ABSTRACT

We present simultaneous 0.65-2.5 \( \mu m \) mid-resolution (3300 ≤ \( R_L \) ≤ 8100) VLT/X-Shooter spectra of the young low-mass (19 ± 5M\textsubscript{Jup}) L-T transition object VHS 1256-1257 b, a known spectroscopic analogue of HR8799d. The companion is a prime target for the JWST Early Release Science (ERS) and one of the highest-amplitude variable brown-dwarfs known to date. We compare the spectrum to the custom grids of cloudless ATMO models exploring different atmospheric composition with the Bayesian inference tool ForRoSA. We also re-analyse low-resolution HST/WFC3 1.10-1.67 \( \mu m \) spectra at minimum and maximum variability to contextualize the X-Shooter data interpretation. The models reproduce the slope and most molecular absorption from 1.10 to 2.48 \( \mu m \) self-consistently but fail to provide a radius consistent with evolutionary model predictions. They do not reproduce consistently the optical spectrum and the depth of the K I doublets in the J-band. We derive \( T_{\text{eff}} \) = 1380±54 K, log(g) = 3.97±0.48 dex, [M/H] = 0.21±0.29, and C/O > 0.63. Our inversion of the HST/WFC3 spectra suggests a relative change of 27\% of the disk-integrated \( T_{\text{eff}} \) correlated with the near-infrared brightness. Our data anchor the characterization of that object in the near-infrared and could be used jointly to the ERS mid-infrared data to provide the most detailed characterization of an ultracool dwarf to date.

Key words. Planets and satellites: atmospheres, composition, individual: VHS J125601.92-125723.9; Techniques: spectroscopic

1. Introduction

Direct imaging and interferometry can yield high quality spectra of young (5-200 Myr) planets made of tens to thousands of data-points in a few hours of telescope time (Biller & Bonnefoy 2018). About a dozen of exoplanets have been directly characterized. The majority occupy a slightly distinct space compared to the well defined sequence of mature field M, L, and T brown dwarfs indicative of different physical and atmospheric properties.

Since 2001, a few tens of free-floating objects sharing the same age and mass range as imaged exoplanets have also been identified in young star forming regions (Lucas et al. 2001) and more recently in young nearby associations where most imaged exoplanets are identified (e.g. Faherty et al. 2016, and ref. therein). They are seconded by a population of ultrawide orbit (≥ 100 au) companions to low-mass stars sharing the same properties (e.g., Béjar et al. 2008; Naud et al. 2014; Artigau et al. 2015). Contrary to imaged planets blurred into the stellar halo, these objects can be characterized at high signal-to-noise (S/N) with seeing-limited spectrographs over a broad spectral range. They have been found to be precious empirical templates to imaged exoplanets having similar placements in color-magnitude diagrams and spectral features at low-resolving powers (e.g., Bonnefoy et al. 2010; Chilcote et al. 2017; Chauvin et al. 2017).

The so-called L–T transition is evidenced by a sharp bluering of near-infrared colors thought to appear at nearly-constant effective temperatures in mature field dwarfs (Filippazzo et al. 2015). The transition appears to be even more extreme for young objects, which are redder and underluminous by up to a few magnitudes compared to mature field dwarf counterparts. Sophisticated models of clouds of different compositions (silicates, sulfites...) have been considered for more than a decade to establish the basis of our understanding of atmospheric physics and reproduce the collected spectra. Although they manage to reproduce the spectra of massive late-M to early-L type young brown dwarfs and exoplanets well, they fail to fit the luminosity and the spectra of cooler L–T transition planets (Bonnefoy et al. 2016). The problem likely arises from uncertainties in the cloud model itself in terms of composition, particle size and density, and also possible cloud deck inhomogeneity. The modification of the cloud vertical and cloud particle distribution is corroborated by recent variability studies that show higher-amplitude variability in young L dwarfs than old ones (Metchev et al. 2015; Manjavacas et al. 2018). Additional processes such as disequilibrium chemistry (Skemer et al. 2014) and related thermo-chemical instability (Tremblin et al. 2015) are now also included in some models. The resulting warming up of the deep atmosphere along the L–T transition is proposed to explain the properties of these objects, including their rotational spectral modulations (Tremblin et al. 2020). However, today’s low-resolution spectra of imaged exoplanets covering a small portion of the planet spectral energy distribution do not allow to explore and remove the atmospheric models degeneracies.

