \frac{1}{4} (c_-(k) c_+(k) f_k (\tau)^2),$$

(4.32)

together with equation (4.30). Note that the second and third terms in equation (4.32) are typically oscillating and they have been dropped in equation (4.31).

Super-adiabatic amplification alone always leads to correlation functions falling in the general class introduced in equation (4.14) but with $F_3 (r) = 0$. The primordial spectrum must be processed and the finite values of the thermal diffusivity as well as of the conductivity lead to an effective ultraviolet cut-off [63].

### 4.2. Primordial or astrophysical seeds?

We are now going to give some examples of magnetic fields that may be generated in the early stages of the life of the Universe. This topic has already been discussed in different review articles (see, for instance, for a short account [48] and [63] for a more extended review). As elaborated in the introduction, the mechanisms for the generation of magnetic fields that may be potentially relevant for CMB physics can be divided, broadly speaking, into two categories: mechanisms operating inside the Hubble radius (such as phase transitions occurring, for instance, at the electroweak or at the QCD epoch) and mechanisms where the correlation scale of the field grows larger than the Hubble radius (as in the case of inflationary mechanisms). Furthermore, there is also the appealing possibility of so-called mixed mechanisms where the magnetic field is created, initially, in the context of some (conventional or unconventional) inflationary model. Then the various modes of the primordial spectrum of the hypercharge field will re-enter at different times during the radiation epoch and, at this stage, will be further amplified by the processes taking place inside the Hubble radius.

In the case of the electroweak phase transition (see, for instance, [62] for a comprehensive review on this subject), the typical strength of the produced seeds may change depending on the order of the phase transition (PT). We do know that, in the framework of the minimal standard model of particle interaction, the phase transition cannot be strongly first order for values of the Higgs mass larger than the mass of the W boson. This conclusion was reached by lattice studies of the phase diagram of the electroweak phase transition [73]. Let us now consider, separately, the cases when the PT is strongly first order and second order.

In a first-order phase transition, the phases of the complex order parameter of the nucleated bubbles are not correlated. The bubbles of the broken phase expand at a velocity $v \sim 10^{-3} c$, where $c$ is the speed of light. At the epoch of the electroweak phase transition, the temperature of the plasma is of the order of 100 GeV while the Hubble radius, i.e. $H_{\text{ew}}^{-1} \sim 3 \text{ cm}$. The average distance between the centres of the nucleated bubbles is of the order of $10^{-8} H_{\text{ew}}^{-1}$ [62, 75].
The finite conductivity effects will give rise to diffusion whose consequence will be to smooth out the oscillations of the created magnetic field. The magnetic flux will escape the intersection regions and penetrate the colliding bubbles where the evolution is governed by ordinary MHD. The magnetic fields will typically have a correlation scale much smaller than the Hubble radius. Even allowing for a rather efficient diffusion of the magnetic flux, the correlation scale of the magnetic field will be at, at most, as large as the Hubble radius. In the absence of any form of inverse cascade, we will have that the typical correlation scale at the onset of galactic rotation will be of the order of 10 to 100 AU (recall that 1 AU = 1.49 × 10^{13} cm). The conservative estimate of [76] is even smaller, i.e. the authors get a magnetic field $|\vec{B}| \sim 10^{-10}$ G over a typical correlation scale of 0.1 AU. As suggested in the introduction, it is plausible that some form of inverse cascade may eventually take place between the electroweak epoch and the time of electron–positron annihilation [58] (see also [63] and references therein). If the PT is of second order the situation is even worse. The correlation scale is likely to be of the order of $10/T_{ew}$, i.e. $10^{-16} H_{-1}^{-1}$ at $T_{ew}$.

There have also been ideas concerning a possible generation of magnetic fields at the time of the QCD phase transition occurring roughly at $T \sim 140$ MeV, i.e. at the moment when free quarks combine to form colourless hadrons. At this time, the Hubble radius is of the order of $4 \times 10^4$ m. The mechanism here is always related to the idea of a Biermann battery with thermoelectric currents developed at the QCD time11. Since the strange quark is heavier than the up and down quarks there may be the possibility that the quarks develop a net positive charge which is compensated by the electric charge in the leptonic sector. Again, invoking the dynamics of a first-order phase transition, it is argued that the shocks affect leptons and quarks in a different way so that electric currents are developed as the bubble wall moves in the quark–gluon plasma. In [77], the magnetic field has been estimated to be $|\vec{B}| \sim G$ at the time of the QCD phase transition and with typical scale of the order of a metre at the same epoch.

In [78, 79], it has been pointed out that, probably, the magnetic fields generated at the time of QCD phase transition may be much stronger than those estimated in [77]. The authors of [78, 79] argue that strong magnetic fields may be generated when the broken and symmetric phases of the theory coexist. The magnetic fields generated at the boundaries between quark and hadron phases can be, according to the authors, as large as $10^6$ G over scales of the order of a metre (and possibly even larger) at the time of the QCD phase transition. At the onset of gravitational collapse and over a typical scale of Mpc, the magnetic field will be of the order of $10^{-26}$ G with a white noise spectrum ($m \sim 0$ in the notation of this section) [78].

A model of variation of gauge couplings motivated by the evolution of the internal dimensions [81] leads to a variety of spectra that may be different, depending on the number of extra dimensions and on their rate of evolution (see also [82–84]). While a phase of expanding internal dimensions may lead to large magnetic fields, the allowed region in the parameter space gets reduced in the case of contracting extra dimensions. In [81] only the gauge zero modes have been considered. In a recent calculation [85], the role of the internal momenta has been taken into account with the result that also in the contracting case large magnetic seeds may be produced. In the case of expanding internal dimensions, the spectral index is $m \sim -1 - n\mu$, where $n$ is the number of internal dimensions and $\mu$ is the exponent parametrizing, on conformal time, their evolution. In the case of Kasner models [81], $\mu = \sqrt{3n}/(n + 2)$. If internal dimensions contract we have, effectively, $m \sim 0$ [85].

Large-scale magnetic fields can also be produced in the context of inflationary models. Here the idea is that quantum fluctuations of an Abelian gauge field (for instance the

11 See later in this section for a general discussion of ‘batteries’ in the framework of the generalized Ohm law.
hypercharge field) are inside the Hubble radius during inflation. Then, these fluctuations exit the horizon and their correlation scale grows faster than the Hubble radius itself. The amount of amplification achieved in these processes depends crucially on the amount of breaking of conformal invariance of the evolution equation of the Abelian gauge fields. A lot of ideas concerning the possible breaking of conformal invariance (see, for instance, [63, 80]) have been proposed so far and it would be impossible to summarize them all in this topical review.

Instead of going through the various ideas it may be more useful to give further details about a specific way of breaking conformal invariance such as that suggested in the context of string cosmological models [86]. The string effective action contains a direct coupling between the (scalar) dilaton field and the electromagnetic field that appears even at tree level in the loop expansion and to lowest order in the string tension expansion. To lowest order the action will then be

\[ S = -\frac{1}{4} \int d^4x \sqrt{-g} \, e^{-\phi} Y_{\alpha\beta} Y^{\alpha\beta}, \]

(4.33)

where \( Y_{\alpha\beta} \) is the field strength. If the gauge coupling evolves during the inflationary dynamics, then the magnetic fields will be amplified over different length scales. In particular, in the model presented in [86], the gauge coupling, i.e. \( e^{\phi/2} \), is a growing function of the cosmic time coordinate. When the Universe becomes dominated by radiation (after inflation) the gauge coupling freezes to a value that is of the order of \( 10^{-2} \). More specifically, there are two phases that characterize the model. In the first phase, the gauge coupling increases sharply (the so-called dilaton-driven phase). In the second phase, the gauge coupling is just slowly increasing (the so-called stringy phase).

