ABSTRACT

We observed the reflection nebula (RN) NGC 7023, with the SH module, and the long-slit SL and LL modules, of the InfraRed Spectrograph (IRS) on Spitzer. We also present InfraRed Array Camera (IRAC) and Multiband Imaging Photometer for Spitzer (MIPS) images of NGC 7023 at 3.6, 4.5, 8.0, and 24 \(\mu\)m. We observe the aromatic emission features (AEFs) at 6.2, 7.7, 8.6, 11.3, and 12.7 \(\mu\)m, plus a wealth of weaker features. We find new unidentified interstellar emission features at 6.7, 10.1, 15.8, 17.4, and 19.0 \(\mu\)m. Possible identifications include aromatic hydrocarbons or nanoparticles of unknown mineralogy. We see variations in relative feature strengths, central wavelengths, and feature widths, in the AEFs and weaker emission features, depending on both distance from the star and nebular position (SE vs. NW).

Subject headings: dust, extinction — infrared: ISM — ISM: individual (NGC 7023) — ISM: lines and bands — ISM: molecules — reflection nebulae

1. Introduction

The interstellar AEFs at 6.2, 7.7, 8.6, 11.3, and 12.7 \(\mu\)m characterize the mid-infrared (mid-IR) emission of the diffuse interstellar medium (ISM) of our own and other star-forming galaxies.
Duley & Williams (1981) first suggested that the AEFs were due to aromatic hydrocarbons. Léger & Puget (1984) and Allamandola, Tielens, & Barker (1985) attributed the AEFs to to polycyclic aromatic hydrocarbon (PAH) molecules with ∼50 carbon atoms. We present here Spitzer (Werner et al. 2004) images and spectroscopy of NGC 7023, a RN with AEFs, illuminated by the Herbig Be star HD 200775, at a distance of 430 pc (van den Ancker et al. 1997).

2. Observations

We imaged NGC 7023 with IRAC (Fazio et al. 2004) in all four channels (3.6, 4.5, 5.8 and 8.0 µm) in two epochs (2003 Oct 10 and 2003 Dec 18). The images were reduced with the Spitzer Science Center (SSC) IRAC reduction pipeline, and combined with the SSC Mosaicer. This processing included dark subtraction, flat fielding, mux-bleed correction, flux calibration, correction of focal plane geometrical distortions and cosmic ray rejection. Figures 1 and 2 show our final images at 3.6, 4.5 and 8.0 µm.

We obtained images at 24, 70, and 160 µm with MIPS (Rieke et al. 2004) on Spitzer, in the scan map mode at medium rate. We covered 10′ × 30′ at all three wavelengths. We reduced the MIPS images using the MIPS Instrument Team Data Analysis Tool (Gordon et al. 2004). The reduction of the 24 µm image (Fig. 2) followed preflight expectations, with a 10% uncertainty on the final absolute calibration. The 70 and 160 µm images will be presented in a later paper.

We measured the Short-High (SH) IRS (Houck et al. 2004) spectrum (9.9 – 19.4 µm; $R = \lambda / \Delta \lambda = 600$) of NGC 7023 on 2003 Sept 19. We obtained Long-Low (LL) long-slit IRS spectra (14.0 – 32.9 µm; $R = 60 – 130$) at two positions on 2003 Oct 1. These observations occurred during the checkout phase of Spitzer, resulting in larger than normal uncertainties in the SH and LL absolute positions of ±5″. We observed the Short-Low (SL) long-slit IRS spectrum (5.1 – 15.1 µm; $R = 60 – 130$) of NGC 7023 on 2003 Oct 25. IRS was sufficiently checked out by this point, resulting in a much smaller absolute positioning for the SL data of ±1″.

The data were reduced and spectra extracted using Cornell IRS Spectroscopy Modeling Analysis and Reduction Tool (Higdon et al. 2004). The spectra were calibrated by applying the spectrum and model template of point source calibrator α Lac to the intermediate unflat-fielded product of the SSC pipeline. We subtracted blank sky spectra only from the SH spectrum, observed as Spitzer cooled, to remove thermal emission from the then warm (∼45 K) baffles of the telescope. All spectra were extracted from fixed pixel ranges over the slit, except for SH where we extracted the spectrum from over the entire aperture.