In 2018, we initiated the X-Shooter spectra of YouNg Exoplanet analogs program (X-SHYNE) to acquire simultaneous medium-resolution 0.3-2.5 \( \mu m \) spectra of forty young M, L, and T-type exoplanet analogs. Medium spectral resolution enables a better deblending of the atomic and the molecular lines and offer the rich perspective to untangle temperature, age, atmospheric composition, cloud properties, and disequilibrium chemistry in the atmosphere.
Table 1. Physical properties of VHS J125601.92-125723.9 AB and b.

| Properties          | Binary | Companion | Ref. |
|---------------------|--------|-----------|------|
| Spectral type       | M7.5 ± 0.5 | L7±1.5 | 1    |
| Luminosity (log L_⊙) | −2.95 ± 0.07 | −4.54 ± 0.07 | 2    |
| T eff (K)            | 29028±53 | 1240 ± 50 | 2, 3 |
| log(g) (dex)         | 5.22±0.01 | 4.55±0.15 | 2, 3 |
| Mass (M_⊙)           | 114±7.5  | 19 ± 5   | 2, 3 |
| Radius (R_⊙)         | 1.33±0.07 | 1.17 ± 0.04 | 2, 3 |
| Distance (pc)        | 22.2±1.1  | 179±9    | 2    |
| Age (Myr)            | 150–300 | 1, 2     |
| Projected sep. (as)  | 0.109±0.002 | 8.06±0.03 | 3    |
| Physical sep. (au)   | 2.4±0.1  | 179±9    | 2    |

Notes. The companion T_eff, mass, radius, and surface gravity are updated from evolutionary model predictions (Baraffe et al. 2003). References: 1 - Gauza et al. (2015), 2 - Dupuy et al. (2020), 3 - this work.

In this letter, we focus on the young L–T transition object VHS J125601.92-125723.9 b (hereafter VHS 1256-1257 b; see Table 1). This companion was detected at 8.06 ± 0.03 au from the 0.1 as equal-magnitude late-M binary VHS J125601.92-125723.9 AB (Gauza et al. 2015; Stone et al. 2016). VHS 1256-1257 b is an excellent spectral analogue of the emblematic exoplanet HR8799d (Gauza et al. 2015; Stone et al. 2016). VHS 1256-1257 b is an equal-magnitude late-M binary VHS J125601.92-125723.9 AB (Baraffe et al. 2003). Referenced in Fig. 1. We decided to exclude data shorter than 8.06 ± 0.03 as (projected physical separation of 179±9 au) from the tight 0.1 as equal-magnitude late-M binary VHS J125601.92-125723.9 AB (Gauza et al. 2015; Stone et al. 2016). VHS 1256-1257 b is an excellent spectral analogue of the emblematic exoplanet HR8799d (Gauza et al. 2015; Stone et al. 2016) and one of the first target observed with the James Webb Space Telescope (JWST) which provides 3 to 28 µm medium-resolution spectra complementary to the X-SHYNE data (Hinkley et al. 2022). In this study, we present in Section 2 the X-SHYNE observations and the data reduction of VHS 1256-1257 b. In Section 3, we describe our empirical study and the forward modeling analysis of the companion spectrum. In Section 4, we discuss atmospheric properties and prospects for future synergy and interpretation with the JWST data.

2. Observation and data reduction

VHS 1256-1257 b was observed on May 28th, 2018 with the X-shooter seeing-limited medium-resolution spectrograph mounted at the VLT/UT2 Cassegrain focus (Vernet et al. 2011). The wide wavelength coverage of the instrument (0.300–2.480 µm) obtained at one shot prevents from uncertainties arising from the collage of spectra of this variable object observed on separate bands at different nights. We chose the 1.6°, 1.2” and 0.6° wide slits for the UVB, VIS, and NIR arms corresponding to resolving powers R = λ/Δλ = 3300, 6700, and 8100, respectively. The slits were oriented perpendicular to the position angles of the companion in order to mitigate the flux contamination of the host stars. The target was observed following an ABBA strategy to evaluate and remove the sky emission during the data processing step. The observing conditions and details of the observing log are reported in Appendix A. We used the ESO reflex framework (Freudling et al. 2013) to run the X-shooter pipeline version 2.9.3 on the raw data (Modigliani et al. 2010). The pipeline produces two-dimensional, curvature-corrected, and flux-calibrated spectra for each target and epoch of observation (trace). The spectra were extracted from the traces using a custom python script. The flux in each wavelength channel at the position of the source was averaged within 720 mas aperture in the UVB and VIS arms, and a 1120 mas aperture in the NIR arm. The script computed the noise at the position of the source into each spectral channel following the procedure described in Petrus et al. (2020). The residual nonlinear pixels in the spectra were removed using the kappa-sigma clipping method. The telluric corrections were evaluated and removed using the molecfit package (Smette et al. 2015; Kausch et al. 2015). The spectra at each epoch were corrected from the barycentric velocity and flux-calibrated using a spectro-photometric standard. Finally, we merged our two spectra in one spectrum.

