A Kubo-Greenwood-like equation for the Gilbert damping parameter $\alpha$ is presented that is based on the linear response formalism. Its implementation using the fully relativistic Korringa-Kohn-Rostoker (KKR) band structure method in combination with Coherent Potential Approximation (CPA) alloy theory allows it to be applied to a wide range of situations. This is demonstrated with results obtained for the bcc alloy system Fe$_x$Co$_{1-x}$ as well as for a series of alloys of permalloy with 5d transition metals. To account for the thermal displacements of atoms as a scattering mechanism, an alloy-analogy model is introduced. The corresponding calculations for Ni correctly describe the rapid change of $\alpha$ when small amounts of substitutional Cu are introduced.

I. INTRODUCTION

The magnetization dynamics that is relevant for the performance of any type of magnetic device is in general governed by damping. In most cases the magnetization dynamics can be modeled successfully by means of the Landau-Lifshitz-Gilbert (LLG) equation \cite{1} that accounts for damping in a phenomenological way. The possibility to calculate the corresponding damping parameter from first principles would open the perspective of optimizing materials for devices and has therefore motivated extensive theoretical work in the past. This led among others to Kambersky’s breathing Fermi surface (BFS) \cite{2} and torque-correlation model (TCM) \cite{3}, that in principle provide a firm basis for numerical investigations based on electronic structure calculations \cite{4, 5}. The spin-orbit coupling that is seen as a key factor in transferring energy from the magnetization to the electronic degrees of freedom is explicitly included in these models. Most ab-initio results have been obtained for the BFS model though the torque-correlation model makes fewer approximations \cite{4, 6}. In particular, it in principle describes the physical processes responsible for Gilbert damping over a wide range of temperatures as well as chemical (alloy) disorder. However, in practice, like many other models it depends on a relaxation time parameter $\tau$ that describes the rate of transfer due to the various types of possible scattering mechanisms. This weak point could be removed recently by Brataas et al. \cite{7} who described the Gilbert damping by means of scattering theory. This development supplied the formal basis for the first parameter-free investigations on disordered alloys for which the dominant scattering mechanism is potential scattering caused by chemical disorder \cite{8}.

As pointed out by Brataas et al. \cite{7}, their approach is completely equivalent to a formulation in terms of the linear response or Kubo formalism. The latter route is taken in this communication that presents a Kubo-Greenwood-like expression for the Gilbert damping parameter. Application of the scheme to disordered alloys demonstrates that this approach is indeed fully equivalent to the scattering theory formulation of Brataas et al. \cite{7}. In addition a scheme is introduced to deal with the temperature dependence of the Gilbert damping parameter.

Following Brataas et al. \cite{7}, the starting point of our scheme is the Landau-Lifshitz-Gilbert (LLG) equation for the time derivative of the magnetization $\vec{M}$:

\[
\frac{1}{\gamma} \frac{d\vec{M}}{d\tau} = -\vec{M} \times \vec{H}_{\text{eff}} + \vec{M} \times \left[ \frac{\vec{G}(\vec{M})}{\gamma^2 M_s^2} \frac{d\vec{M}}{d\tau} \right],
\]

where $M_s$ is the saturation magnetization, $\gamma$ the gyromagnetic ratio and $\vec{G}$ the Gilbert damping tensor. Accordingly, the time derivative of the magnetic energy is given by:

\[
\dot{E}_{\text{mag}} = \vec{H}_{\text{eff}} \cdot \frac{d\vec{M}}{d\tau} = \frac{1}{\gamma^2} \dot{\vec{m}} [\vec{G}(\vec{m}) \dot{\vec{m}}]
\]

in terms of the normalized magnetization $\vec{m} = \vec{M}/M_s$. On the other hand the energy dissipation of the electronic system $\dot{E}_{\text{dis}} = \left\langle \frac{d\vec{m}}{d\tau} \right\rangle$ is determined by the underlying Hamiltonian $\dot{H}(\tau)$. Expanding the normalized magnetization $\vec{m}(\tau)$, that determines the time dependence of $\dot{H}(\tau)$ about its equilibrium value, $\vec{m}(\tau) = \vec{m}_0 + \vec{u}(\tau)$, one has:

\[
\dot{H} = H_0(\vec{m}_0) + \sum_{\mu} \vec{u}_\mu \frac{\partial}{\partial \vec{u}_\mu} H(\vec{m}_0).
\]

Using the linear response formalism, $\dot{E}_{\text{dis}}$ can be written...
version of multiple scattering theory \[9\] that allows us to treat magnetic solids:

\[ G^+(\vec{r}_n, \vec{r}_m', E) = \sum_{\Lambda\Lambda'} Z_{\Lambda}^n (\vec{r}_n, E) \tau_{\Lambda\Lambda'}^m (E) Z_{\Lambda'}^{m*} (\vec{r}_m', E) \]

\[ - \sum_{\Lambda} Z_{\Lambda}\langle \vec{r}_n, E \rangle J_{\Lambda\Lambda}^{nm} (\vec{r}_m', E) \delta_{nm}. \quad (9) \]