In the context of string cosmological models, there are two possible ranges in the values of \( m \), i.e. the spectral index of the produced magnetic fields. If the relevant modes (i.e. comoving scales larger than the Mpc scale) exit the Hubble radius for the first time during the so-called dilaton-driven phase, the resulting spectrum leads to \( m \) that could be written as [86]

\[ m \approx -\sqrt{3 + 3\sqrt{1 - \Sigma}}. \]

(4.34)

where \( \Sigma = \sum_{i} \beta_i^2 \) represents the possible effect of internal dimensions whose radii \( b_i \) shrink, during the pre-big bang phase, like \((-t)^{\beta_i}\) for \( t \to 0^- \). In the case \( \Sigma = 0 \), we will have \( m \approx -\sqrt{3} \).

The second possibility is that the relevant large-scale modes left the Hubble radius during the so-called string phase. During this phase the ratio between the (cosmic) time derivative of the dilaton field and the Hubble rate is roughly constant. Defining the mentioned ratio \( \dot{\phi}/2H \) as \( \beta \), we will have that \( m \approx 1 - 2\beta \). If the value of \( \beta \) gets frozen at the value corresponding to the last e-folds of the pre-big bang phase, we will have, for instance, allowed values between \( \beta \approx 1.8 \) and \( \beta \approx 2 \) corresponding to \( m \approx -3 \) (i.e. \(-2.9, -2.8\)). This parameter can be computed once a specific model of the high-curvature (stringy) regime is given but it cannot be obtained, at present, from more general arguments. Note that, in this case, \( B_L \) may even be of the order of \( 10^{-10} \) corresponding to a ratio between the magnetic and radiation energy density of the order of \( 10^{-8} \) [86].

It is also possible to generate large-scale magnetic fields within the Abelian Higgs model where the Higgs current densities allow us to obtain a (minute) amplification of the hypermagnetic field. The amplitude of these fields is irrelevant for applications (i.e. the produced field intensity is 30 orders of magnitude smaller than the most optimistic dynamo requirements). The typical spectral slope is \( m = 1 \), which corresponds to the magnetic spectrum of the vacuum once the canonical quantum mechanical normalization is imposed

\[ \sum_{i} \beta_i^2 = \Sigma = 0 \]

where \( \Sigma = \sum_{i} \beta_i^2 \) represents the possible effect of internal dimensions whose radii \( b_i \) shrink, during the pre-big bang phase, like \((-t)^{\beta_i}\) for \( t \to 0^- \). In the case \( \Sigma = 0 \), we will have \( m \approx -\sqrt{3} \).

The second possibility is that the relevant large-scale modes left the Hubble radius during the so-called string phase. During this phase the ratio between the (cosmic) time derivative of the dilaton field and the Hubble rate is roughly constant. Defining the mentioned ratio \( \dot{\phi}/2H \) as \( \beta \), we will have that \( m \approx 1 - 2\beta \). If the value of \( \beta \) gets frozen at the value corresponding to the last e-folds of the pre-big bang phase, we will have, for instance, allowed values between \( \beta \approx 1.8 \) and \( \beta \approx 2 \) corresponding to \( m \approx -3 \) (i.e. \(-2.9, -2.8\)). This parameter can be computed once a specific model of the high-curvature (stringy) regime is given but it cannot be obtained, at present, from more general arguments. Note that, in this case, \( B_L \) may even be of the order of \( 10^{-10} \) corresponding to a ratio between the magnetic and radiation energy density of the order of \( 10^{-8} \) [86].

It is also possible to generate large-scale magnetic fields within the Abelian Higgs model where the Higgs current densities allow us to obtain a (minute) amplification of the hypermagnetic field. The amplitude of these fields is irrelevant for applications (i.e. the produced field intensity is 30 orders of magnitude smaller than the most optimistic dynamo requirements). The typical spectral slope is \( m = 1 \), which corresponds to the magnetic spectrum of the vacuum once the canonical quantum mechanical normalization is imposed.
on the vector potentials. Slightly different spectra can be obtained in the case of the models proposed in [87–89] where various charged scalars are considered together (see also [90]).

It is appropriate to comment here on the possibility that large-scale magnetization is a purely astrophysical phenomenon. As in the case of the primordial hypothesis, it is rather difficult to summarize, in a reasonably self-contained manner, all the hypothesis that have been put forward in the last 50 years. An (incomplete) list of proposals can be found, for instance, in [63, 91, 92]. The modest aim of the remaining part of this section will therefore be to introduce the general framework.

Many (if not all) of the astrophysical mechanisms proposed so far are related to what is called, in the jargon, a battery. The idea is, in short, the following. MHD, as previously stressed in this section, can be ‘derived’ from a two-fluid theory by appropriately defined one-fluid variables that obey a set of effective Maxwell’s equations supplemented by Ohm’s law (i.e. equation (4.5)) and coupled to the Navier–Stokes equation. Now, we already remarked right before equation (4.5) that the proposed form of the ohmic electric field would contain, in principle, also a thermoelectric term that is a remnant of the subtraction of the momentum conservation equations that hold separately (for electrons and ions) in the two-fluid description from which MHD is derived. The explicit form of the generalized ohmic electric field in the presence of thermoelectric corrections can be written as

\[ \vec{E} = -\vec{v} \times \vec{B} + \frac{\vec{v} \times \vec{B}}{4\pi \sigma} - \frac{\vec{\nabla} P_e}{en_e}. \tag{4.35} \]

By comparing equation (4.5) with equation (4.35), it is clear that the additional term on the right-hand side receives a contribution from a temperature gradient. In fact, restoring for a moment the Boltzmann constant \( k_B \), we have that since \( P_e = k_B n_e T_e \), the additional term depends upon the gradients of the temperature, hence the name thermoelectric. It is interesting to see under which conditions the curl of the electric field receives contribution from the thermoelectric effect. Taking the curl of both sides of equation (4.35) we obtain

\[ \vec{\nabla} \times \vec{E} = \frac{1}{4\pi \sigma} \nabla^2 \vec{B} + \vec{\nabla} \times (\vec{v} \times \vec{B}) - \frac{\vec{\nabla} n_e \times \vec{\nabla} P_e}{en_e^2} = -\frac{\partial \vec{B}}{\partial t}, \tag{4.36} \]

where the second equality is a consequence of Maxwell’s equations. From equation (4.36) it is clear that the evolution of the magnetic field inherits a source term iff (i.e. if and only if) the gradients in the pressure and electron density are not parallel. If \( \vec{\nabla} P_e || \vec{\nabla} n_e \), a fully valid solution of equation (4.36) is \( \vec{B} = 0 \). In the opposite case a seed magnetic field is naturally provided by the thermoelectric term. The usual (and rather general) observation that one can make in connection with the geometrical properties of the thermoelectric term is that cosmic ionization fronts may play an important role. For instance, when quasars emit ultraviolet photons, cosmic ionization fronts are produced. Then the intergalactic medium may be ionized. It should also be recalled, however, that the temperature gradients are usually normal to the ionization front. In spite of this, it is also plausible to think that density gradients can arise in arbitrary directions due to the stochastic nature of density fluctuations.