Figure 2 shows that the SL slit intersects the filaments seen to the NW of HD 200775. Our primary LL slit intersects both the NW filaments and HD 200775 (Fig. 2). The SL slit crosses our
secondary LL slit at Position A, shown on Figure 2. We obtained the SH spectrum at Position B, also marked on Figure 2.

3. Results

We present our spectra of NGC 7023 in Figures 3, 4, and 5. Table 1 gives the central wavelengths and nebular positions at which we discovered new interstellar, spectrally resolved, emission features.

| New Infrared Emission Features | Positions |
|--------------------------------|-----------|
| \( \lambda_c \) (\( \mu \)m) | Detected* |
| 6.7                           | S1–3      |
| 10.1                          | B, S1–3   |
| 15.8                          | A, L6–7   |
| 17.4                          | A, B, L4–6|
| 19.0                          | L1–5      |

(a) Positions where features are detected. The nebular offset from HD 200775 of each position is labeled on Figure 3 (Positions A, B), Figure 4 (Positions S1–S8) and Figure 5 (Positions L1–L7).

Figure 3a shows the combined SL and LL spectrum (5 – 33 \( \mu \)m) at Position A. The absolute flux calibrations of SL1 and SL2 are uncertain by 25\%, yet the relative agreement between them is much better than this factor. The SL and LL spectra were not expected to match and we had to divide the LL2 and LL1 spectra by factors of \( \sim 2 – 3 \), after correction for beam size, to get all spectral segments to match. We emphasize that this composite spectrum of Position A shows qualitatively the spectral features observed in this nebular region, and should *not* be used for quantitative analysis. The brightest spectral emission features seen in the spectrum are the AEFs at 6.2, 7.7, 8.6, 11.3, and 12.7 \( \mu \)m. Weaker emission features are also present, both spectrally resolved emission features and unresolved \( \text{H}_2 \) emission lines.

Figure 3b shows our SH spectrum (9.9 – 19.4 \( \mu \)m) at Position B. Moutou et al. (2000) and Van Kerckhoven et al. (2000) have observed this wavelength region in NGC 7023 at a similar resolution but a different spatial position, using the SWS spectrometer on ISO, at a lower signal-to-noise. Position A is near the \( \text{H}_2 \)-emitting NW filament, while Position B is in a region with little \( \text{H}_2 \) emission (Lemaire et al. 1996). These two positions sample different physical conditions, yet
show similar spectra. The higher spectral resolution of our SH spectrum (Fig. 3b) allows us to easily distinguish between unresolved emission lines, such as the $0 - 0 \text{S(1)}$ $\text{H}_2$ line at 17.03 \(\mu\text{m}\), and resolved emission features, such as the adjacent 17.4 \(\mu\text{m}\) feature. Weak emission features that are barely spectrally resolved in Figure 3a are clearly resolved in Figure 3b.

One of the great strengths of Spitzer is the multiplex advantage, and the ability to discern spectral and spatial differences, of the long-slit spectrographs SL and LL. In Figure 4, we present the results from our long-slit SL observations. The AEFs are the brightest spectral features at all positions. We detect, in SL spectra closest to the star (S1 – S4), the split between the 7.6 and 7.8 \(\mu\text{m}\) features that mainly comprise the “7.7” \(\mu\text{m}\) AEF (Fig. 4).

The 11.0 \(\mu\text{m}\) feature is clearly separated from the 11.3 \(\mu\text{m}\) AEF in Figure 3b. In Figure 4, we can observe the 11.0 \(\mu\text{m}\) feature blended with the 11.3 \(\mu\text{m}\) AEF, in SL spectra closest to the star (S1 – S3). This blend, and its spatial variations, causes the 11.3 \(\mu\text{m}\) AEF to appear to decrease in FWHM and shift to longer wavelengths with increasing distance, \(d_\ast\), from the star.

Figure 5 illustrates our LL2 spectra (14.0 – 21.1 \(\mu\text{m}\)) along the long-slit of IRS-LL. Figure 5, together with Figure 3, demonstrate that longward of the five bright AEFs, there continues to be complex spectral structure. Most prominent in Figure 5 is an emission feature at 16.4 \(\mu\text{m}\), NW of the star (L4 – L7). Fig. 5 also illustrates emission features NW of the star, at 15.8 \(\mu\text{m}\), 17.4 \(\mu\text{m}\), and 17.8 \(\mu\text{m}\). These features to the NW are confirmed by the SL+LL spectrum of Position A (Fig. 3a) and the SH spectrum of Position B (Fig. 3b). Figure 5 also shows an emission feature both SE and NW of the star at 19.0 \(\mu\text{m}\). Figures 3, 4, and 5 yield abundant evidence of pure rotational lines of $\text{H}_2$, marked on Figures 4 and 5. Fuente et al. (1999, 2000) have previously studied pure rotational lines of $\text{H}_2$ in NGC 7023.

