Resistance between two ferromagnetic electrodes coupled to a normal channel depends on their relative magnetizations. The spin-dependent component, $R$, of the resistance changes with magnetic field, $B$, normal to the directions of magnetizations. In the field of spin transport, this change, $R(B)$, originating from the Larmour spin precession, is called the Hanle curve. We demonstrate that the shape of the Hanle curve evolves upon application of an ac drive and study this evolution theoretically as a function of the amplitude, $B_1$, and frequency, $\omega$, of the drive. If the distance between the electrodes, $L$, is smaller than the spin-diffusion length, $\lambda_s$, the ac drive affects the Hanle curve if the drive amplitude exceeds the spin relaxation rate, $\tau_s^{-1}$, i.e. at $B_1\tau_s \gtrsim 1$. The prime effect of the drive is the elimination of a minimum in $R(B)$. Linearly polarized drive has a fundamentally different effect on the Hanle curve, affecting not its shape, but rather its width.

I. INTRODUCTION

In the past decade there has been remarkable progress in the fabrication of lateral F-N-F structures, see Fig. 1 which exhibit spin transport. In the pioneering experiment Ref. 1 the existence of spin transport in an Al strip was demonstrated by measuring a voltage, $V$, generated between the strip and Co electrode upon injecting a current, $I$, through the other Co electrode. The sign of voltage could be reversed upon reversal of the relative magnetizations of the electrodes. Quantitative information about the spin transport was inferred from the dependence of the generated voltage on a weak external field, $B$, which caused the spin precession. In particular, it was observed that for the average spin precession angle $180^\circ$ the generated voltage changes the sign.

A theory for the $\frac{V}{I} = R(B)$ dependence, i.e. for the Hanle profile, was first developed in Refs. 2, 3. Following Ref. 1, a concise derivation of the analytical result of Refs. 2, 3 goes as follows. Suppose that the magnetizations of the injector and detector are directed along the $x$–axis, while the field, $B$, is directed along the $z$–axis. After a time, $t$, from the moment of injection the average $x$–projection of spin of a given electron is $S_x(t) = e^{-t/\tau_s} \cos \omega_L t$, where $\omega_L = \gamma B$ is the Larmour frequency ($\gamma$ is the gyromagnetic ratio), and $\tau_s$ is the spin-flip time in the nonmagnetic material. If the motion of electron between the electrodes is a 1D drift, then the times of arrival to the detector are distributed as $P(t) = \frac{1}{\sqrt{4\pi D t}} \exp \left[ -\left( L - v_d t \right)^2 / 4 D t \right]$. Here $L$ is the distance between the electrodes, see Fig. 1, $v_d$ is the drift velocity, and $D$ is the diffusion coefficient. Then the nonlocal resistance, $R(B)$, is proportional $S_x(t)$ weighted with the distribution $P(t)$, i.e.

$$R(B) = R_0 \int_0^\infty \frac{dt}{\sqrt{4\pi D t}} \exp \left[ -\frac{t}{\tau_s} - \frac{(L - v_d t)^2}{4 D t} \right].$$

The integral Eq. (1) contains four parameters of the device: $D$, $\tau_s$, $L$, and $v_d$. In fact, the $B$ dependence of $R$ is governed by only two dimensionless combinations:
\[ \omega_L \tilde{\tau}_s, \text{ where } \tilde{\tau}_s \text{ is the renormalized spin-flip time} \]
\[ \tilde{\tau}_s = \frac{\tau_s}{1 + \frac{v_F^2}{4D}}. \quad (2) \]
and the dimensionless length
\[ \hat{L} = \frac{L}{(4D\tilde{\tau}_s)^{1/2}}. \quad (3) \]

