Abstract

Microbialites accrete where environmental conditions and microbial metabolisms promote lithification, commonly through carbonate cementation. On Little Ambergris Cay, Turks and Caicos Islands, microbial mats occur widely in peritidal environments above ooid sand, but they do not become lithified or preserved. Sediment cores and porewater geochemistry indicate that aerobic respiration and sulfide oxidation inhibit lithification, dissolving calcium carbonate sand despite widespread aragonite precipitation from platform surface waters. In tidally pumped environments, primary productivity and respiration can negate the effects of taphonomically-favorable seawater chemistry on carbonate mineral saturation and microbialite development.

Main Text

Microbialites—sedimentary rocks with fabric that reflects the influence of benthic microbial communities—capture biogeochemical interactions between microbes and their environment throughout Earth’s history e.g., 2,3. Microbial mats are often considered steady-state ecosystems whose constituents consume each other’s metabolic products4. To be preserved as microbialites, organic trapping and binding of sediment alone is insufficient because eventually organisms in the lower parts of the mat consume the material binding grains5. Canonically, then, propitious microbial metabolisms drive microbialite formation by promoting authigenic cementation e.g., 6,7. Lithification occurs most readily where microbial processes within the mat locally increase carbonate mineral saturation, typically in environments where photosynthesis exceeds respiration and fermentation rates8–10. However, microbial metabolisms that inhibit lithification can only do so by consuming the products of other metabolisms that promote lithification—at worst, there can be no net diminishment of favorable ambient conditions for lithification. Microbial mats often grow in environments otherwise characterized by widespread carbonate precipitation, so why do they rarely form microbialites? We find insight into this apparent paradox on Little Ambergris Cay, Turks and Caicos Islands, where the net metabolic activity of widespread microbial mats inhibits—rather than promotes—lithification.

Little Ambergris Cay formed in the lee of Big Ambergris Cay at the eastern end of a 20 km-long ooid shoal, near the eastern margin of the Caicos platform (Fig. 1a)11–14. The shoal is characterized by well sorted medium sand-sized ooids with hardgrounds, grapestone sand, and cemented intraclasts on its northern flank11,15–17. Little Ambergris Cay (Fig. 1b) grew through shoreface accretion of ooid sand18. Eolian ridges rim a shallow interior basin that contains sand flats with widespread microbial mats (Fig. 1c)11,18–22. Foreshore and interior basin sands are less well sorted and contain more skeletal allochems than the shoal, especially where concentrated in tidal lags15,16,18.

Three microbial mat types occur in the interior basin: smooth mats, tufted polygonal mats, and colloform blister mats18,19. In the shallowest subtidal parts of the interior basin, smooth mats form pigmented mucilaginous blankets covered in beige extracellular polymeric substances (Fig. 1d). On intertidal sand
flats and around mangrove thickets, polygonal mats form dark green decimeter-scale domal biscuits, often with millimeter-scale dark gray-green filamentous tufts (Fig. 1e). In supratidal environments on interior flanks of the eolian ridges, blister mats form centimeter-scale fenestral dark green to gray colloform bumps (Fig. 1f). Discontinuous crusts less than 1 cm thick underlie some mats, but many mats grow on poorly cohesive ooid sand. The upper few millimeters of ooid sands are often stabilized by microbial communities that may desiccate to form the crusts or be dislodged to form flat, angular intraclasts. All three mat types contain similar microbial communities, indicating that their textures reflect environmental controls more so than taxonomy\textsuperscript{18–21}. The mats contain benthic foraminifera and cerithid gastropods (Fig. 1f), and calcareous (e.g., \textit{Halimeda} and \textit{Penicillus}) and non-calcareous algae (e.g., \textit{Bataphora}) live in subtidal portions of the interior basin.