3. Results

The X-shooter extracted spectrum of VHS 1256-1257 b is reported in Fig. 1. We decided to exclude data shorter than 0.65 µm due to the low S/N at these wavelengths. We performed
an empirical analysis that confirmed the young age of this target (see Appendix B).

To explore the spectral diversity of the photometric and spectroscopic observations, we used ForMoSA, a tool based on a forward-modelling approach that compares observations with grids of pre-computed synthetic atmospheric models using Bayesian inference methods. This code is presented in Petrus et al. (2020) and Petrus et al. (2021) but has been updated for this study. The grids of synthetic spectra used as input are now provided in the standardized NetCDF4 format through the use of the xarray module, created and maintained by the community of meteorologists and geophysicists, which allows the labeling of N-dimensional grids, as well as parallel computations on these grids (interpolations, extrapolations, and arithmetic).

We used the grids of synthetic spectra produced by the last generation of the ATMO (Tremblin et al. 2015) models. Its specificities and the parameter space that it explores are described in the Appendix C. To limit the impact of possible bias on our estimates of the atmospheric parameters, we applied the strategy described by Petrus et al. (2020) which consists in defining different optimal wavelength ranges for different adjustments according to the specific parameter studied. Thus, to estimate the $\xi_{\text{eff}}$ and the radius, we have performed a fit between 1.10 and 2.48 $\mu$m, masking out the optical part of the spectrum that is not well reproduced by the models (panel (E) of Figure 2). The radius is estimated using the dilution factor $C_1 = (R/d)^2$, with $R$ the target’s radius and $d$ the distance. To estimate the surface gravity, the metallicity, the radial velocity, and the rotational velocity, we have chosen to take advantage of the absorption doublet $K_1$ with the higher S/N which is sensitive to these parameters. We therefore fit our data between 1.225 and 1.275 $\mu$m, without the continuum, to avoid the contribution of the pseudo-continuum and molecular absorption to the fit. We also fit our data between 2.28 and 2.41 $\mu$m to exploit the CO overtones, particularly sensitive to C/O. For these two last configurations, the dilution factor $C_2$ is calculated analytically using the relation of Cushing et al. (2008). These different fits are shown on Figure 2.

We also performed independent fits on the $J$, $H$, $K$-band, in addition to the $L_P$ spectrum of VHS 1256-12257 b from Miles et al. 2018. The adopted parameters from each run is given in the Table D.1.

### 4. Discussion

In the context of the discovery of VHS 1256-1257 b, Gauza et al. (2015) led a first empirical characterization to derive the spectral type, but also the bulk properties of the companion. Confronting the luminosity of VHS 1256-1257 b, derived from the near-infrared photometry, bolometric correction and first parallax estimate ($\pi = 78.8 \pm 6.4$ mas, $12.7 \pm 1.0$ pc), to the predictions of the BT-SETTL evolutionary models, they derived physical values for the luminosity, effective temperature, surface gravity and mass of: $L = -5.05 \pm 0.22$ dex, $\xi_{\text{eff}} = 880^{+140}_{-110}$ K, $\log(g) = 4.25^{+0.35}_{-0.10}$ and $M = 11.2^{+1.8}_{-0.7}$ $M_{\text{Jup}}$, respectively. Their solutions led to a rather cool atmosphere and unusually under-luminous object given its spectral type. The parallax measurement was recently revised by Dupuy et al. (2020) based on CFHT and Pan-STARRS observations placing this system at larger distances: $51.6 \pm 3.0$ mas ($22.2^{+1.2}_{-1.1}$ pc). This new estimate implies higher values for the mass ($19 \pm 5 M_{\text{Jup}}$), surface gravity ($\log(g) = 4.55^{+0.15}_{-0.10}$), radius ($1.17^{+0.04}_{-0.02}$ $R_{\text{Jup}}$), and warmer temperature ($1240 \pm 50$ K) from the Saumon & Marley (2008) hybrid evolutionary models. It brings the absolute magnitudes of all three components in better agreement with known young objects. From a first atmospheric model analysis using near-infrared spectra (NTT/SOFI, 0.95-2.52 $\mu$m, $R_s = 600$) and L spectra (Keck/NIRSPEC at L$_P$-band, $R_s = 1300$), Miles et al. (2018) had already derived a warmer temperature of 1240 K with photospheric clouds for VHS 1256-1257 b although surface gravity and radius estimates were still affected by the early, wrong distance determination. From their $L_P$-band spectra, Miles et al. (2018) also reported the detection of low abundances of CH$_4$, suggesting non-equilibrium chemistry processes at play between CO and CH$_4$. The upper atmospheres of their best-fit models depart from equilibrium abundances of CH$_4$ by factors of 10–100.