Figures 3, 4, and 5 all show a faint but non-zero continuum, observed at 5 – 20 \(\mu\text{m}\), in addition to spectral features and lines. This continuum emission is also detected spectroscopically at 2 – 4 \(\mu\text{m}\) in NGC 7023 (Sellgren, Werner, & Dinerstein 1983; Martini, Sellgren, & DePoy 1999), along with a strong 3.3 \(\mu\text{m}\) AEF and plateau of emission at 3.2 – 3.6 \(\mu\text{m}\). These spectra demonstrate clearly that the emission in the IRAC 3.6 \(\mu\text{m}\) filter (3.2 – 3.9 \(\mu\text{m}\)) in NGC 7023 (Fig. 1) is due to a mix of this continuum emission with the 3.3 \(\mu\text{m}\) AEF and its accompanying 3.2 – 3.6 \(\mu\text{m}\) plateau emission.

Sellgren et al. (1983) and Sellgren (1984) proposed that the 2 – 5 \(\mu\text{m}\) continuum in NGC 7023 and other similar RN is due to non-equilibrium thermal emission from tiny grains ($\sim 1 \text{ nm}$), stochastically heated to high temperatures ($\sim 1000 \text{ K}$) for a brief time by single stellar photons. The IRAC 4.5 \(\mu\text{m}\) filter covers 4.0 – 5.0 \(\mu\text{m}\), a region in which no significant PAH features have been identified. We believe, therefore, that the emission within the IRAC 4.5 \(\mu\text{m}\) filter is completely due to this tiny grain continuum emission. The IRAC 8.0 \(\mu\text{m}\) filter covers 6.5 – 9.3 \(\mu\text{m}\). Figures
3a and 4 clearly demonstrate that the IRAC 8.0 \( \mu m \) filter is dominated by AEF emission at 7.7 and 8.6 \( \mu m \).

The 20 – 33 \( \mu m \) spectrum of Position A (Fig. 3a) shows a strong rise to longer wavelengths, producing the emission in the 24 \( \mu m \) MIPS images (Fig. 2). IRAS 25 \( \mu m \) observations of the RN 23 Tau (Castelaz, Sellgren, & Werner 1987) agree with predictions (Draine & Anderson 1985) that emission in this wavelength region is due to stochastically heated tiny grains. We expect this to be true of NGC 7023 as well.

4. Discussion

4.1. Discoveries of new emission features

We have discovered new ISM emission features at 6.7, 10.1, 15.8, 17.4, and 19.0 \( \mu m \) in NGC 7023. These features are spectrally resolved, so are not atomic or molecular emission lines. All five new features are observed in multiple positions with SH, SL or LL, giving confidence that they are not instrumental artifacts. The 10.1 \( \mu m \) feature seen in SL, and the 17.4 \( \mu m \) feature seen in LL, are both clearly detected in SH. These ISM spectral emission features are among the first spectroscopic discoveries made by Spitzer.

Currently, these features have no identification. Possible identifications could include PAH bands, such as C–H out-of-plane bending modes for 10.1 \( \mu m \) (Hony et al. 2001), or C–C–C bending modes for 15.8, 17.4, and 19.0 \( \mu m \) (Van Kerckhoven et al. 2000). The spectral structure at 6 – 9 \( \mu m \) is quite complicated, with only tentative identifications for well-known features (Peeters et al. 2002), making it difficult to predict whether the 6.7 \( \mu m \) feature might fit into the PAH model. Alternate possibilities, particularly at the longer wavelengths, include nanoparticles (\( \sim \) 1 nm) of a specific mineral composition. For instance, Molster et al. (2001) identify a mixture of PAH species between 3 and 12 \( \mu m \), and various crystalline and amorphous silicates beyond 18 \( \mu m \), in the spectrum of the planetary nebula NGC 6302. Other mineral species, such as simple metal oxides, or other combinations of abundant refractory materials, also remain to be explored.