**SEDIMENTS BENEATH MICROBIAL MATS**

Eight vibracores (Fig. 1b) were collected across Little Ambergris Cay in August 2017. Vibracores, up to 3 m long, included active microbial mats up to 12 cm thick (Fig. 2a) above ooid sand with lesser skeletal sand to gravel and ooid grainstone intraclasts (Fig. 2b). Skeletal material was predominately disarticulated and/or fragmented coralline red algae, calcareous green algae (mainly \textit{Halimeda}), cerithid gastropods, venerid and arcoid bivalves, benthic foraminifera, and serpulid worm tubes. Ooid grainstone intraclasts included angular, flat 1 to 4 cm flakes and rounded 3 to 5 cm nodules preserving cm-scale burrows and macroalgal holdfasts. Muddy ooid or foraminiferal sand layers represented less than 5% of the sediment and were 1 to 5 cm thick. Below about 1 m, the cores were partially indurated, occasionally preserving burrows, holdfasts, and ripple cross lamination (Fig. 2c). In thin sections, ooid-skeletal sand was heavily microbored and displayed pervasive fabrics indicative of dissolution, including solution-enlarged microbores, irregular grain boundaries, and selective leaching of micrite envelopes and micritized borings (Fig. 2d). Calcium carbonate $\delta^{13}$C values in the sediment ranged from 3.8 to 5.2‰ and increased with depth in the uppermost 50 cm of the cores.

Apart from the active mats at core tops, organic material was mainly limited to rare plant debris. Beneath blister mats on the edge of a tidal channel (core VC-05), we found a single occurrence of faintly laminated organic material in a 2 cm-thick, tan, muddy ooid-cerithid gastropod layer at 60 cm depth (Fig. 2e). This material displayed characteristic spectral features of chlorophyll $a$ and bacteriochlorophyll $a$ pigments—two main light-gathering pigments seen in the polygonal mats\textsuperscript{18}.

An isolated occurrence of calcified, decimeter-scale bulbous domes was found rimming a 1.4 m-deep pond in the accretionary beach ridges on the windward facing southern part of Little Ambergris Cay (Fig. 2f). The pond, surrounded by shrubland vegetation, was filled with tannic, salinity-stratified (43 to 48 ppt), hypersaline water. The domes comprised centimeter-thick fenestral palisades of carbonate-coated filaments and mangrove leaves (Fig. 2g). These mineralized bulbous domes were unlike any of the three mat textures elsewhere on the island. Decaying microbial mats were observed in summer 2016 but were not present when the crusts were resampled in 2017; nearby ponds did contain active mats.
POREWATER GEOCHEMISTRY

Porewater was sampled from 3 vibracores situated in low supratidal polygonal mats (VC-01), intertidal polygonal mats (VC-03), and a subtidal, muddy Batophora algal substrate (VC-04). Stations for groundwater sampling at low and high tide were installed across a tidal bar and channel (Fig. 1b) at 0.2, 0.5, and 1 m depths. Water was also sampled at 7 depths from the hypersaline pond at the southern end of the cay (Fig. 1b). Porewaters, groundwaters, and pond waters ranged from normal marine to hypersaline (34 to 50 ppt), and evaporation factors relative to platform seawater, calculated from chlorinity data, ranged from 1 to 2.4 (Fig. 3). The highest evaporation factors were observed in the supratidal core, VC-01. Groundwater was salinity-stratified at high tide, with ca. 40 ppt water at 1 m below the surface. At low tide, groundwater was temperature-stratified, as surface waters warmed above 33°C while water at 1 m depth only warmed to 29°C.

DIC and alkalinity ranged from seawater concentrations (ca. 2.1 mmol/kg) to 6.01 mmol/kg in the pond surface water and to 10.81 mmol/kg in porewater (Fig. 3). Chloride-normalized sulfate concentrations ranged from 17% lower to 18% higher than seawater, and sulfide concentrations were up to 1.76 mM. Porewater DIC δ¹³C values increased with depth from -6.1‰ to 0.5‰. Groundwater and pond DIC δ¹³C values also increased with depth, but uppermost water was about -2‰. Calculated aragonite saturation states (Ω) in intertidal cores were less than 2.5 but exceeded 6 in the supratidal core. In the pond, Ω generally decreased with depth from 18.8 to 2.2. Groundwater chemistry varied substantially through a tidal cycle, with transient aragonite saturation indices as low as 0.1 and as high as 17.