In one way or the other, astrophysical mechanisms for the generation of magnetic fields use an incarnation of the thermoelectric effect. In the 1960s and 1970s, for instance, it was rather popular to think that the correct ‘geometrical’ properties of the thermoelectric term may

---

12 For simplicity, we shall neglect the Hall contribution arising in the generalized Ohm’s law. The Hall contribution would produce, in equation (4.35), a term \( J \times \vec{B}/n_e e \) that is of higher order in the magnetic field and that is proportional to the Lorentz force. The Hall term will play no role in the subsequent considerations. However, it should be borne in mind that the Hall contribution may be rather interesting in connection with the presence of strong magnetic fields such as those of neutron stars (i.e. \( 10^{13} \) G). This occurrence is even more interesting since in the outer regions of neutron stars strong density gradients are expected.
be provided by a large-scale vorticity. As will also be discussed later, this assumption seems to be, at least naively, in contradiction with the formulation of inflationary models whose prediction would actually be that the large-scale vector modes are completely washed out by the expansion of the Universe. Indeed, all through the 1980s and 1990s the idea of primordial vorticity received just minor attention.

The attention then focused on the possibility that objects of rather small size may provide intense seeds. After all we do know that these objects may exist. For instance, the Crab nebula has a typical size of roughly 1 pc and a magnetic field that is a fraction of mG. These seeds will then combine and diffuse leading, ultimately, to a weaker seed but with large correlation scale. This aspect may be physically a bit controversial since we do observe magnetic fields in galaxies and clusters that are ordered over very large length scales. It would then seem necessary that the seed fields produced in a small object (or in several small objects) undergo some type of dynamical self-organization whose final effect is a seed coherent over length scales four or five orders of magnitude larger than the correlation scale of the original battery.

An interesting idea could be that qualitatively different batteries lead to some type of conspiracy that may produce a strong large-scale seed. In [92], it has been suggested that Population III stars may become magnetized thanks to a battery operating at stellar scale. Then if these stars were to explode as supernovae (or if they were to eject a magnetized stellar wind) the pre-galactic environment may be magnetized and the remnants of the process incorporated in the galactic disc. In a complementary perspective, a similar chain of events may take place over a different physical scale. A battery could arise in fact in active galactic nuclei at high redshift. Then the magnetic field could be ejected leading to intense fields in the lobes of ‘young’ radio-galaxies. These fields will be somehow inherited by the ‘older’ disc galaxies and the final seed field may be, according to [92], as large as $10^{-9}$ G at the pre-galactic stage.

Up to now only a necessarily reduced account of the primordial and the astrophysical hypotheses has been presented. In spite of the mechanism leading to a seed field, the crucial problem will be how to go from the seed to the actual galactic (or even cluster) magnetic field. The galactic rotation period is of the order of $3 \times 10^8$ years. This scale should be compared with the typical age of the galaxy. All along this rather large dynamical time scale the effort has been directed, since the fifties, to the justification that a substantial portion of the kinetic energy of the system (provided by the differential rotation) may be converted into magnetic energy amplifying, in this way, the seed field up to the observed value of the magnetic field, for instance in galaxies and in clusters. In recent years, a lot of progress has been made both in the context of small- and large-scale dynamos. This progress was also driven by the higher resolution of the numerical simulations and by the improvement in the understanding of the largest magnetized system that is rather close to us, i.e. the sun. More complete accounts of this progress can be found in the second paper of [93] and, more comprehensively, in [94]. The main ingredients of the large-scale dynamo can also be found in [63]. Apart from the aspects involving solar physics and numerical analysis, better physical understanding of the role of the magnetic helicity in the dynamo action has been reached. This point is crucially connected with the two conservation laws arising in MHD, i.e. the magnetic flux and magnetic helicity conservation whose relevance has already been emphasized, respectively, in equations (4.6) and (4.7). Even if the rich interplay between small- and large-scale dynamos is rather important, let us focus on the problem of large-scale dynamo action that is, at least superficially, more central for the considerations developed in the present review. In short, the picture of large-scale dynamos can be summarized as follows. In a turbulent environment, the MHD equations can be appropriately averaged with the result that the mean magnetic seed is amplified exponentially fast. This approach is described in detail in [94] (see also [95]). The most important point to bear in mind is that the turbulent velocity field (whose correlation scale
is typically shorter than the correlation scale of the magnetic seed) *must* lack mirror symmetry. In other words, the velocity field must be parity-odd. This occurrence necessarily implies that the (averaged) magnetic diffusivity equation inherits a term that is proportional to the curl of the magnetic field though a coefficient, the celebrated \( \alpha \) term, that would vanish if the velocity field were parity-even. It can be demonstrated that the \( \alpha \) term is indeed proportional, in turn, to the average *kinetic* helicity, i.e. \( \langle \vec{v} \cdot \vec{\nabla} \times \vec{v} \rangle \). The \( \alpha \) term decreases more slowly, at large length scales, than the diffusivity terms. Therefore, for sufficiently large scales the magnetic seed can be efficiently (exponentially?) amplified. For a long time this oversimplified picture was thought to be essentially consistent even if computationally challenging.

Already at a qualitative level it is clear that there is a clash between the absence of mirror-symmetry of the plasma, the quasi-exponential amplification of the seed and the conservation of magnetic flux and helicity in the high (or more precisely infinite) conductivity limit. The easiest clash to understand, intuitively, is the flux conservation versus the exponential amplification: both flux freezing and exponential amplification have to take place in the *same* superconductive (i.e. \( \sigma^{-1} \to 0 \)) limit. The clash between helicity conservation and dynamo action can also be understood in general terms: the dynamo action implies a topology change of the configuration since the magnetic flux lines cross each other constantly [93].

A recent progress in this framework is a more consistent formulation of the large-scale dynamo problem [93, 94]: large-scale dynamos produce small-scale helical fields that quench (i.e. prematurely saturate) the \( \alpha \) effect. In other words, the conservation of the magnetic helicity can be seen, according to the recent view, as a fundamental constraint on the dynamo action. In connection with the last point, it should be mentioned that, in the past, a rather different argument was suggested [96]: it was argued that the dynamo action not only leads to the amplification of the large-scale field but also to that of the random field component. The random field would then strongly suppress the dynamo action. According to the considerations based on the conservation of the magnetic helicity this argument seems to be incorrect since the increase of the random component would also entail an increase of the rate of the topology change, i.e. a magnetic helicity non-conservation.

In summary we can therefore say that

- both the primordial and the astrophysical hypotheses for the origin of the seeds demand an efficient (large scale) dynamo action;
- due to the constraints arising from the conservation of magnetic helicity and magnetic flux the values of the required seed fields may turn out to be larger than previously thought at least in the case when the amplification is only driven by a large-scale dynamo action\(^{13}\);
- magnetic flux conservation during gravitational collapse of the proto-galaxy may increase, by compressional amplification, the initial seed by even four orders of magnitude;
- compressional amplification, as well as large-scale dynamo, is much less effective in clusters; therefore, the magnetic field of clusters is probably connected to the specific way the dynamo saturates, and, in this sense, is harder to predict from a specific value of the initial seed.

5. Magnetized metric perturbations

Consider a conformally flat background geometry

\[
\bar{g}_{\mu\nu} = a^2(\tau) \eta_{\mu\nu},
\]

(5.1)

\(^{13}\) The situation may change if the magnetic fields originate from the combined action of small- and large-scale dynamos as in the case of the two-step process described in [92].
where $\eta_{\mu\nu} = \text{diag}(1, -1, -1, -1)$ is the flat Minkowski metric. Then the fluctuations of the metric may be written as

$$\delta g_{\mu\nu} = \delta_t g_{\mu\nu} + \delta_v g_{\mu\nu} + \delta_s g_{\mu\nu},$$  \hspace{1cm} (5.2)

where $\delta_t$, $\delta_v$ and $\delta_s$ denote the tensor, vector and scalar fluctuation of the geometry, respectively.