Our atmospheric forward-modeling analysis of the X-shooter spectra confirms the temperature of 1326 ± 2 K with ATMO models for a full fitting applied between 1.10 and 2.48 $\mu$m. Nevertheless, this estimate varies significantly with the choice of the wavelength ranges used for the fit from 1145 ± 13 K for the $L_P$-band to 1417 ± 17 K for the $K$-band. For the surface gravity determination, we focused on the fitting of the gravity-sensitive K I lines between 1.225-1.275 $\mu$m. The resulting solution indicates surface gravity of $\log(g) = 4.25 \pm 0.20$ dex. But this estimate tends to be lower ($< 4.0$ dex) when the fit is performed on a larger wavelength range ($J$, $H$, $K$-bands). Although, effective temperature and surface gravity are relatively consistent with the evolutionary model, the radius estimate (R between 0.81 and 0.91 $R_{\text{Jup}}$) given by the ATMO models is not, and definitively needs to be further investigated for this family of models. At the moment, pressure levels that are impacted by the reduced temperature gradient is assumed to be a function of surface gravity (see Appendix C for details), an adjustment of the size of the layer impacted by the reduced temperature gradient might be needed to get a radius in better agreement with evolutionary models. We notice also that the radius estimated from the $L_P$-band is consistent with the evolutionary model but the surface gravity is inconsistent with that obtained on the other band and too low with respect to evolutionary model predictions.

Finally, accessing spectral resolution up to 8100 at $K$-band, for which water and carbon monoxide are detected, enables us to constrain the C/O ratio between solar and super-solar values with C/O ≥ 0.63. The metallicity appears to be solar to super-solar for all the fits (except at $K$-band and $H$-band). In the context of the cloudless ATMO models, the adiabatic index value of $\gamma = 1.02 \pm 0.01$ is consistent with a decrease of the adiabatic index in the lower part of the atmospheres, and processes of non-equilibrium chemistry and quench CO/CH$_4$ (i.e. prevent the formation of CH$_4$), as expected for young late-L dwarfs subject in this scenario to a CO/CH$_4$ thermo-chemical instability Tremblin et al. (2016). Finally, we also derived radial and rotational velocities of RV between -4.58 and 8.77 km s$^{-1}$, and $v\sin(i) < 37$ km s$^{-1}$ (limited by the spectral resolution of X-shooter), compatible with the NIRSPEC data (RV = 2.1$^{+1.2}_{-1.0}$ km s$^{-1}$ and $v\sin(i) = 13.5^{+3.6}_{-4.1}$ km s$^{-1}$, Bryan et al. 2018).

The [M/H] and the C/O ratio that we measured are very similar to those measured for HR8799 b (C/O = 0.61$^{+0.09}_{-0.07}$, Barman et al. 2015), HR8799 c (C/O = 0.65$^{+0.10}_{-0.05}$, Konopacky et al. 2013), and HR8799 e ([M/H] = 0.48$^{+0.25}_{-0.20}$ and C/O = 0.60$^{+0.05}_{-0.03}$, Mollière et al. 2020). The solar to super-solar composition of VHS 1256-1257 b could indicate a specific atmospheric metal enrichment of solids and gas during its phases of formation and evolution if formed within a disk by core accretion or even gravitational instability (Mollière et al. 2022). However, the existence of such a massive planet-forming disk, as well as the presence of giant planets...
planets, is not expected given the very-low mass of the central binary (Burn et al. 2021). In addition, the hierarchical architecture of the whole system, a tight equal-mass binary with a planetary-mass companion orbiting at wide orbit, strongly supports a stellar-like formation by gravo-turbulent fragmentation. Further spectroscopic observations to directly measure of the atmospheric composition of the central binary will be important. More extended atmosphere modeling will be crucial to confirm the composition of VHS 1256-1257 b, but also its photometric temporal variability.