CONTROLS ON MAT PRESERVATION

The Caicos platform exhibits widespread inorganic precipitation as ooids and hardgrounds and has surface seawater supersaturated with respect to aragonite¹¹,¹⁵,¹⁷. These conditions should permit cementation that would preserve microbial mat textures throughout the interior basin, but the microbial mats remain un lithified. The thin muddy layer with poorly preserved, pigmented, laminated organic material—likely a decaying, buried mat—did not capture residual textures that would be identifiable in a microbialite (Fig. 2e). Cored sediments were compositionally similar to the ooid-skeletal sand to gravel found on the open shoal and shoreface environments around Little Ambergris Cay, but the presence of minor amounts of mud in some intervals (Fig. 2e and Supporting Information) indicated that sedimentary textures developed in an episodically lower-energy environment. Angular crust intraclasts, cerithid gastropods, and minor mangrove debris—features unique to the interior basin—were found throughout the cores. This indicates that cored ooids formed in a shoreface or shoal environment and were transported to and reworked in a restricted environment by storms, tidal currents, and bioturbation. The modern interior basin environment is dominated by mats, so we infer that mats were present in the past but not preserved beyond the rare horizons of decaying organic material. We cannot resolve when mats first colonized Little Ambergris Cay, nor predict if a future sedimentary package might preserve a facies change from massive ooid-skeletal grainstone to one more diagnostic of mat colonization. Nonetheless, lithification of the extant mats is inhibited and therefore their preservation is unlikely.
Two synergistic processes limit lithification in the shallowest subsurface: efficient organic matter decay and tidal pumping of oxidants and dissolved organic matter. Aerobic respiration and oxidation of sulfide to sulfate decrease $\Omega$ by adding DIC, removing alkalinity, or both. In response to this, aragonite sand dissolves, adding DIC and alkalinity to subsurface waters until porewaters reach aragonite saturation (Fig. 4a). Tidal pumping enables net aragonite dissolution (Fig. 3d). At low tide, sulfate reduction occurs beneath a thermally stratified upper groundwater lid, and groundwater seepage of saline, sulfidic water with high $\Omega$ emerges in tidal channels. At high tide, seawater seeps into the shallow subsurface, oxidizing sulfide and driving aragonite undersaturation. In core porewaters, sulfate depletions relative to chlorinity represent net microbial sulfate reduction in excess of the observed sulfide concentrations. In iron-poor carbonate sediments, most of the sulfide produced is reoxidized. Sulfate excesses of up to 18% indicate that sulfide is not always reoxidized in situ. Mangrove root xylem tissue on Little Ambergris Cay contains sulfate with $^{34}S/^{32}S$ nearly 30‰ lower than that of seawater sulfate, suggesting that the oxygenic mangrove roots facilitate sulfide oxidation in the groundwater. Sulfidic groundwater dynamics on Little Ambergris Cay therefore differ from those in euxinic tidal ponds in fine-grained sedimentary environments, in which the delivery of oxidants are limited by diffusion and consequently the fraction of sulfide that is reoxidized is low.

Carbon isotope measurements provide a means to identify the carbon sources in groundwater. Inorganic carbon sources in this system include seawater DIC that has a $\delta^{13}C$ value of ~0.85‰, ooid sand that has a $\delta^{13}C$ value of ~5‰, and atmospheric CO$_2$ that has a $\delta^{13}C$ value of ~-8‰. Organic matter in the microbial mats has a $\delta^{13}C$ value of ~-13‰. In the shallowest porewater, which had the lowest DIC $\delta^{13}C$ values (Fig. 4c), carbon isotope mass balance dictates that about half of the DIC derived from remineralized organic material and the remainder from subequal parts seawater and dissolved carbonate, consistent with the stoichiometry of respiration-driven dissolution driven by complete oxidation of organic matter to CO$_2$ (Fig. 4b). Slightly lower $\delta^{13}C$ values of carbonate sand within the uppermost 50 cm of cored sediments (Fig. 3) additionally suggest that a low $\delta^{13}C$ phase may precipitate in the shallowest sediments and/or preferentially dissolve at depth; this may be selective dissolution of micrite envelopes and solution enlargement of microbores (Fig. 2d and Supplemental Information).