The evolution of the various modes of the geometry is sourced by the corresponding modes of the energy–momentum tensor of the fluid sources and the magnetic field. In particular, denoting by $T_{\mu\nu}$ the energy–momentum tensor of the magnetic field we will have, following the notation of equation (5.2), that

$$\delta T_{\mu\nu} = \delta_t T_{\mu\nu} + \delta_v T_{\mu\nu} + \delta_s T_{\mu\nu}. \hspace{1cm} (5.3)$$

The fluctuations $\delta T_{\mu\nu}$ are quadratic in the intensity of the fully inhomogeneous magnetic fields. This means that a non-Gaussian signal should be, in general, expected. The rationale for this statement is that while the fluctuations of fully inhomogeneous magnetic fields may be Gaussian (see, for instance, equation (4.9)), the fluctuations of the energy–momentum tensor will be distributed as the square of a Gaussian variable and will therefore be non-Gaussian. Recently, more accurate calculations of the possible non-Gaussian effects arising in the presence of fully inhomogeneous magnetic fields have been presented [97].

In the following, the evolution equations of tensor, vector and scalar modes will be treated within a (first-order) ‘Bardeen’ approach [98] (see also [40] for an introduction to the key features of the problem in the absence of magnetic fields). The evolution of fully inhomogeneous magnetic fields can be usefully treated also within a covariant formalism. For this type of analysis see the interesting studies reported in [99–101].

5.1. Magnetized tensor modes

The tensor fluctuations of the metric defined as

$$\delta g_{ij} = -a^2 h_{ij}, \quad \partial_i h_{ij} = 0, \quad h^i = 0, \hspace{1cm} (5.4)$$

are automatically invariant under infinitesimal coordinate transformations. Equation (5.4) implies that $h_{ij}$ carries two independent degrees of freedom. From the fluctuation of the Ricci tensor, it is easy to obtain that the evolution equations are

$$h_{ij}'' + 2\mathcal{H} h_{ij}' - \nabla^2 h_{ij} = -16\pi G a^2 \delta_i T^i_j, \hspace{1cm} (5.5)$$

where, as mentioned before, $\delta_i T^i_j$ is the transverse and traceless component of the energy–momentum tensor of the electromagnetic fields. Given the specific magnetic field configuration, equation (5.5) allows us to determine the amplitude of the gravitational waves. The determination of $h_{ij}$ allows the determination of the tensor Sachs–Wolfe contribution, i.e.

$$\left(\frac{\Delta T}{T}\right)_t = \frac{1}{2} \int_{\tau_0}^{\tau_f} h_{ij} n^i n^j d\tau. \hspace{1cm} (5.6)$$

In the tensor case, the fluctuations of the geometry do not mix with the fluctuations of the fluid sources. Furthermore, in the tensor case, as is well known, only the Sachs–Wolfe integral contributes. Tensor modes have been discussed in a number of papers. In [30, 102], the possible stochastic backgrounds of gravitational radiation stemming from inhomogeneous magnetic fields have been computed with particular attention to configurations carrying non-vanishing magnetic gyrotropy. Recently gravitational waves produced through a phase of helical turbulence have been discussed in [103]. For a discussion of the interplay of gravitational waves and inhomogeneous magnetic fields see also [104].
5.2. Magnetized vector modes

The evolution equations arising in the case of vector modes are a bit more complicated than those in the case of tensor modes. The vector modes of the geometry are parametrized in the following way:

\[ \delta v^g_0 = -a^2 Q_i, \]
\[ \delta v^g_{ij} = a^2 (\partial_i W_j + \partial_j W_i), \] (5.7)

where \( \partial_i Q^i = 0 \) and \( \partial_i W^i = 0. \)

The perturbed Einstein and covariant conservation equations read

\[ \delta v^R_{\mu} = 8\pi G (\delta v^T^\mu_\nu + \delta v^T^\nu_\mu), \] (5.8)
\[ \nabla_\mu \delta v^\mu_\nu + \nabla_\mu \delta v^\nu_\mu = 0, \] (5.9)

where

\[ \delta v^T^\mu_\nu = (p + \rho) (u_\mu \delta v^u_\nu + \delta v^u_\mu u^\nu), \] (5.10)
\[ \delta v^T^\mu_\nu = \frac{1}{4\pi} \left( -F^\mu_\alpha F^\alpha_\nu + \frac{1}{4} \delta^\mu_\nu F_{\alpha\beta} F^{\alpha\beta} \right). \] (5.11)

Equations (5.8) and (5.11) have to be supplemented by Maxwell’s equations together with the generalized Ohm’s law:

\[ \nabla_\mu F^{\mu_\nu} = 4\pi j^\mu, \quad j^\mu = \sigma c F^{\mu_\nu} u_\nu. \] (5.12)

Recall first that

\[ \delta v^R^i_0 = \frac{2}{a^2} Q^i (H^i - \dot{H}^i) + \frac{1}{2a^2} \nabla^2 V^i, \] (5.13)
\[ \delta v^R^i_1 = \frac{1}{2a^2} [(\partial_i V^j + \partial_j V^i) + 2\dot{\gamma} (\partial_i V^j + \partial_j V^i)]. \]

where

\[ \vec{V} = \vec{Q} + \vec{W}'. \] (5.14)

The vector \( \vec{V} \) is gauge invariant. In fact, for infinitesimal gauge transformations preserving the vector nature of the fluctuation we have, indeed,

\[ Q_i \rightarrow \bar{Q}_i = Q_i - \zeta'_i, \] (5.15)
\[ W_i \rightarrow \bar{W}_i = W_i + \zeta_i. \] (5.16)

From equation (5.10), recalling that

\[ u_0 \delta v^i = -(V^i + Q^i), \] (5.17)

we simply have

\[ \delta v^R^i_0 = -(p + \rho) (V^i + Q^i). \] (5.18)

Equation (5.11) becomes, in explicit terms,

\[ \delta v^T^i_0 = \frac{1}{4\pi} (\vec{E} \times \vec{B})^i \equiv \frac{1}{4\pi a^2} (\vec{E} \times \vec{B})^i, \] (5.19)
\[ \delta v^T^i_1 = \frac{1}{4\pi} \left[ E_i E^j + B_i B^j - \frac{1}{2} \delta^j_i (\vec{B}^2 + \vec{E}^2) \right] \]
\[ = \frac{1}{4\pi a^2} \left[ E_i E^j + B_i B^j - \frac{1}{2} \delta^j_i (\vec{B}^2 + \vec{E}^2) \right]. \] (5.20)
where the following conventions have been adopted:

\[
\begin{align*}
F_0 &= a^2 \mathcal{E}_i, & F^{0i} &= -\frac{1}{a^2} \mathcal{E}^i, \\
F_{ij} &= -a^2 \epsilon_{ijk} B^k, & F^{ij} &= -\frac{1}{a^2} \epsilon^{ijk} B_k, \\
\vec{E} &= a^2 \vec{E}, & \vec{B} &= a^2 \vec{B}.
\end{align*}
\] (5.21)

Therefore, the perturbed set of equations can be written, in the gauge \( W_i = 0 \), as

\[
\nabla^2 \vec{Q} = -16\pi G a^2 (p + \rho) \vec{V} + \frac{16\pi G}{a^2} \vec{F}_B(\vec{x}),
\] (5.22)

\[
\nabla^2 (\tilde{Q}' + 2\mathcal{H} \vec{Q}) = \frac{16\pi G}{a^2} \vec{F}_B(\vec{x}),
\] (5.23)

\[
\tilde{\mathcal{V}}' + \left[ 4\mathcal{H} + \frac{p' + \rho'}{p + \rho} \right] \tilde{\mathcal{V}} + \frac{\vec{F}_B(\vec{x})}{a^2 (p + \rho)} = 0,
\] (5.24)

where

\[
\vec{F}_B = \frac{1}{4\pi} (\vec{\nabla} \times \vec{B}) \times \vec{B}.
\] (5.25)

Note that the divergence-full part of the Lorentz force (i.e. \( \vec{\nabla} \cdot \vec{F}_B \)) does not contribute to the evolution equations of the vectors but it does contribute to the evolution equations of the scalar modes. The second term on the right-hand side of equation (5.22) contains, in the denominator, \( \sigma = a\sigma_c \), i.e. the rescaled conductivity. This term, coming from the MHD form of the Poynting vector, is negligible in the infinite conductivity limit and it is usually dropped.