Besides, the integral can be evaluated analytically, and expressed in terms of the function \( f(y) \) defined as
\[ f(y) = \int_0^\infty ds \exp \left[ -\frac{1}{s} - ys \right] = \left( \frac{\pi}{y} \right)^{1/2} \exp \left[ -2y^{1/2} \right]. \quad (4) \]
Then the \( B \)-dependence of the nonlocal resistance is simply given by
\[ R(B) \propto f_\gamma(y) = Rf(y) \]
\[ = \left( \frac{\pi}{|y|} \right)^{1/2} \exp \left[ -2|y|^{1/2} \cos \frac{\phi}{2} \right] \cos \left( \frac{\phi}{2} + 2|y|^{1/2} \sin \frac{\phi}{2} \right), \quad (5) \]
where the absolute value, \( |y| \), and the phase, \( \phi \), of the complex argument, \( y \), are defined as
\[ |y| = \hat{L}^2 \left( 1 + \omega_L^2 \hat{\tau}_s^2 \right)^{1/2}, \quad \phi = \arctan (\omega_L \tilde{\tau}_s). \quad (6) \]

It follows from Eq. (5) that there are two characteristic shapes of the Hanle curve, loosely speaking, short-device shape and long-device shape. They are illustrated in Fig. 1.

With regard to experiments, Eq. (1) provides a remarkably accurate description of the Hanle curves measured in various spin-transport devices. Both shapes of \( R(B) \) have been reported in many papers, see e.g. Refs. [4] [23]. Usually the value \( \tau_s \) is inferred from \( R(B) \), since \( R(B) \) falls off at values \( \omega_L \sim \tau_s^{-1} \). For example, in silicon-based [35,36] and germanium-based [21,22] structures the widths of the Hanle curves are \( \sim 5 \text{ mT} \), so that the values of \( \tau_s \) is long, \( \tau_s \sim 5 \text{ ns} \). Equally, in GaAs the Hanle curves are narrow [21,22] with similar widths. On the other hand, in graphene-based [10,20] the Hanle curves are broad with widths \( \sim 100 \text{ mT} \). In InGaAs [21,22] the widths are intermediate \( \sim 20 \text{ mT} \).

It should be noted that determination of both \( \tau_s \) and the spin-diffusion length, \( \lambda_s = (D\tau_s)^{1/2} \), from a single measured Hanle curve is somewhat ambiguous, in the sense, that the same \( R(B) \) can be very well fitted with two significantly different sets of \( \tau_s \) and \( \lambda_s \). To improve the accuracy of determination of these parameters in Ref. [12] the Hanle curves for several values of \( L \) were analyzed.

Overall, the excellent agreement of the experimentally measured Hanle profiles with theoretical prediction Eq. (5) seems surprising, since the theory is based on a rather crude description of the spin dynamics of injected carriers. For example, this description completely neglects the details of injection, such as geometry of electrodes. Modeling the transport as a purely 1D diffusion is also somewhat questionable. On the other hand, a complete understanding of the domain of applicability and limitations of the drift-diffusion theory of spin transport seems crucial, since the contemporary research on inverse spin Hall effect [10,21,26,28] and its possible applications in the logic devices contains the drift-diffusion description at its core. One way of testing the drift-diffusion theory, which have already been realized experimentally [21,22], is to operate with spatially inhomogeneous spin-density profiles. For example in Ref. [20] this profile was created using the interference of two laser beams.

In the present manuscript we suggest another “knob” to test the drift-diffusion theory. Namely, we demonstrate that the Hanle profile can be manipulated by the ac drive. More specifically, we assume that, in addition to a static field \( B_0 \), an ac field in the \( x-y \) plane is applied. On general grounds, one can expect that the ac drive suppresses the \( R(B) \) response by affecting the steady precession \( S_+(t) = \cos \omega_L t \). It is also apparent that the drive should make the most pronounced effect on \( R(B) \) if the drive frequency, \( \omega \), is comparable to \( \tilde{\omega}_L \), the value corresponding to the width of the Hanle curve in the absence of drive. For \( \omega \gg \tilde{\omega}_L \), the ac field oscillates many times as an electron travels between the injector and detector, so that the effect of a weak drive with amplitude \( \gamma B_1 \ll \omega \) averages out. It is somewhat unexpected that, in addition to a simple broadening, the drive gives rise to specific features in the shape of the Hanle curves.