Porewater compositions evolved with depth from the shallow endmember (comprised of DIC from respired organic matter and respiration-driven dissolution of aragonite) towards a mixture of seawater and a high DIC endmember (10.8 mmol/kg) that has a $\delta^{13}C$ value of -1.25‰ (Fig. 4c). Groundwater salinities were normal marine to hypersaline (Fig. 3), indicating that atmospheric CO$_2$ dissolved in fresh, meteoric water did not drive significant dissolution or contribute measurably to the subsurface DIC inventory. Similarly, seawater-derived DIC would have had to have been concentrated nearly three-fold by evaporation for its admixture to satisfy the groundwater $\delta^{13}C$ composition without additional organic carbon or dissolved carbonate input, but no such high-salinity waters were observed (Fig. 3). Thus, further dissolution of carbonate sand in the subsurface below the mats contributed to the DIC with high $\delta^{13}C$ values.
The stoichiometry of respiration-driven dissolution makes the prediction that the deep groundwater in equilibrium with aragonite should have nearly 50% of the DIC from respired carbon (Fig. 4a), but the DIC $\delta^{13}C$ budget indicates that only approximately 30% of DIC derived from respired organic matter (Fig. 4d). To reconcile this, carbon must leak out of the subsurface. For example, incomplete oxidation of butyrate or lactate by sulfate reducing microorganisms produces acetate and sulfide (Fig. 4b). These organic acids could flush out during ebb tides but would not oxidize as readily as the sulfide during tidal inundation with oxic waters—a process that occurs rapidly even in the absence of microbial catalysis. This leak of partially oxidized, dissolved organic material out of the Little Ambergris system was observed as plumes of brown, tannic groundwater seeping from tidal channels (Supplemental Information).

**MICROBIALITE TAPHONOMIC BIAS**

Across the vast majority of Little Ambergris Cay, expansive mats developed throughout the island interior do not lithify despite widespread inorganic precipitation of ooid sand, crusts, and hardgrounds. Over the entirety of the island’s surface and subsurface ecosystem, microbial processes result in net dissolution that inhibits preservation of mats—and, in fact, dissolves both autochthonous and allochthonous carbonate—regardless of any microbial processes within the mats that may modulate calcium carbonate precipitation. In other words, the microbes in very shallow groundwater, especially sulfate reducing organisms, interact with the mats and ultimately limit their organic preservation or lithification.

To drive lithification, processes such as evaporation or photosynthesis must create enough carbonate mineral supersaturation that cement precipitation rates exceed the rate saturation is decreased by aerobic respiration and sulfide oxidation to sulfate $^{7,30}$. Little Ambergris Cay is dominated by these processes inhibiting lithification—facilitated by tidal advection—that result from this microbial ecosystem’s high gross productivity but low net productivity. Microbial processes that might have aided carbonate precipitation (e.g., oxygenic photosynthesis and anaerobic respiration) create products (e.g., organic matter and sulfide) that enable net dissolution. This results in interior basin surface waters that have lower aragonite saturation states (4.3) than the surrounding platform waters (4.5 – 5.6), in spite of higher salinities and extensive benthic photosynthesis $^{15}$. Consequently, the thick, luxuriant mats present across Little Ambergris Cay are not preserved in the subsurface. Perhaps unsurprisingly, ancient carbonate rocks rarely contain evidence for textures that look like lithified microbial peats $^{31}$. From the perspective of preservation, a robust microbial ecosystem can be too much of a good thing—fueling rapid respiration and preventing early lithification.