Formally, the solution of the above system of equations can be written as

\[
\vec{V}(\vec{x}, \eta) = -\frac{1}{a^4(\eta)(p + \rho)} \int \vec{F}_B(\vec{x}, \eta) \, d\eta - \frac{\vec{C}(\vec{x})}{16\pi G a^4(\eta)(p + \rho)},
\] (5.26)

Finally, the vector contribution to the Sachs–Wolfe effect can be written, in the gauge \( W_i = 0 \), as

\[
\frac{\Delta T}{T} = [\vec{\nabla} \cdot \vec{n}] T' + \frac{1}{2} \int_{\Sigma} (\partial_i Q_j + \partial_j Q_i) n^i n^j \, d\tau.
\] (5.27)

In the absence of large-scale magnetic field, the only solution of the above system is that denoted by the integration constant \( C \). In this case, if the Universe expands, the vector modes can only decay (see, however, [105–107]).

In a series of papers, Barrow and Subramanian [108, 109] analysed the effects of tangled magnetic fields both on the temperature and polarization anisotropies. More recently, the vector modes have been analysed numerically in [110] (see also [111]). The obtained results are in qualitative agreement with the semi-analytical estimates presented in [108, 109]. In [110], the effect of the neutrinos has been accurately parametrized in the evolution equations. In the equations for the vector modes written above, the (divergenceless) velocity field \( \vec{V} \) has been taken as generic. However, when the plasma content before decoupling is specified, \( \vec{V} \), i.e. the total velocity field, will receive contributions from all the species present in the plasma. A similar situation will be encountered in the case of scalar modes and will be briefly discussed there.
5.3. Magnetized scalar modes

The evolution of scalar fluctuations is, technically, more complicated than the vector and tensor problems. In the case of scalar fluctuations, the magnetic fields enter the evolution equations through the magnetic energy density and through the divergence of the Lorentz force. Furthermore, in the scalar case, the possible gauge choices increase with respect to the case of the vector modes.

In the absence of magnetic fields, we do know that the most general initial conditions for CMB anisotropies consist of one adiabatic mode and four non-adiabatic (or isocurvature) modes (see, for instance, [40]). In the case of adiabatic modes, the fluctuations in the specific entropy vanish for typical length scales larger than the Hubble radius. This occurrence implies a specific relation among the density contrasts of the various species present in the plasma. Consider, indeed, the simple case of a system formed by cold dark matter (CDM) and radiation. In this case, the specific entropy $\varsigma$ and its relative fluctuations $S$ can be written as

$$\varsigma = \frac{T^3}{n_c}, \quad S = \frac{\delta \varsigma}{\varsigma} = \frac{3}{4} \delta_\gamma - \delta_c. \quad (5.28)$$

where $n_c$ is the number density of CDM particles; $\delta_\gamma$ and $\delta_c$ are the density contrasts of the fluctuations in radiation and in CDM. If $S \approx 0$ for scales larger than the Hubble radius, the fluctuations are said to be adiabatic.

This naive definition can be generalized in various ways. One can, for instance, give a more general gauge-invariant definition by introducing two generic fluids, the a-fluid and the b-fluid. In this case, it is rather natural to define the two gauge-invariant variables

$$\zeta_a = -\psi - \frac{\mathcal{H}}{\rho_a} \frac{\delta \rho_a}{\rho'_a}, \quad (5.29)$$
$$\zeta_b = -\psi - \frac{\mathcal{H}}{\rho_b} \frac{\delta \rho_b}{\rho'_b}, \quad (5.30)$$

which can be interpreted, respectively, as the curvature fluctuations on uniform a-density and b-density hypersurfaces (see, for instance, [112] and references therein). The (total) curvature fluctuations on uniform density hypersurfaces are then

$$\zeta = \frac{\rho_b}{\rho} \zeta_a + \frac{\rho_a}{\rho} \zeta_b = -\psi - \mathcal{H} \frac{\delta \rho}{\rho'}, \quad (5.31)$$

where $\rho = \rho_a + \rho_b$. From equations (5.29) and (5.30), it is possible to define the generalized entropy fluctuations as

$$S = -3(\zeta_b - \zeta_a) = \frac{\delta_b}{1 + w_b} - \frac{\delta_a}{1 + w_a}, \quad (5.32)$$

where the second equality follows from the first equality by using the covariant conservation equation for each of the two fluids; $w_a$ and $w_b$ are, respectively, the barotropic indices for the a-fluid and the b-fluid. In the case $w_b = w_\gamma = 1/3$ and $w_a = 0$, equation (5.32) reproduces equation (5.28).

If we now consider the plasma after equality but before decoupling, the total entropy fluctuations will vanish iff

$$\delta_\gamma \simeq \delta_\nu \simeq \frac{4}{3} \delta_c \simeq \frac{4}{3} \delta_b, \quad (5.33)$$

where the density contrast in the neutrinos and in the baryons, i.e. $\delta_\nu$ and $\delta_b$, has been introduced.

If magnetic fields are included in the game, then the adiabatic mode, together with the four isocurvature modes, can be generalized. The logic will then be the following:
• the evolution equations of the whole system must be written including the contribution of the large-scale magnetic fields;
• the system includes, on top of the magnetic field and the scalar fluctuations of the geometry, also the neutrinos, the photons, the baryons and the CDM particles;
• the equations must be solved when the relevant modes are larger than the Hubble radius;
• the obtained solutions will serve as initial conditions for the lowest multipoles of the Boltzmann hierarchy.

It is difficult, in the scalar case, to go through all the previous steps without changing gauge. Indeed it is well known, also in the absence of large-scale magnetic fields, that some isocurvature modes (for which the presence of anisotropic stresses is crucial) are regular in the synchronous gauge but are divergent (at early times) in the longitudinal gauge. This is just an example and, in the following, the magnetized adiabatic mode will be mainly discussed, quoting, when appropriate, some results of more technical investigations [113].

5.3.1. Magnetized adiabatic mode. Consider, for simplicity, the system of scalar fluctuations in the longitudinal gauge where the metric fluctuations can be written in terms of the two functions $\phi$ and $\psi$, i.e.

$$\delta_{SG0} = 2a^2 \phi, \quad \delta_{SGij} = 2a^2 \psi \delta_{ij}. \quad (5.34)$$

In the following, the relevant equations of the system will be discussed starting with the evolution equations of the fluctuations. As mentioned before, the plasma content is assumed to be formed by neutrinos, photons, baryons, CDM particles and fully inhomogeneous magnetic fields.