Below we find and analyze the expression for \( R(B) \) for ac field with arbitrary amplitude and frequency for the case when it is circularly polarized. The prime effect is the shift of the center of \( R(B) \) to the left or to the right depending whether the polarization of the drive is left or right. We also analyze the evolution of the Hanle curves with increasing drive for the case when the drive is linearly polarized. In particular, we identify two peculiar regimes of the spin dynamics which are specific to linear polarization. They are realized when the drive is either very fast or very strong. We discuss how this dynamics manifests itself in the Hanle profile.

II. DYNAMICS OF THE LARMOUR SPIN PRECESSION IN THE PRESENCE OF THE AC DRIVE

To find the shape of the Hanle curve in the presence of the ac drive, \( B_1(t) \), it is necessary to solve the equation for the spin dynamics
\[ \frac{dS}{dt} + \gamma \left( B + B_1(t) \right) \times S = 0 \quad (7) \]
with initial conditions $S_x(0) = 1$, $S_y(0) = S_z(0) = 0$. Then the solution should be substituted into Eq. 1 instead of $\cos \omega L t$. We assume that external field is directed along $z$, i.e. $B = B_0 \mathbf{k}$, while for the ac field lies in the $x$-$y$ plane. For this field we will consider the cases of circular and linear polarization separately.

### A. Circular polarization

It is important that the components of the ac drive

$$B_x = B_1 \cos(\omega t + \varphi) \quad B_y = B_1 \sin(\omega t + \varphi) \quad (8)$$

contain a random initial phase, $\varphi$. It emerges as a result of the randomness of the time moments at which electrons are injected from the electrode. The nonlocal resistance should be averaged over this phase.

For circular polarization the dynamics of the spin components can be found exactly, since in the rotating frame the ac field is static. We reproduce this textbook solution to track the random phase, $\varphi$, which leads to averaging out of certain contributions to $R(B)$.

In the rotating frame, $x' = x \cos \omega t + y \sin \omega t$, $y' = y \cos \omega t - x \sin \omega t$, the general solution of the Bloch equation has the Rabi form

$$S'(t) = \left( S_0 - \frac{(H \cdot S_0) H}{H^2} \right) \cos \gamma H t + \frac{H \times S_0}{H} \sin \gamma H t + \frac{(H \cdot S_0) H}{H^2}, \quad (9)$$

where the projections of the vector $H$, which is the effective magnetic field in the rotating frame, are defined as $H_x' = B_1 \cos \varphi$, $H_y' = B_1 \sin \varphi$, and $H_z' = B_0 - \frac{\omega}{\gamma}$. After implementing the initial condition $S_x(0) = 1$ it is instructive to rewrite Eq. 9 in components

$$S_x'(t) = \left( 1 - \frac{B_1^2 \cos^2 \varphi}{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2} \right) \cos \gamma H t + \frac{B_1^2 \cos^2 \varphi}{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2},$$

$$S_y'(t) = \frac{B_1^2 \cos \varphi \sin \varphi}{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2} (1 - \cos \gamma H t) + \frac{B_0 - \frac{\omega}{\gamma}}{\sqrt{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2}} \sin \gamma H t,$$

$$S_z'(t) = -\frac{B_1 \left( B_0 - \frac{\omega}{\gamma} \right) \cos \varphi}{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2} (1 - \cos \gamma H t) + \frac{B_1 \sin \varphi}{\sqrt{B_1^2 + \left( B_0 - \frac{\omega}{\gamma} \right)^2}} \sin \gamma H t. \quad (10)$$

It is now seen from Eq. 10 that $S_x'$ vanishes after averaging and so does the first term in $S_y'$. In the remaining terms the averaging amounts to the replacement of $\cos^2 \varphi$ by $1/2$.

Going back to the laboratory system: $S_x = S_x' \cos \omega t - S_y' \sin \omega t$, $S_y = S_y' \cos \omega t + S_z' \sin \omega t$, we get

$$\langle S_x(t) \rangle = \frac{B_1^2}{2H^2} \cos \omega t + \frac{1}{2} \left( 1 - \frac{B_1^2}{2H^2} + \frac{B_0 - \frac{\omega}{\gamma}}{H} \right) \cos [(\gamma H + \omega)t] + \frac{1}{2} \left( 1 - \frac{B_1^2}{2H^2} - \frac{B_0 - \frac{\omega}{\gamma}}{H} \right) \cos [(\gamma H - \omega)t], \quad (11)$$

$$\langle S_y(t) \rangle = \frac{B_1^2}{2H^2} \sin \omega t + \frac{1}{2} \left( 1 - \frac{B_1^2}{2H^2} + \frac{B_0 - \frac{\omega}{\gamma}}{H} \right) \sin [(\gamma H + \omega)t] - \frac{1}{2} \left( 1 - \frac{B_1^2}{2H^2} - \frac{B_0 - \frac{\omega}{\gamma}}{H} \right) \sin [(\gamma H - \omega)t]. \quad (12)$$