Given a certain carbonate mineral saturation state as a boundary condition, factors that would promote microbialite preservation include higher organic carbon burial efficiency, less dioxygen delivery, or more iron (permitting sulfide removal as pyrite). The limited encrusted domes along the pond rim (Fig. 2f), interpreted as lithified mats, provide an important example. Recalcitrant plant material in the pond may decay more slowly than the microbial mats, or saline, turbid conditions in the pond may limit robust mat growth and respiration compared to the interior basin. Incomplete respiration of organic matter and
diminished tidal advection permit calcification to proceed. Similarly, sediment-rich mats, such as those forming subtidal stromatolites in other Bahamian tidal channels, may also have less productivity and slower respiration, allowing ambient conditions to control lithification6,9.

Seafloor cementation and sediment trapping and binding have demonstrable roles in microbialite formation. While microbial mats are the sine qua non of microbialites, our observations suggest that mat productivity also influences preservation. Mats in sandy, high-energy depositional environments with permeable sediments and advective water fluxes that supply plentiful dioxygen may be especially prone to decay. Somewhat paradoxically, perhaps the most productive past mats are rare or absent in the rock record.

Declarations

ACKNOWLEDGEMENTS

We thank the Agouron Institute and Simons Collaboration on the Origins of Life for funding; the Turks and Caicos Islands Department of Environment and Coastal Resources for Scientific Research Permit 17-06-02-12; the Tarika family, P. Mahoney, J. Seymour, and J. Grancich for logistical support; A. Simms and L. Reynolds for coring advice; K. Dawson, G. Ames, F. Wu, A. Kupfer-Harris, and D. Brenner for lab and analytical support; and J. Alleon, A. Bahniuk, H. Grotzinger, K. Metcalf, D. Morris, E. Orzechowski, D. Quinn, C. Sanders, E. Sibert, and J. Strauss for assisting fieldwork. Methods

Vibracores were obtained by clamping 10 ft. core barrels (3" OD, 0.083" wall thickness aluminum 6063 irrigation tubing) to a concrete vibrator (Oztec H2500Z 2.5" x 13" steel pencil head) driven by a portable gasoline motor (Honda GX-160, 5.5 hp) with an 18 ft. flexible shaft (Oztec FS180Z). The vibrating barrels were sunk into the sediment by a team of handlers using guide ropes tied to the top of the barrel and
sealed with a 3” gripper plug prior to recovery. No core catchers were used, and core recovery in the grainy, non-cohesive sediments was maximized by rapidly pulling the cores from the ground without mechanical assist. Core compaction and recovery were calculated from measurements of core barrel penetration, depth of core top prior to gripper plug emplacement, and length of recovered sediment (Supplemental Table 1). Recovered cores were laid flat, excess barrel length removed with a reciprocating saw, and sealed with low-density polyethylene pipe covers (Caplugs SC-3 sleeve caps) and electrical tape.

At each groundwater sampling station, 3/8” polyvinyl chloride tubing (1/4” ID, McMaster-Carr Masterkleer 5233K56) with 60 µm polyester filter fabric (McMaster-Carr Ultra-thin Filter Fabric 92255T72) covering the buried end was set to a depth of 20 cm, 50 cm, and 100 cm. Surface water and water from each tube at each depth was sampled at both low and high tide with a hand-operated vacuum pump. Tubing was also suspended over a hypersaline pond at the southern end of the cay at 0, 20, 40, 60, 80, 100, and 140 cm depths to sample the water column geochemical structure. Porewaters from vibracores were pulled into syringes from porous ceramic water samplers (Rhizosphere Rhizon CSS 19.21.23F) inserted into holes drilled through the core casing at 3 to 10 cm intervals.