In the gauge of equation (5.34), the Hamiltonian constraint reads

$$-3H(\dot{H} \phi + \dot{\psi}') - k^2 \psi = \frac{1}{2} H^2 \left[ 4(R_\nu \delta_\nu + (1 - R_\nu)\delta_\gamma) + \Omega_B(k) + \Omega_\theta b + \Omega_\theta c \right], \quad (5.35)$$

where, for $N_\nu$ species of massless neutrinos,

$$R = \frac{7}{8} N_\nu \left( \frac{4}{11} \right)^{4/3}, \quad R_\nu = \frac{R}{1 + R}, \quad R_\gamma = 1 - R_\nu, \quad (5.36)$$

so that $R_\nu$ and $R_\gamma$ represent the fractional contributions of photons and neutrinos to the total density at early times deep within the radiation-dominated epoch.

In equation (5.35), the contribution of the magnetic energy density has been parametrized, in the Fourier space, as

$$\Omega_B(k, \eta) = \frac{\rho_B}{\rho} = \frac{1}{8\pi \rho a^4} \int d^3 p \right| \tilde{p} - \tilde{k} \left| B^i(p). \quad (5.37)$$

The appearance of convolutions in the expressions of the magnetic energy density is a direct consequence of the absence of a uniform component of the magnetic field whose background contribution, as repeatedly stressed, is vanishing. Note also that $\rho$ appearing in equation (5.37) is the energy density of the dominant component of the fluid, so, for instance, in the radiation-dominated epoch $\rho \equiv \rho_\gamma, \quad a^4 \rho_\gamma \sim \text{constant}$ and $\Omega_B \sim \text{constant}.

While the Hamiltonian constraint relates the metric fluctuations (and their first time derivatives) to the density contrasts of the various species, the momentum constraints relate the metric fluctuations (and their first derivatives) to the divergence-full part of the peculiar velocity field and to the MHD expression of the Poynting vector$^{14}$

$$k^2(\dot{H} \phi + \dot{\psi}') = \frac{3}{2} H^2 \left[ \frac{4}{3} (R_\nu \theta_\nu + (1 - R_\nu)\theta_\gamma) + \frac{T_{\theta B}(k)}{4\pi \sigma a^4 \rho} + \theta_b \Omega_B + \theta_c \Omega_c \right], \quad (5.38)$$

$^{14}$ In the following $\theta_\gamma = \delta_\gamma v_\gamma, \quad \theta_b = \delta_b v_b$ and so on for the two remaining species, i.e. $\theta_b$ and $\theta_c$. 

where $\mathcal{F}_B(k, \eta)$ is the Fourier transform of the generalized Lorentz force, i.e.

$$\mathbf{\nabla} \cdot \{[\mathbf{\nabla} \times \mathbf{B}] \times \mathbf{B}\} = \int d^3k \mathcal{F}_B(k) e^{i\mathbf{k} \cdot \mathbf{x}}, \quad (5.39)$$

and $\mathcal{F}_B(k)$ is given by the following convolution:

$$\int d^3p \{[(\mathbf{k} \cdot \mathbf{p}) B_j(p) B_j(|\mathbf{k} - \mathbf{p}|) - (k_i - p_i) B_j(|\mathbf{k} - \mathbf{p}|) B_j(|\mathbf{k} - \mathbf{p}|) B_j(p)]\}. \quad (5.40)$$

Note that a consistent treatment of fully inhomogeneous magnetic fields implies that

$$\Omega_B \ll 1, \quad \frac{\mathcal{F}_B}{4\pi k^2 \rho a^2} \ll 1, \quad (5.41)$$

in order not to overclose the Universe. In the ideal MHD limit, i.e. $\sigma \to \infty$, the contribution of $\mathcal{F}_B(k)$ disappears from equation (5.38).

Another important condition on the difference of the conformally Newtonian potentials comes from the $(i \neq j)$ components of the perturbed Einstein equations:

$$k^2(\phi - \psi) = \frac{9}{2} \mathcal{H}^2 \left[-\frac{4}{3} \sigma \mathcal{R} \delta_{\gamma} - \sigma_B(k)\right], \quad (5.42)$$

having defined

$$\sigma_B = \frac{\Omega_B(k)}{3} - \frac{\mathcal{F}_B(k)}{4\pi a^4 \rho k^2}. \quad (5.43)$$

The quantity $\sigma_B$ can be interpreted as the anisotropic stress arising thanks to the inhomogeneous magnetic field and, in the force-free case, $\sigma_B = \Omega_B/3$. Equation (5.42) relates the difference of the two metric fluctuations to a combination of the neutrino and magnetic anisotropic stresses.

Let us finally come to the equation stemming from the perturbed $(i = j)$ components of the Einstein equations:

$$\psi'' + (2\psi' + \phi')\mathcal{H} + (2\mathcal{H}' + \mathcal{H}^2)\phi - \frac{k^2}{3}(\phi - \psi) = \frac{1}{2} \mathcal{H}^2 \left[(\mathcal{R} \delta_{\gamma} + (1 - \mathcal{R})) \delta_{\gamma} + \Omega_B(k)\right], \quad (5.44)$$

where the contribution of the other species vanishes since both baryons and CDM particles have a vanishing barotropic index, i.e. $w_b = w_c = 0$.

Equations (5.35), (5.38), (5.42) and (5.44) should be supplemented by the evolution equations of the various plasma quantities. For doing so, there are two complementary approaches. In the first approach, one may note that the perturbed Einstein equations only involve the density contrasts and the peculiar velocities of the various species, i.e. the monopoles and the dipoles of the (perturbed) phase-space distributions. Therefore, the simplest approach is to describe the evolution of the different species of the plasma through an appropriate set of fluid equations (following from the covariant conservation equations for each species). The exception in this statement is represented by the neutrinos whose evolution includes also the quadrupole of the neutrino phase-space distribution, i.e. $\sigma_{\nu}$. To treat neutrinos one should include, therefore, also higher multipoles in the Boltzmann hierarchy. Alternatively, one may treat all the species through a Boltzmann hierarchy. This is the second, complementary, approach to the problem of initial conditions.

Proceeding along the improved fluid approach, the covariant conservation equations for photons and baryons imply, respectively,

$$\theta'_b + \mathcal{H}\theta_b = k^2\phi + \frac{\mathcal{F}_b(k)}{4\pi a^4 \rho_b} + \frac{4 \Omega_{\nu}}{3 \Omega_b} a n_{\nu} x_{\nu} \sigma_{\nu} (\theta_{\nu} - \theta_b) = 0 \quad (5.45)$$

$$\delta'_b = 3\psi' - \theta_b \quad (5.46)$$
\[ \delta' = -\frac{4}{3} \theta + 4 \psi', \quad (5.47) \]
\[ \theta' = \frac{k^2}{4} \delta + k^2 \phi + a_n \sigma_T \theta_b, \quad (5.48) \]

In equations (5.45) and (5.48), the Thompson scattering term has been added. At early times, baryons and photons are synchronized so well that, to the lowest order in the tight-coupling approximation, \( \sigma_T \to \infty \) and \( \theta \approx \theta_b \).

The evolution of the CDM particles follows from the fluctuations of the covariant conservation equation whose first-order fluctuation leads, in the Fourier space, to
\[ \theta' + H \theta_c = k^2 \phi, \quad (5.49) \]
\[ \delta' = 3 \psi' - \theta_c. \quad (5.50) \]

To describe neutrinos during and after horizon crossing requires a Boltzmann hierarchy for \( \delta_{\nu}, \theta_{\nu} \) and for the higher multipole moments, i.e. \( \ell \geq 2 \), of the neutrino phase-space density \( F_{\nu\ell} \). With this caveat in mind, after neutrino decoupling, at temperatures of about 1 MeV, massless neutrinos obey, in the Fourier space, the following set of equations:
\[ \delta' = -\frac{4}{3} \theta_{\nu} + 4 \psi', \quad (5.51) \]
\[ \theta' = \frac{k^2}{4} \delta_{\nu} - k^2 \sigma_{\nu} + k^2 \phi, \quad (5.52) \]
\[ \sigma' = \frac{4}{15} \theta_{\nu} - \frac{3}{10} k F_{\nu}, \quad (5.53) \]

where \( \sigma_{\nu} = F_{\nu 2}/2 \) is the quadrupole moment of the (perturbed) neutrino phase-space distribution and, as introduced above, \( F_{\nu\ell} \) is the \( \ell \)th multipole.