Here coordinates \( \vec{r}_n \) referring to the center of cell \( n \) have been used with \( |\vec{r}_n| = \min(|\vec{r}_n|, |\vec{r}_n'|) \) and \( |\vec{r}_m'| = \max(|\vec{r}_n|, |\vec{r}_n'|) \). The four component wave functions \( Z_{\Lambda}^n (\vec{r}, E) \left( J_{\Lambda}^{n*} (\vec{r}, E) \right) \) are regular (irregular) solutions to the single-site Dirac equation for site \( n \) and \( \tau_{\Lambda\Lambda'}^m (E) \) is the so-called scattering path operator that transfers an electronic wave coming in at site \( m \) into a wave going out from site \( n \) with all possible intermediate scattering events accounted for coherently.

Using matrix notation, this leads to the following expression for the damping parameter:

\[ \alpha_{\mu\nu} = \frac{g}{\pi \mu_{\text{tot}}} \sum_n \text{Tr} \left( \hat{T}_{\mu}^{n0} \hat{T}_{\nu}^{n0} \right) \quad (10) \]

with the g-factor \( 2(1 + \mu_{\text{orb}}/\mu_{\text{spin}}) \) in terms of the spin and orbital moments, \( \mu_{\text{spin}} \) and \( \mu_{\text{orb}} \), respectively, the total magnetic moment \( \mu_{\text{tot}} = \mu_{\text{spin}} + \mu_{\text{orb}} \), and \( \tilde{Z}_{\Lambda\Lambda'}^n = 1 / \sum_{\Lambda} Z_{\Lambda}^n (\vec{r}_n, E) \left( \sum_{\Lambda'} J_{\Lambda\Lambda'}^{n*} (\vec{r}_m', E) \right) \delta_{mn} \) and the energy argument \( E \) omitted. The matrix elements of the torque operator \( T^{\mu\nu} \) are identical to those occurring in the context of exchange coupling \[11\] and can be expressed in terms of the spin-dependent part \( B \) of the electronic potential with matrix elements:

\[ T_{\mu\nu}^{nm} = \int d^3 r Z_{\Lambda\Lambda'}^{nm*} (\vec{r}) [\beta \sigma_{\mu} B_{\nu}(\vec{r})] Z_{\Lambda'}^{n*} (\vec{r}). \quad (11) \]

As indicated above, the expressions in Eqs. \([6] - [11]\) can be applied straightforwardly to disordered alloys. In this case the brackets \( \langle \ldots \rangle_c \) indicate the necessary configurational average. This can be done by describing in a first step the underlying electronic structure (for \( T = 0 \) K) on the basis of the Coherent Potential Approximation (CPA) alloy theory. In the next step the configurational average in Eq. \([7]\) is taken following the scheme worked out by Butler \[12\] when dealing with the electrical conducting at \( T = 0 \) K or residual resistivity respectively, of disordered alloys. This implies in particular that so-called vertex corrections of the type \( \left( T_{\mu} \text{Im} G^+ T_{\nu} \text{Im} G^+ \right)_c - \left( T_{\mu} \text{Im} G^+ \right)_c \left( T_{\nu} \text{Im} G^+ \right)_c \) that account for scattering-in processes in the language of the Boltzmann transport formalism are properly accounted for.

Thermal vibrations as a source of electron scattering can in principle be accounted for by a generalization of Eqs. \([6] - [11]\) to finite temperatures and by including the electron-phonon self-energy \( \Sigma_{el-ph} \) when calculating the Greens function \( G^+ \). Here we restrict ourselves to elastic scattering processes by using a quasi-static representation of the thermal displacements of the
At a given temperature $T$ the function $\alpha$ for $x \leq 0.7$. The calculated damping parameter $\alpha(x)$ for $T = 0$ K is found in very good agreement with the results based on the scattering theory approach [8] demonstrating numerically the equivalence of the two approaches. An indispensable requirement to achieve this agreement is to include the vertex corrections mentioned above. In fact, ignoring them leads in some cases to completely unphysical results. To check the reliability of the standard CPA, that implies a single-site approximation when performing the configurational average, we performed calculations on the basis of the non-local CPA [15]. In this case four atom cluster have been used leading - apart from the very dilute case - practically to the same results as the CPA. As found before for fcc Fe$_x$Ni$_{1-x}$ [8] the theoretical results for $\alpha$ reproduce the concentration dependence of the experimental data quite well but are found too low (see below). As suggested by Eq. 10 the variation of $\alpha(x)$ with concentration $x$ may reflect to some extent the variation of the average magnetic moment $\mu_{tot}$ of alloy. As the moments as well as the spin-orbit coupling strength of Fe and Co don’t differ too much, the variation of $\alpha(x)$ should be determined in the concentrated regime primarily by the electronic structure at the Fermi energy $E_F$. 