We see the averaged dynamics of $S_x$ and $S_y$ represents oscillations with driving frequency, $\omega$, which are modulated by the “Rabi” envelope with frequency $\gamma$.

$$\gamma H = \sqrt{(\omega - \gamma B_0)^2 + (\gamma B_1)^2}. \quad (13)$$
III. NONLOCAL RESISTANCE

Three contributions to $S_x$ in Eq. (11) give rise to three terms in the nonlocal resistance, $R(B)$. It is convenient to express $R(B)$ through the same function, $f_r(y)$, which describes the Hanle shape in the absence of drive and is defined by Eq. (14). One finds

$$R(B) \propto \left\{ \frac{B^2}{2H^2} f_r(y_\omega) + \frac{1}{2} \left( 1 - \frac{B^2}{2H^2} + \frac{B_0 - \frac{\omega}{H}}{H} \right) f_r(y_{\omega + \gamma H}) \right. $$

$$+ \left. \frac{1}{2} \left( 1 - \frac{B^2}{2H^2} - \frac{B_0 - \frac{\omega}{H}}{H} \right) f_r(y_{\omega - \gamma H}) \right\}. \quad (14)$$

Here the arguments $y_\omega$ and $y_{\omega + \gamma H}$ are defined by Eq. (6) with $\omega_L$ replaced by $\omega$ and $\pm \omega + \gamma H$, respectively. It is convenient to analyze the shape of the Hanle curves for short and long devices separately.

A. Small distance between the electrodes

In the limit of small $\hat{L} \ll 1$ the function Eq. (5) for nonlocal resistance in the absence of drive simplifies to

$$R(B) \propto \frac{L}{(2\pi)^{1/2}} f_r(\omega_L) \bigg|_{L \ll 1}. \quad (15)$$

Naturally, it contains only a single scale $\omega_L \sim \tau_\omega^{-1}$.

If the magnetization of the injector is along the $x$-axis while the magnetization of the detector is along the $y$-axis, then the Hanle signal is proportional to $S_y(t)$. The corresponding expression for nonlocal resistance reads

$$\tilde{R}(B) \propto \left\{ \frac{B^2}{2H^2} f_i(y_\omega) + \frac{1}{2} \left( 1 - \frac{B^2}{2H^2} + \frac{B_0 - \frac{\omega}{H}}{H} \right) f_i(y_{\omega + \gamma H}) \right. $$

$$\left. - \frac{1}{2} \left( 1 - \frac{B^2}{2H^2} - \frac{B_0 - \frac{\omega}{H}}{H} \right) f_i(y_{\omega - \gamma H}) \right\}, \quad (16)$$

where the function $f_i(y)$ is defined through Eq. (5) as $\text{Im} f(y)$, which amounts to the change of cosine by sine in the right-hand-side. In the absence of drive, the resistance $\tilde{R}(B)$ is an odd function of magnetic field. In the limit of small $\hat{L}$ it simplifies to

$$\tilde{R}(B) \propto \frac{\sqrt{1 + \omega^2 + \tau_\omega^2} - 1}{\sqrt{1 + \omega^2 + \tau_\omega^2}} = \frac{\hat{L}}{(2\pi)^{1/2}} f_i(\omega_L) \bigg|_{L \ll 1}. \quad (17)$$