The closed system formed by the perturbed Einstein equations and by the fluid equations may be solved. For illustrative purposes, consider the magnetized adiabatic mode in the force-free case. The solution can be obtained as an expansion in \( k \tau \) which is small, i.e. \( k \tau < 1 \) when the relevant modes are outside the horizon. In the presence of a magnetic field the density contrasts turn out to be
\[ \delta_{b,c} = \frac{3}{4} \Omega_B - \left[ \frac{69 - 61 R - 8 R^2}{60 (25 + 2 R_c)} \right] \Omega_B k^2 \tau^2, \quad (5.54) \]
\[ \delta_{\nu} = \frac{237 + 152 R + 16 R^2}{90 (25 + 2 R_c)} \Omega_B k^2 \tau^2, \quad (5.55) \]
\[ \delta_{\nu} = \frac{375 - 207 R - 152 R^2 - 16 R^3}{90 R_c (25 + 2 R_c)} \Omega_B k^2 \tau^2, \quad (5.56) \]

where the bar quantities denote the adiabatic mode in the absence of magnetic field. In particular, for the density contrasts in the absence of inhomogeneous magnetic field we have
\[ \overline{\delta}_{b,c} = \frac{3}{2} \phi_0 - \frac{525 + 188 R + 16 R^2}{60 (25 + 2 R_c)} \phi_0 k^2 \tau^2, \quad (5.57) \]
\[
\delta \gamma = \delta \nu = -2\phi_0 - \frac{(525 + 188\nu + 16\nu^2)}{45(25 + 2\nu)} k^2 \tau^2,
\]

(5.58)

where \(\phi_0\) is the constant value of \(\phi\) to the lowest order in \(k\tau\). While in the absence of magnetic field the adiabaticity condition of equation (5.33) is verified both to the lowest and to higher order in \(k\tau\), in the presence of magnetic field the adiabaticity condition is violated to next-to-leading order.

With similar notation, we can also report the evolution for the metric fluctuations

\[
\phi = \bar{\phi} - \left[ \frac{6 - 8\nu + 2\nu^2}{45(25 + 2\nu)} \Omega B \right] k^2 \tau^2,
\]

(5.59)

\[
\psi = \bar{\psi} - \left[ \frac{69 - 61\nu - 8\nu^2}{180(25 + 2\nu)} \Omega B \right] k^2 \tau^2,
\]

(5.60)

where, as before, \(\bar{\phi}\) and \(\bar{\psi}\) denote the standard adiabatic solutions, i.e.

\[
\bar{\phi} = \phi_0 - \frac{(75 + 14\nu)}{90(25 + 2\nu)} \phi_0 k^2 \tau^2,
\]

(5.61)

\[
\bar{\psi} = \psi_0 - \frac{(75 + 79\nu + 8\nu^2)}{90(25 + 2\nu)} \phi_0 k^2 \tau^2.
\]

(5.62)

As in the standard adiabatic case, \(\psi_0\) is determined in terms of \(\phi_0\) by the neutrino anisotropic stress. In the magnetized case, the relation is modified as

\[
\psi_0 = \phi_0 \left(1 + \frac{2}{5}\nu\right) - \frac{\Omega B}{5} (\nu - 1).
\]

(5.63)

The solution for the velocity fields is finally

\[
\theta_\gamma = \bar{\theta}_\gamma - \left[ \frac{\Omega B}{4} k^2 \tau + \frac{(7 + 8\nu)}{40(25 + 2\nu)} \Omega B k^4 \tau^3 \right],
\]

(5.64)

\[
\theta_\nu = \bar{\theta}_\nu - \frac{\Omega B \nu}{4\nu} k^2 \tau - \left[ \frac{45 - 29\nu - 16\nu^2}{72\nu(25 + 2\nu)} \Omega B \right] k^4 \tau^3,
\]

(5.65)

\[
\theta_\beta = \theta_\gamma - \bar{\theta}_\gamma = \bar{\theta}_\nu - \left[ \frac{6 - 8\nu + 2\nu^2}{180(25 + 2\nu)} \Omega B \right] k^4 \tau^3,
\]

(5.66)

where, following the same notation used before, the standard adiabatic solution is

\[
\bar{\theta}_\gamma = \frac{\phi_0}{2} k^2 \tau - \frac{(65 + 16\nu)}{36(25 + 2\nu)} \phi_0 k^4 \tau^3,
\]

(5.67)

\[
\bar{\theta}_\nu = \frac{\phi_0}{2} k^2 \tau - \frac{(75 + 14\nu - 8\nu^2)}{360(25 + 2\nu)} \phi_0 k^4 \tau^3,
\]

(5.68)

\[
\bar{\theta}_\beta = \frac{\phi_0}{2} k^2 \tau - \frac{(75 + 14\nu - 8\nu^2)}{360(25 + 2\nu)} \phi_0 k^4 \tau^3,
\]

(5.69)

\[
\bar{\theta}_\gamma = \frac{\phi_0}{2} k^2 \tau - \frac{(25 + 8\nu)}{20(25 + 2\nu)} \phi_0 k^2 \tau^2.
\]

(5.70)
Note that while to leading order all the peculiar velocities of the plasma coincide, to next-to-leading order they are different: this occurs already in the standard adiabatic case. Since the adiabaticity condition is only realized to the lowest order in $k\tau$, it is legitimate to name the solution presented in equations (5.54)–(5.66) quasi-adiabatic. The corrections to adiabaticity are of order $1/\Omega_1A$, and they are suppressed outside the horizon and also, by virtue of equation (5.41), by $\Omega_B$. Note that three regimes emerge naturally. The quasi-adiabatic regime where $\Omega_B(k) \leq \phi_0(k)$, the isocurvature regime $\Omega_B(k) > \phi_0(k)$ and the fully adiabatic regime, i.e. $\Omega_B(k) \ll \phi_0(k)$.

It is useful to recall that the presence of fully inhomogeneous magnetic fields changes the qualitative features of the tight-coupling expansion [113]. As is well known, the idea of the tight-coupling approximation is to tailor a systematic expansion in powers of the inverse optical depth, i.e. $1/\epsilon'$, in the notation employed equation (3.40). Instead of being interested in the brightness perturbations related to $Q$ and $U$ we shall be interested in the brightness perturbation related to $I$, i.e. the intensity of the scattered radiation. To derive the evolution equations in the tight-coupling approximation for a magnetoactive plasma we recall that the equation for $\Delta I$ can be written as

$$\Delta I + i k \mu \Delta I = \left( \psi' - i k \mu \phi \right) + \tau' \left[ -\Delta I + \Delta \phi + \mu \psi \right] - \frac{i}{2} P_2(\mu) S_Q,$$

(5.71)

where we defined $\psi = \theta_0/(ik)$ and $S_Q$ is the same quantity already introduced in equation (3.51). The equation for $\psi$ can be readily obtained from equation (5.45) and it is given by

$$\psi' + \mathcal{H} \psi = -ik\phi - \frac{\tau'}{\alpha} \left[ 3i \Delta I + \psi \right] - i \mathcal{V}_B(k),$$