VHS 1256-1257 b has been identified as one of the most variable substellar object (19.3% spectroscopic variations between 1.1 and 1.7 \( \mu \)m) by Bowler et al. (2020), thanks to a sequence of 11 observations (8.5 hr) performed with HST. The presence of inhomogeneous cloud covers has been proposed and explored for this companion by Zhou et al. (2020), but the existence of temperature fluctuations arising in a convective atmosphere could be an alternative explanation (Tremblin et al. 2020). To explore the impact of this spectroscopic variability, we applied ForMoSA using the ATMO models on the faintest and brightest state of this spectroscopic sequence to estimate the \( T_{\text{eff}} \) and compared them with the \( T_{\text{eff}} \) estimated from our X-shooter data. For these fits, we calculated the dilution factor \( C_k \) analytically and calculated the likelihood using the same wavelength range. The Figure 3 illustrates the fits of the HST data (Left panel) and the corresponding \( T_{\text{eff}} \) posteriors (Right panel). The difference of temperatures between the faintest and brightest states could be indicative of a temperature fluctuation in the atmosphere of VHS 1256-1257 b. Modulations of the temperature gradient in the region around one bar could also explain the possible CH\(_4\) variability detection observed by (Bowler et al. 2020). Finally, we note also that the \( T_{\text{eff}} \) estimate from our X-shooter data, using the same wavelength range than the HST data (gray posterior), is coherent with the \( T_{\text{eff}} \) estimate with the brightest state of the HST spectra.

VHS 1256-1257 AB and b is a prime target of the JWST Early Release Science (ERS) program (Hinkley et al. 2022, PI: S. Hinkey) that acquired high-fidelity spectra with NIRSpec and MIRI at medium spectral resolution over a broad wavelength range from 1 to 28 \( \mu \)m (\( R_\lambda \sim 1500–3000 \)), respectively. The characterization of these spectra using the forward modeling approach will be treated in a future paper. This will be particu-

Fig. 2. X-shooter spectra of VHS 1256-1257 b (black) compared to the best fit ATMO model (red). Residuals from the best fit are shown at the bottom of each panel. Fit between (A): 1.10 and 2.48 \( \mu \)m; (B): 1.225 and 1.275 \( \mu \)m; (C): 2.28 and 2.41 \( \mu \)m; (D): 2.90 and 4.14 \( \mu \)m. (E): 0.65-2.48 \( \mu \)m fit evidencing the model departure at optical wavelengths.
annularly interesting to accurately constrain the effective temperature of VHS1256b, the abundances of important secondary gases (CO, H₂O, CH₃), the importance of thermo-chemical instability, patchy cloud decks, and non-equilibrium chemistry processes at play. As proposed by Tremblin et al. (2020), the detection of direct cloud spectral signatures such as the silicate absorption feature at 10 μm, as detected for ultracool dwarfs observed with Spitzer (Suárez & Metchev 2022), will help to confirm the presence of clouds and their contribution to the spectral energy distribution and modulation of VHS 1256-1257 b. The ERS program will serve as benchmark for future characterization studies of young brown dwarfs and exoplanetary atmospheres.

Appendix A: X-shooter Observing Log

The Table A.1 reports the observing conditions during our data acquisition.

Appendix B: Empirical analysis

The medium spectral resolution of our data allows us to identify several strong absorption lines between 0.8 and 1.3 µm, like the neutral cesium (Cs, 0.852 µm), and the neutral potassium (K I) doublets (1.168, 1.177 µm and 1.243, 1.254 µm). The sodium (Na I) doublet (1.138 and 1.141 µm) is also detected. These lines were not resolved in the early study of Gauza et al. (2015) given the lower spectral resolution of the GTC/OSIRIS optical and NTT/SOFI nIR spectra. We therefore derived the equivalent width (EW) of the K I lines and compared them with the ones obtained by Martin et al. (2017) for a sample of old and young (low gravity and intermediate gravity) brown dwarfs as shown in Fig. B.1.