To find the shape of the Hanle curve in the presence of drive, the asymptote Eq. (15) should be substituted into Eq. (14). In Fig. 2 we plot the modified Hanle curves calculated for the driving frequency $\omega \tau_\omega = 7$ and two magnitudes of the drive $\gamma B_1 \tau_\omega = 4$ and $\gamma B_1 \tau_\omega = 6$. We also plot the corresponding curves for $R(B)$. The chosen value of $\omega$ is so big because the FWHM value of $R(B)$ in the absence of drive is also big, approximately $4/\tau_\omega$. One can identify in Fig. 2 three major features caused by the drive:

(i) The shift of the maximum. The origin of this shift is the interplay of the prefactor and the function $f_r(y_{\omega + \gamma H})$ in the third term of Eq. (14). Firstly, this term gives the dominant contribution to $R(B)$ for small $B_1$. This is because the prefactor in the first term is $\propto B_1^2$, while the prefactor in the second term is $\propto B_1^2/\omega L$. On the other hand, the prefactor in the third term changes rapidly from 1 to 0 at $\omega_L = \omega$. With regard to $f_r(y_{\omega + \gamma H})$, it has two peaks at $\omega_L = \omega \pm \sqrt{\omega^2 - (\gamma B_1)^2}$. \quad (18)

The peak at $\omega_+$ is eliminated by the prefactor, while the peak at $\omega_-$, which behaves with $(\gamma B_1)^2/2\omega$ at small $B_1$, survives and defines the position of maximum in $R(B)$. For the two driving amplitudes plotted in Fig. 2 the expected shifts of the maxima are related as 9 : 4, which is indeed the case.

(ii) The Hanle curves broaden with increasing the drive amplitude. Formally, this follows from the broadening of the step-like behavior of the prefactor in the third term with $B_1$.

(iii) Upon increasing $B_1$, the Hanle curves exhibit signatures of magnetic resonance. True magnetic resonance, $\omega_L = \omega$, is certainly present only in the dynamics of $S_x$. In the dynamics of $S_x$ and $S_y$ the manifestations of
magnetic resonance is vague and originates from the fact that the derivative of the arguments \( \omega \pm \gamma H \) with respect to \( B \) is equal to \( (\omega \pm \gamma B_0)/\gamma H \). It passes through zero at the magnetic-resonance condition and changes rapidly from \(-1\) to \(1\) in its vicinity. This change translates into a kink-like behavior indicated in Fig. 2. More pronounced signatures of the magnetic resonance can be seen in the derivative \( dR/dB \) also shown in Fig. 2. The derivative develops a plateau.

The shapes of \( \tilde{R}(B) \) shown in Fig. 2 evolve with the drive in a predictable fashion. Namely, the position of zero shifts to finite magnetic field \( \omega \gamma B \mp \gamma H \). The curves broaden. The signatures of magnetic resonance are more pronounced in \( \tilde{R}(B) \). As seen in Fig. 2, the derivative \( dR/dB \) exhibits a jump-like behavior near \( \omega_L = \omega \).

**B. The injector and the detector are far apart**

In a long device, \( L \gg 1 \), the nonlocal resistance Eq. (5) exhibits oscillations decaying with magnetic field. First two zeros correspond to magnetic fields \( \omega_L \tau_\omega \approx \pi/2L \) and \( \omega_L \tau_\omega \approx 3\pi/2L \). The effect of the ac drive on \( R(B) \) is most pronounced when the driving frequency lies between these two values. This is illustrated in Fig. 3. Two sets of curves in Fig. 3 correspond to the same values of the drive amplitudes but to different driving frequencies. In the left and right sets the frequency differ by a factor of \( 5 \). It is seen that the Hanle shapes in the right set do not respond to the drive. The reason for that is that the value \( \omega \tau_\omega \) for this set is \( 5 \), which is much bigger than \( \pi/L \approx 1.4 \). For the left set, \( \omega \tau_\omega = 1.1 \), which is close to \( \pi/L \). The lively response of \( R(B) \) and \( \tilde{R}(B) \) to the drive at this frequency originates from the fact that a non-driven curve is flat around \( \omega_L \tau_\omega \approx 1.2 \). With the choice \( \omega \tau_\omega = 1.1 \) this \( \omega_L \) is near magnetic resonance and fast change of the prefactors in Eq. (14) with \( \omega_L \) is not overshadowed by the change of the function \( f_r(y) \).