(5.72)

where

$$\mathcal{V}_B(k) = \frac{\mathcal{F}_B}{4\pi k \rho_B a^2},$$

(5.73)

$$\alpha = \frac{3}{4} \rho_B.$$

(5.74)

It should be noticed that even if the magnetic field does not appear directly in equation (5.71), it does appear in equation (5.72). This implies that the equation for $\Delta I$ (already to zeroth order in the tight-coupling expansion) inherits an extra source term that depends on the divergence of the Lorentz force. This statement can be verified by expanding, consistently, the evolution equations for the brightness perturbations in powers of $1/\epsilon'$ [113]. For instance, to the zeroth order in the tight-coupling expansion the (decoupled) evolution equation for the monopole can be written as

$$\Delta I'' + \frac{\alpha'}{\alpha + 1} \Delta I' + \frac{k^2}{3(\alpha + 1)} \Delta \phi = \left[ \psi'' + \frac{\alpha'}{\alpha + 1} \psi' - \frac{k^2}{3} \phi \right] - \frac{\alpha}{\alpha + 1} \frac{\mathcal{F}_B}{12\pi \rho_B a^2}.$$

(5.75)

In the limit $\mathcal{F}_B \to 0$, the usual decoupled equation for the evolution of the monopole is clearly recovered.

5.4. Constraints on fully inhomogeneous fields

In the following, we will refer exclusively to the fully inhomogeneous case since the uniform case has already been discussed in section 3. In [115], the effects of a fully inhomogeneous magnetic field have been considered semi-analytically. The analysis of [115] was motivated by the results where, in a specific model, quite sizable large-scale magnetic fields could be obtained. In particular, the energy spectrum could be, in that case, quasi-flat, i.e. in the
notation of section 4, \( m \simeq -2.9 \). It was then noted that a rough limit on the magnetic field intensity could be obtained, i.e. \( B_L \lesssim 10^{-9} \) where we follow the notation of section 4 and take as comoving scale of regularization Mpc.

A semi-analytical analysis of the tensor and vector modes was performed in [72]. The authors discussed correctly two opposite regimes. In the case \( m < -3/2 \), the two-point function of the Lorentz force is dominated by the large-scale features of the magnetic field. In contrast, if \( m > -3/2 \) the two-point function of the Lorentz force is dominated by the high \( k \)-modes and hence by diffusion. In fact, the power spectrum of the Lorentz force term can be estimated as

\[
P(k) \simeq \frac{1}{\pi(2m+3)} \left( \frac{2\pi^{m+3}B_L^2}{\Gamma \left( \frac{m+2}{2} \right) \rho_y} \right)^2 \left[ \left( \frac{k_D}{k_L} \right)^{2m+3} \left( \frac{k}{k_L} \right)^3 + m \left( \frac{k}{k_L} \right)^{2m+3} \right],
\]

where \( k_D \) is the diffusion scale. The diffusion scale can be estimated, for instance, from the considerations of [16] where it was argued that the diffusion length scale is basically determined by the Alfvén velocity times the Silk length scale. From equation (5.76), we can see that the second term dominates for \(-3 < m < -3/2\) while the first term dominates for \( m > -3/2 \). For \( m = -3/2 \) both terms may be of the same order. Note that, in equation (5.76), \( k_L = 2\pi/L \) and \( L \) is the regularization length scale introduced at the end of the previous section (see equation (4.22)).

In [72] the TT, EE, TE and BB correlations\(^{15}\) for vector and tensor modes have been estimated semi-analytically. Using 10% estimates the authors of [72] obtain for \( m \sim -3 \) (e.g. \( m \sim -2.9 \)) a limit \( B_L \lesssim 7 \times 10^{-9} \) G. This type of limit becomes more stringent as \( m \) increases: for \( = 0 \) we have \( B_L \lesssim 10^{-10} \) G, while for \( m \gtrsim 2 \) we would have \( B_L \lesssim 10^{-13} \) G.

Recently in [111] the calculation of the vector and tensor modes has been pushed to \( \ell \sim 2000 \). It is clear from the reported results [111] that for a magnetic field with \( B_L \sim 10^{-9} \) G and \( m \sim -2.9 \) the TT correlations induced by the vector modes become of the same order to the TT power spectrum (in the absence of magnetic field) for \( \ell > 2000 \). Expected numerical disagreements with the semi-analytical estimates of [72] have also been found for \( \ell \gtrsim 100 \). In figure 5, the results obtained in the case of vectors for a typical magnetic field \( B_L \sim 3 \times 10^{-9} \) G are reported (see [110]).

Scalar modes have been less studied than the vector and tensor modes. The expectation is that scalar modes do not give stronger constraints than vectors or tensors. It would be, however, desirable to bring the analysis of the scalar problem to the same standard of ordinary CMB calculations where the adiabatic mode and the different isocurvature modes are constrained to a given confidence level. For instance, the results reported in [114] are difficult to interpret since bounds on the magnetic field intensity are claimed but the initial conditions for the analysis are not clearly specified.

### 5.5. Other effects

On top on the effects of large-scale magnetic fields on anisotropies there are effects directly connected with a CMB spectrum like the possible distortions. These have been studied in [117] (see also [118]). The possible distortions of the Planckian spectrum of CMB are usually discussed in terms of a chemical potential which is bounded, by experimental data, to \( |\mu| < 9 \times 10^{-5} \). Magnetic field dissipation at high redshift implies the presence of a chemical potential. Hence, bounds on the distortion of the Planckian spectrum of the CMB can be turned into bounds on the magnetic field strength at various scales. In particular, in [117] the

\(^{15}\) See the discussion in section 3 on the cross power spectra whose general definition is given in equation (3.66).
obtained bound is such that $B < 3 \times 10^{-8}$ G for comoving coherence lengths between 0.4 kpc and 500 kpc.

As in the case of synchrotron emission also Faraday rotation measurements can be used as a diagnostic for foreground contamination. The idea would be, in this context, to look for cross correlations in the Faraday rotation measure of extra-galactic sources and the measured microwave signal at the same angular position. A recent analysis has been reported [119] (see also [120–122]).

6. Concluding remarks

Simple logic dictates that if the origin of the large-scale magnetic fields is primordial (as opposed to astrophysical), it is plausible to expect the presence of magnetic fields in the primeval plasma also before the decoupling of radiation from matter. As was argued in the present topical review, CMB anisotropies are germane to several aspects of large-scale magnetization. CMB physics may be the tool that will finally enable us either to confirm or to rule out the primordial nature of galactic and cluster magnetic fields seeds. In the next 5 to 10 years the forthcoming CMB precision polarization experiments will be sensitive in various frequency channels between above 100 GHz and roughly below 900 GHz. The observations will be conducted both via satellites (such as the Planck satellite) and via ground-based detectors (such as in the case of the QUIET arrays). In a complementary view, the SKA telescope will provide full-sky surveys of Faraday rotation that may even get close to 20 GHz.

In an optimistic perspective the forthcoming experimental data together with the steady progress in the understanding of the dynamo theory will hopefully explain the rationale for the ubiquitous nature of large-scale magnetization. In a pessimistic perspective, the primordial nature of magnetic seeds will neither be confirmed nor ruled out. The plausibility of (highly speculative) theoretical scenarios for the origin of primordial magnetic fields cannot be decided only using the fertile imagination of theoretical physicists. It would be wiser, at the same time,
to adopt a model-independent approach by sharpening those theoretical tools that may allow, in the near future, a direct observational test of the effects of large-scale magnetic fields on CMB anisotropies.