Porewaters, groundwaters, and pond waters were aliquoted through 0.2 µm syringe filters into vials for geochemical analyses. Approximately 10 mL were dispensed into plastic tubes for temperature, pH, and salinity measurement and discarded. Temperature and pH were measured by an electrode (WTW 3310 pH meter with SenTix 41 pH probe) calibrated with NBS buffers daily at pH 4, 7, and 10. Salinity was estimated with an optical refractometer (ATAGO S-28E). Two mL were dispensed into microcentrifuge tubes with 100 µL of 3% zinc acetate for sulfate and sulfide concentration measurement, 4 mL were dispensed into borosilicate glass vials with conical polypropylene-lined caps for titration of total alkalinity, and 1 mL was dispensed via a needle into helium-flushed 12 mL borosilicate vials (Labco Exetainer 9RK8W) with 100 µL of 42% H$_3$PO$_4$ and sealed with chlorobutyl septa (Labco VW101) for determination of dissolved inorganic carbon (DIC) concentration and carbon isotopic composition. Following pore fluid sampling, cores were split with a circular saw on a jig with the blade depth set to the tube wall thickness, followed by a wire to split the sediment into even halves. Graphic logs of vibracore sedimentology, prepared with Sedlog$^{32}$, are shown in the Supplemental Information.

DIC concentrations and δ$^{13}$C values were determined using a Thermo Fisher Scientific Gasbench II and Thermo Scientific Delta V Plus continuous flow mass spectrometer$^{33}$ with an 88% He dilution of headspace CO$_2$. Concentrations were determined from a bicarbonate solution calibration curve, and carbon isotopic compositions determined with three in-house calcite reference materials used for detector linearity and drift correction. Precision and accuracy of DIC concentrations were determined with Dickson seawater reference material, and of δ$^{13}$C with a fourth in-house carbonate reference material. DIC concentration precision was between 1% and 5% (1 relative standard deviation [s.d.]) and δ$^{13}$C precision between 0.03‰ and 0.1‰ (1 s.d.).

Total alkalinity was determined by Gran titration at Caltech using a Metrohm 907 Titrando$^{34,35}$. Samples were diluted to a total volume of 16 mL and then titrated using 0.01 mL injections of 0.025 M HCl.
Measurement accuracy was monitored using both Dickson seawater reference material and an in-house standard composed of 19.148 meq/kg NaHCO$_3$ solution in 0.5 N NaCl. Replicate measurements of a 1.310 meq/kg total alkalinity artificial seawater standard were used to assess acid and electrode drift. Reproducibility was 0.15% (1 relative s.d.), corresponding to less than 28 µeq/kg for field samples and the high-alkalinity in-house standard and 2 µeq/kg for Dickson seawater.

Aragonite saturation states were calculated from DIC and alkalinity measurements using a MATLAB implementation of CO2SYS$^{36,37}$. Measured temperatures and salinities were used when available or approximated from nearby data as described in the Supplemental Data. Aragonite saturation indices, $\Omega$, were calculated from the temperature and salinity-dependent stoichiometric solubility product, $K_{sp}^*$, as $[\text{Ca}^{2+}][\text{CO}_3^{2-}]/K_{sp}^*$ by assuming that calcium is conservative with salinity; $\Omega = 1$ at aragonite saturation. This treatment neglected non-conservative deviations in the calcium ion concentration, such as due to carbonate precipitation or dissolution.

Sulfate and chloride concentrations were determined on an ion chromatograph (Dionex DX-120). Standards were prepared by dilution of Multi Ion anion IC standard solution in H$_2$O (Dionex Specpure 35565). Precision was 0.5% (1 relative s.d.) for sulfate and 0.7% (1 relative s.d.) for chloride based on replicate measurements.

Sulfide concentrations were determined spectrophotometrically via the Cline method$^{38}$. Sulfide standards were made on the day of analysis by dissolving sodium sulfide nonahydrate and zinc chloride in water deoxygenated by purging with N$_2$ gas and stored on ice. Samples were diluted with deoxygenated water and stored on ice. Sulfide reagents (LaMotte 3654-01-SC Sulfide Test) were mixed immediately prior to addition. Absorbances were measured at 670 nm on a Thermo Scientific Genesys 10S UV-Vis Spectrophotometer. Precision was 5% (1 relative s.d.) based on replicate measurements.