As Fig. 1 shows, there is indeed a close correlation of the density of states $n(E_F)$ that may be seen as a measure for the available relaxation channels.

While the scattering and linear response approach are completely equivalent when dealing with bulk alloys the latter allows us to perform the necessary configuration averaging in a much more efficient way. This allows us to study with moderate effort the influence of varying the alloy composition on the damping parameter $\alpha$. Corresponding work has been done in particular using permalloy as a starting material and adding transition metals (TM) [10] or rare earth metals [17]. Fig. 2 (top) shows results obtained by substituting Fe and Ni atoms in permalloy by 5d TM. As found by experiment [16] $\alpha$ increases in all cases nearly linearly with the 5d TM content. The total damping for 10% 5d TM content shown in the middle panel of Fig. 2 varies roughly parabolically over the 5d TM series. In contrast to the Fe$_x$Co$_{1-x}$ alloys considered above, there is now an S-like variation of the moments $\mu_{spin}^{5d}$ over the series (Fig. 2 bottom), characteristic of 5d impurities in the pure hosts Fe and Ni [18, 19]. In spite of this behaviour of $\mu_{spin}^{5d}$ the variation

FIG. 1: Gilbert damping parameter for bcc Fe$_x$Co$_{1-x}$ as a function of Co concentration: full circles - the present results within CPA, empty circles - within non-local CPA (NL CPA), and full diamonds - experimental data by Oogane [14].

FIG. 2: Top: Change of the Gilbert damping parameter $\Delta \alpha$ w.r.t. permalloy (Py) for various Py/5d TM systems as a function of 5d TM concentration; Middle: Gilbert damping parameter $\alpha$ for Py/5d TM systems with 10% 5d TM content in comparison with experiment [16]; Bottom: spin magnetic moment $n_{spin}^{5d}$ and density of states $n(E_F)$ at the Fermi energy of the 5d component in Py/5d TM systems with 10% 5d TM content.
of $\alpha(x)$ seems again to be correlated with the density of states $n_5d(E_F)$ (Fig. 2 bottom). Again the trend of the experimental data is well reproduced by the theoretical ones that are however somewhat too low.

One of the possible reasons for the discrepancy of the theoretical and experimental results shown in Figs. 1 and 2 might be the neglect of the influence of finite temperatures. This can be incorporated as indicated above by accounting for the thermal displacement of the atoms in a quasi-static way and performing a configurational average over the displacements using the CPA. This leads even for pure systems to a scattering mechanism and this way to a finite value for $\alpha$. Corresponding results for pure Ni are given in Fig. 3 that show in full accordance with experiment a rapid decrease of $\alpha$ with increasing temperature until a regime with a weak variation of $\alpha$ with $T$ is reached. This behavior is commonly interpreted as a transition from conductivity-like to resistivity-like behaviour reflecting the dominance of intra- and inter-band transition, respectively [3], that is related to the increase of the broadening of electron energy bands caused by the increase of scattering events with temperature. Adding only less than 1 at. % Cu to Ni, the conductivity-like behavior at low temperatures is strongly reduced while the high temperature behavior is hardly changed. A further increase of the Cu content leads to the impurity-scattering processes responsible for the band broadening dominating $\alpha$. This effect completely suppresses the conductivity-like behavior in the low-temperature regime because of the increase of scattering events due to chemical disorder. Again this is fully in line with the experimental data, providing a straightforward explanation for their peculiar variation with temperature and composition.

From the results obtained for Ni one may conclude that thermal lattice displacements are only partly responsible for the finding that the damping parameters obtained for Py doped with the 5d TM series, and Fe$_x$Co$_{1-x}$ are somewhat low compared with experiment. This indicates that additional relaxation mechanisms like magnon scattering contribute. Again, these can be included at least in a quasi-static way by adopting the point of view of a disordered local moment picture. This implies scattering due to random temperature-dependent fluctuations of the spin moments that can also be dealt with using the CPA.

In summary, a formulation for the Gilbert damping parameter $\alpha$ in terms of a torque-torque-correlation function was derived that led to a Kubo-Greenwood-like equation. The scheme was implemented using the fully relativistic KKR band structure method in combination with the CPA alloy theory. This allows us to account for various types of scattering mechanisms in a parameter-free way. Corresponding applications to disordered transition metal alloys led to very good agreement with results based on the scattering theory approach of Brataas et al. demonstrating the equivalence of both approaches. The flexibility and numerical efficiency of the present scheme was demonstrated by a study on a series of permalloy-5d TM systems. To investigate the influence of finite temperatures on $\alpha$, a so-called alloy-analogy model was introduced that deals with the thermal displacement of atoms in a quasi-static manner. Applications to pure Ni gave results in very good agreement with experiment and in particular reproduced the dramatic change of $\alpha$ when Cu is added to Ni.