The EW of alkaline lines in the NIR have been shown to correlate with surface gravity (Cushing et al. 2005; Allers & Liu 2013; Bonnefoy et al. 2014; Manjavacas et al. 2020). The strength of these lines increases with the surface gravity due to a higher pressure in the photosphere. Therefore, they are great tracers of age. To calculate these EWs, we have exploited the resolution of X-Shooter by applying the following procedure. We constructed 100 spectra whose flux at each wavelength is randomly generated with a Gaussian law of mean the initial data resolution of X-Shooter by applying the following procedure. We estimated the pseudo-continuum at the position of the line value and standard deviation the data error. For each spectrum, we estimated the pseudo-continuum at the position of the line by subtracting a Lorentzian law, fitted on the line, to the spectrum, which is then degrade to a resolution $R_0 = 250$. The EW is calculated with:

$$EW = \sum_{i=1}^{n} \left[ 1 - \frac{f(\lambda_i)}{f_c(\lambda_i)} \right] \Delta \lambda_i \quad (B.1)$$

with $f(\lambda_i)$ and $f_c(\lambda_i)$ the flux of the line and the pseudo-continuum, respectively, for each wavelength $\lambda_i$. $\Delta \lambda_i$ is the wavelength step. We estimated the final EW from the mean of the series of these 100 EWs and the final error from its standard deviation.

The Figure B.1 compares the EW of each K I lines calculated for VHS1256 b and the EWs calculated by Martin et al. (2017). The 20 bars limit is scaled by $10^{(\log(g)-5)}$ at other surface gravities. Out-of-equilibrium chemistry is used with $k_{\text{Z}} = 10^2$ cm$^2$/s at log(g) = 5.0 and are scaled by $10^{2.5\times(\log(g)-5)}$ at other surface gravities. The mixing length is assumed to be 2 scale height at 20 bars and higher pressures at log(g) = 5.0 and is scaled down by the ratio between the local pressure and the pressure at 20 bars for lower pressures. The 20 bars limit is scaled by $10^{(\log(g)-5)}$ at other surface gravities.

The chemistry includes 277 species and out-of-equilibrium chemistry has been performed using the model of Venot et al. (2012), rainout is assumed to occur for species that are not included in the out-of-equilibrium model. Opacity sources include $H_2$, $H$, $He$, $H_2O$, $CO_2$, $CO$, $CH_4$, $NH_3$, Na, K, Li, Rh, Cs, TiO, VO, FeH, PH$_3$, $H_2S$, HCN, $C_2H_2$, SO$_2$, Fe, H$^+$, and the Rayleigh scattering opacities for $H_2$, He, CO, N$_2$, CH$_4$, NH$_3$, $H_2O$, CO$_2$, H$_2$S, SO$_2$. The grids explore the following parameters: effective temperatures between 500 and 3000K (step 100K); log(g) between 2.5 and 5.5 (step 0.5); effective adiabatic index (redenning) with three values 1.05, 1.03, 1.01; metallicity with five values -0.6, -0.3, 0, +0.3, +0.6; C/O ratio with three values 0.3, solar, 0.7. The last version has been used to generate a grid of synthetic spectra at medium resolution ($R_d \sim 10000$) from 0.83 to 2.5 µm as well as lower resolution synthetic spectra ($R_d \sim 1000$) between 0.8 and 20 µm.