**IV. LINEAR POLARIZATION OF THE DRIVE**

The expressions for nonlocal resistance obtained in the previous section are exact, in the sense, that they apply at arbitrary strengths and frequencies of the circularly polarized drive. We analyzed them for the situation when both \( \gamma B_1 \) and \( \omega \) are comparable to the width of the Hanle curve. It is easy to see from Eq. (14) what happens to the Hanle curve when both \( \gamma B_1 \) and \( \omega \) are much bigger than \( \gamma B_0 \). With the shape of the Hanle curve dominated by the third term in Eq. (14), the argument \(-\omega + \gamma H\) of \( f_r \) in this term can, at low \( B_0 \), be expanded as

\[
-\omega + \gamma H \approx -\omega + \left[ (\gamma B_1)^2 + \omega^2 \right]^{1/2} - \frac{\gamma B_1 \omega}{\left[ (\gamma B_1)^2 + \omega^2 \right]^{1/2}}.
\]

Eq. (19) suggests that under a fast and strong circularly-polarized drive the Hanle curve simply shifts to the right preserving its shape. This is illustrated in Fig. 4 where the \( R(B) \) curves are plotted from Eq. (14) for fast and strong drives. We intentionally chose a very high driving frequency \( \omega \tau_\omega = 30 \) to allow the \( R(B) \) peak to shift substantially with increasing \( \gamma B_1 \tau_\omega \).

Obviously, under a linearly polarized drive, the \( R(B) \) dependence maintains its symmetry with respect to...
function, we get moving into the frame rotating around the ac field; the physical meaning of the above transformation is

Assume that the driving field oscillates along the x-axis, $\mathbf{B}_1(t) = iB_1 \cos(\omega t + \varphi)$. Then equations of motion for the spin projections assume the form

$$\frac{dS_x}{dt} = -\gamma B_0 S_y,$$
$$\frac{dS_y}{dt} = \gamma B_0 S_x - \gamma B_1 S_z \cos \omega t,$$
$$\frac{dS_z}{dt} = \gamma B_1 S_y \cos \omega t. \quad (22)$$

To handle the fast linearly polarized drive it is convenient to switch to the variables

$$S_{x'} = S_x,$$
$$S_{y'} = S_y \cos \theta(t) + S_z \sin \theta(t),$$
$$S_{z'} = -S_y \sin \theta(t) + S_z \cos \theta(t), \quad (23)$$

where the angle $\theta(t)$ is defined as

$$\theta(t) = \frac{B_1}{\omega} \sin(\omega t + \varphi) \quad (26)$$

The physical meaning of the above transformation is moving into the frame rotating around the ac field; the ac field is “canceled” in the new frame. The equations of motion for the new variables read

$$\frac{dS_{x'}}{dt} = \gamma B_0 S_{x'} \sin \theta(t) - \gamma B_0 S_{y'} \cos \theta(t),$$
$$\frac{dS_{y'}}{dt} = \gamma B_0 S_{x'} \cos \theta(t),$$
$$\frac{dS_{z'}}{dt} = -\gamma B_0 S_{x'} \sin \theta(t). \quad (29)$$

One can see that there are two natural frequencies in the system Eq. (27), one is $\gamma B_0$ and the other is $\omega$. Since the second frequency is much bigger than the first, we can average the equations over time interval $\left( -\frac{\pi}{\omega}, \frac{\pi}{\omega} \right)$ assuming that the spin projections do not change significantly during this interval. Taking into account that $\langle \cos(\theta) \rangle = J_0(\gamma B_1/\omega)$, where $J_0(z)$ is a zero-order Bessel function, we get

$$\frac{dS_{x'}}{dt} = -\gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) S_{y'},$$
$$\frac{dS_{y'}}{dt} = \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) S_{x'},$$
$$\frac{dS_{z'}}{dt} = 0. \quad (32)$$

We see that the dynamics after averaging is slow, which justifies the averaging performed. Upon returning to the lab frame the solution of the system Eq. (30) satisfying the condition $S_z(0) = 1$ reads

$$S_x(t) = \cos \left[ \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) t \right], \quad (33)$$
$$S_y(t) = \sin \left[ \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) t \right] \cos \left[ \gamma B_1 \frac{\sin(\omega t + \varphi)}{\omega} \right], \quad (34)$$
$$S_z(t) = \sin \left[ \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) t \right] \sin \left[ \gamma B_1 \frac{\sin(\omega t + \varphi)}{\omega} \right]. \quad (35)$$