For carbonate mineral $\delta^{13}$C and $\delta^{18}$O analyses, carbonate grains from 2 to 4 g of sediment were sieved to <250 µm, rinsed with deionized water, and dried overnight in a 50 – 80 °C oven. Ooids were picked from bulk sediment under a dissecting microscope. Samples of both sieved, washed bulk sediment and the ooid fraction were powdered and 250 – 350 µg were placed into 12 mL round-bottom borosilicate vials (Labco Exetainer 938W), which were subsequently flushed with helium. Carbon dioxide was generated by reaction with 100 µL >100% H$_3$PO$_4$ at 25°C in a Thermo Fisher Scientific GasBench II heating block at 30°C overnight. $\delta^{13}$C and $\delta^{18}$O compositions were determined on a Thermo Scientific MAT253 gas isotope ratio mass spectrometer in continuous flow mode relative to in-house standards calibrated to NBS-18 and IAEA-603. Reproducibility was better than 0.1‰ for $d^{13}$C values and 0.2‰ for $d^{18}$O values based on replicate measurements of standards.

![Figure 1](image-url)
Microbial mats and their environment on Little Ambergris Cay. (a) Caicos platform and its location in the southeastern Bahamian archipelago (inset). Satellite imagery from Google Earth23. (b) Little Ambergris Cay drone orthomosaic18 marked with core, pond, and groundwater sampling locations. (c) Aerial view southeast over interior basin rimmed by eolian grainstone ridge at the eastern end of Little Ambergris Cay. (d) Shallowest subtidal smooth mats on the edge of a tidal creek. (e) Intertidal polygonal mats. (f) Supratidal and upper intertidal blister mats with cerithid gastropods. Scales in top panels of d-f are 15 cm.
Figure 2

Sediments associated with microbial mats and crusts. (a) Top of core VC-03 with polygonal microbial mat overlying ooid-skeletal sand with cerithid gastropods (black arrows) and bivalve fragments (white arrows). (b) VC-03 consists of ooid-skeletal sand throughout its 223 cm length. (c) Nodule in partially indurated interval of core VC-03 at 178 cm preserving small burrows and ripple cross-lamination. (d) Plane-polarized light photomicrograph showing dissolution features in ooid-Halimeda sand in VC-03 at 150 cm. (e) Laminated organic material interpreted as a decaying mat in VC-05 at 60 cm, and thin mud-rich interval at 42 cm. (f) Calcifying mats (arrows) along the rim of the hypersaline pond. Researcher for scale. (g) Mineralization of mangrove leaves and filaments in the calcified mats rimming the pond.
Figure 3

Geochemical data and graphic logs showing the effects of tidal pumping and biogeochemical processes on aragonite saturation. Additional logs from cores without porewater sampling are in the Supplemental Information. (a) Core VC-01, situated in low supratidal polygonal mats on the flank of the eolian grainstone berm. (b) Core VC-03, located in intertidal polygonal mats near a mangrove thicket. (c) Core VC-04, situated in a subtidal, muddy Batophora algae patch. (d) Low and high tide structure of groundwater temperature, salinity, aragonite saturation, and sulfate anomaly at the interior basin inlet on southwestern side of cay.
Figure 4

Processes that impact shallow subsurface carbonate mineral saturation and drive dissolution. (a) DIC and alkalinity data show that dissolution of ooid-skeletal sand contributed to increasing groundwater carbon content and maintained aragonite saturation. If respiration-driven dissolution occurred by completely oxidizing organic matter, the highest DIC groundwater must have ~5 mmol/kg of respired carbon. Symbols colored by depth on scale shown in panel (c). (b) Geochemical reactions that may non-uniquely sum to produce the DIC and alkalinity relationship observed. (c) DIC concentration and DIC $\delta^{13}$C data show that core tops are dominated by DIC from respired organic material and core bottoms contain increasing amounts of DIC from dissolved aragonite sand. (d) Ternary diagram of inorganic carbon sources in the highest DIC groundwater (10.8 mmol/kg), which has a $\delta^{13}$C value of -1.25‰. It cannot have more than ~30% contribution from seawater DIC without exceeding observed salinities (white breaks in the color scale), so isotope mass balance indicates that it cannot have more than about 30% (~3 mmol/kg) contribution from respired carbon. This discrepancy with the stoichiometry of respiration-driven dissolution in panel (a) implicates a leak of unoxidized organic matter.