Appendix C: Grid description

In this Appendix we will briefly describe the main properties of the ATMO (Tremblin et al. 2015) models and the grids that they generated and that have been used in our study (see the Table C.1). These grids are publicly available at https://opendata.erc-atmo.eu. The ATMO models assume that clouds are not needed to reproduce the shape of the SED of brown dwarfs (apart from the 10-µm silicate feature). Tremblin et al. (2016) have proposed that diabatic convective processes (Tremblin et al. 2019) induced by out-of-equilibrium chemistry of CO/CH$_4$ and N$_2$/NH$_3$ can reduce the temperature gradient in the atmosphere and reproduce the reddening previously thought to occur by clouds. The grids assume a modification of the temperature gradient with an effective adiabatic index. The levels modified are in between 2 and 200 bars at log(g) = 5.0 and are scaled by $10^{(\log(g)-5)}$ at other surface gravities. The mixing length is assumed to be 2 scale height at 20 bars and higher pressures at log(g) = 5.0 and is scaled down by the ratio between the local pressure and the pressure at 20 bars for lower pressures. The 20 bars limit is scaled by $10^{(\log(g)-5)}$ at other surface gravities. The grids explore the following parameters: effective temperatures between 500 and 3000K (step 100K); log(g) between 2.5 and 5.5 (step 0.5); effective adiabatic index (redenning) with three values 1.05, 1.03, 1.01; metallicity with five values -0.6, -0.3, 0, +0.3, +0.6; C/O ratio with three values 0.3, solar, 0.7. The last version has been used to generate a grid of synthetic spectra at medium resolution ($R_d \sim 10000$) from 0.83 to 2.5 µm as well as lower resolution synthetic spectra ($R_d \sim 1000$) between 0.8 and 20 µm.

Appendix D: Estimates of atmospheric and dynamic parameters

As illustrated in the Table D.1, the estimate of each parameter is strongly dependent on the wavelength range used for the fit. To take into account these variations and propose a conservative estimate of the atmospheric parameters of VHS1256 b, we followed the method described in Petrus et al. (2020):
Table A.1. Observing log

| Seq | Date UT Start-Time | DIT | NDIT | NEXP | <Seeing> | Airmass |
|-----|-------------------|------|------|------|---------|---------|
|     | (yyy-mm-dd) (hh:mm) | (s)  |      |      |         |         |
| 1   | 2018-05-28 01:36  | 670/670/234 | 1/1/3 | 12/12/12 | 0.68    | 1.05    |
| 2   | 2018-05-28 02:36  | 670/670/234 | 1/1/3 | 12/12/12 | 0.74    | 1.17    |

Notes. The seeing is measured at 0.5 µm and given for the visible arm. The DIT (Detector Integration Time) values refer to the individual exposure time per frame in the UVB, VIS, and NIR arms respectively. NDIT are the number of individual frames per exposure, and N_{EXP} the number of exposures in the UVB, VIS, and NIR arms.

Table C.1. Parameters space of the grid of synthetic spectra ATMO. T_{eff} is the effective temperature, log(g) is the surface gravity, [M/H] is the metallicity, C/O is the carbon-oxygen ratio, and γ is the reduced adiabatic index.

| ATMO       |                  |                  |
|------------|------------------|------------------|
| T_{eff} (K)| Range [800, 3000]|
|            | Step 50          |
| log(g) (dex)| Range [2.5, 5.5]|
|            | Step 0.5         |
| [M/H]      | Range [-0.6, 0.6]|
|            | Step 0.3         |
| C/O        | Range [0.3, 0.7]  |
|            | Step 0.25        |
| γ          | Range [1.01, 1.05]|
|            | Step 0.02        |

- The final T_{eff} is mainly constrained by the low-resolution spectral information. It is defined by the extreme estimates from the fits that used the JHK-, J-, H-, and K-bands.
- The final log(g) is constrained by the low-resolution spectral information, but also by the molecular and atomic absorption. It is defined by the extreme estimates from the fits that used the [1.225–1.275] μm wavelength range, and the JHK-, J-, H-, and K-bands.
- Two modes seem to be observed for the metallicity. One solar (∼0.0) and one super-solar (∼0.5). That is why we have chosen to let it unconstrained by defining its final value based on the extreme estimates from all of the fits.
- For most of the fits, the C/O converges to the upper edge of the grid. We defined its adopted values as the most conservative lower limit.
- For most of the fits, the γ converges to the lower edge of the grid. We defined its adopted values as the most conservative upper limit.
- Because the fit between 0.670 and 1.100 μm does not seem to reproduce the data, it has been excluded to estimate the radius. Its adopted value is based on the extreme estimates from all of the other fits.
- The adopted value of the radial velocity is defined as the extreme estimates from all of the fits.
- For the same reason as for the radius, we excluded the fit on the RI-band to estimate the bolometric luminosity. Its adopted value is defined as the extreme estimates from all of the other fits.
### Table D.1. Atmospheric parameters of VHS 1256-1257 b inferred from different wavelength ranges, using ForMoSA and the ATMO model grid. NC is for “No Constraint”. The error bars given here are purely statistical and derived from the propagation of the small error bars of our data through the Bayesian inversion. The method used to estimate the final values is described in the Appendix D.