As a final step, we average over the initial phase, $\varphi$, and obtain

$$\langle S_x(t) \rangle = \cos \left[ \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) t \right], \quad (36)$$
$$\langle S_y(t) \rangle = J_0 \left( \frac{\gamma B_1}{\omega} \right) \sin \left[ \gamma B_0 J_0 \left( \frac{\gamma B_1}{\omega} \right) t \right], \quad (37)$$
$$\langle S_z(t) \rangle = 0. \quad (38)$$

The above result leads us to the conclusion that, with fast linearly polarized drive, the curves $R(B)$ and $\tilde{R}(B)$ have exactly the same shape as in the absence of drive. The only difference is that the Larmour frequency, $\omega_L$, gets replaced by $\omega_L J_0(\gamma B_1/\omega)$, signifying the broadening of the curves, which oscillates with the drive amplitude.

### A. Strong drive

Another regime of the spin dynamics specific for a linearly polarized drive is realized when the drive is very strong, $B_1 \gg B_0$. We will describe this regime qualitatively. As $\mathbf{B}_1(t)$ oscillates, it exceeds the static field $B_0$ during, practically, the entire period, $2\pi/\omega$. Then $B_0$ has a negligible effect on the spin dynamics. However, during short time intervals, $\delta t$, when $\mathbf{B}_1(t)$ passes through zero, the electron spin is affected by $B_0$ only. During each of these intervals the spin rotates by the angle $\sim B_0 \delta t$. Thus, the net rotation after time $t$ is $\sim (B_0 \delta t) \omega t$. Now the value $\delta t$ can be estimated from the relation $B_1(\omega \delta t) = B_0$. This leads us to the conclusion that the spin dynamics, averaged over the period of drive, is still a regular spin precession around the $z$-axis but with effective frequency $\sim \gamma B_0^2/B_1$ instead of $\omega_L$. One consequence of the replacement of $\omega_L$ by $\gamma B_0^2/B_1 \ll \omega_L$ in Eq. (4) is a general broadening of the Hanle profile, which can be controlled by the strength of the drive. The other consequence is that the Hanle profile acquires a flat top.

### V. Discussion

- Our overall conclusion is that the ac drive with frequency, $\omega$, affects nonlocal spin transport if its am-
FIG. 5: At strong drive $\gamma B_1 > \omega$. The zero-drive Hanle curves not only lose their symmetry but acquire additional maxima and minima. The evolution of the Hanle shapes for a given $\gamma B_1 \tau_s = 2$ and $L/\lambda = 1.4$ is plotted from Eq. (14) for driving frequencies $\omega \tau_s$ taking the values between 0 and 1 with a step 0.1. Arrow shows the direction of the increase of the driving frequency.

- The effect of the ac drive on the Hanle curve is more pronounced for circular polarization of the drive when the symmetry of the curve is broken. In experiment, the circular polarization of microwaves is achieved with the help of two crossed microstrip resonators. In particular, in Ref. (35) it was demonstrated that ODMR spectrum of the nitrogen vacancies in diamond depends on the direction of the circular polarization of microwaves.

- Sensitivity of the Hanle curves to the ac-drive can serve as additional proof that a spin-polarized current indeed flows through the channel of the device. This proof is especially important for three-terminal devices where the question about the spin injection is still controversial. In these devices, with only one of electrodes being a ferromagnet, the spin-dependent buildup of a voltage between injector and detector observed in experiment, and even sensitivity of this voltage to the magnetic field, can be caused by different delicate mechanisms. For example, a small inhomogeneity of the magnetization of the electrode might cause this sensitivity. Obviously, this source of magnetoresistance would not be sensitive to the ac-drive.

VI. ACKNOWLEDGEMENTS

We are grateful to C. Boehme and H. Malissa for insightful discussions. This work was supported by NSF through MRSEC DMR-1121252.