4.2. Spatial variations in spectral features

We observe marked changes in spectral features across NGC 7023. The nebula SE of the star is where the new 19.0 \( \mu m \) feature is brightest. To the NW of HD 200775, the 19.0 \( \mu m \) feature fades and the 16.4 \( \mu m \) feature becomes the brightest feature in our LL2 spectra.

Our long-slit observations show that the relative strengths of various pairs of emission features
vary with $d_\ast$. We consider feature pairs observed in the same order and module of IRS and find that the ratios 7.8 $\mu$m/7.6 $\mu$m, 7.4 $\mu$m/7.6 $\mu$m, 11.3 $\mu$m/11.0 $\mu$m, and 11.3 $\mu$m/7.7 $\mu$m increase with increasing $d_\ast$.

One of the most marked spectral changes is an apparent weakening of the 8.6 $\mu$m AEF with increasing $d_\ast$. Uchida et al. (2000) and Cesarsky et al. (2000) observe this same phenomenon in other RN, and attribute it to a broadening of the 7.7 $\mu$m AEF with increasing $d_\ast$. We confirm that the 7.7 $\mu$m AEF is broader, and also find that its central wavelength increases with increasing $d_\ast$. This suggests that the wing of the 7.8 $\mu$m feature, as it grows in strength relative to the 7.6 $\mu$m feature, steadily overwhelms the 8.6 $\mu$m AEF until it is barely visible. The 6.2 $\mu$m AEF, like the 7.7 $\mu$m AEF, appears broader at larger $d_\ast$. The equivalent width of the 6.2 $\mu$m AEF also markedly decreases with increasing $d_\ast$.

Another striking spectral variation with $d_\ast$ is the changes in the 11 – 14 $\mu$m region. Close to the star, distinct features at 11.0, 11.3, 12.0, and 12.7 $\mu$m can be distinguished. Far from the star, this spectral region can only be fit by a blend of the 11.3 $\mu$m AEF and a broad bump of emission, centered at 12.5 $\mu$m and having a FWHM of 2.0 $\mu$m. This broad 12.5 $\mu$m feature increases with increasing $d_\ast$, and is not observed close to the star. The same 11 – 14 $\mu$m behavior with increasing $d_\ast$ has been observed in the RN Ced 201 (Cesarsky et al. 2000).

4.3. Imaging

In the inner regions of the nebula, we find strong similarities between the IRAC 4.5 $\mu$m continuum image and the IRAC 8.0 $\mu$m AEF image. The ring of emission between HD 200775 and the NW filaments is real, and is observed in ground-based images of the 3.3 $\mu$m AEF (An & Sellgren 2003).

On the largest scales (~6′, or ~0.8 pc), our 4.5, 8.0, and 24 $\mu$m images show an hour-glass shape, containing little IR emission, which is clearly outlined by a narrow rim of IR emission. The filaments within ~1′ of HD 200775 define the narrow waist of the hourglass shape. This spatial structure has been observed before, in 1–0 $^{13}$CO, 2–1 $^{12}$CO, and 3–2 $^{13}$CO (Gerin et al. 1998; Fuente et al. 1998), at 10 – 20″ resolution. Watt et al. (1986) and Fuente et al. (1998) have argued that the hourglass shape is the fossil remnant of a bipolar outflow from the Herbig Be star HD 200775, implying that the large-scale mid-IR emission outlines the walls of the cavity produced by the earlier outflow.

*Note added in manuscript.*—After this paper was completed, M. Jura of UCLA kindly pointed out to us that the positions and widths of the new 17.4 and 19.0 $\mu$m features agree rather well with those of the two lower frequency transitions of the $C_{60}$ molecule (Frum et al. 1991). It is not possible
to establish detection of interstellar C\textsubscript{60} on the basis of the data in the present paper, but we will explore this potential identification with additional observations and analysis. Note, however, that Moutou et al. (1999) have set limits on the abundance of C\textsubscript{60} and C\textsubscript{60}\textsuperscript{+} in NGC 7023 based on nondetection of the two higher frequency vibrational transitions between 7 and 9 \textmu m.

We thank the people whose dedicated work made the Spitzer Space Telescope a reality (see Werner et al. 2004). This work is based on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407. Support for this work was provided by NASA through Contract Number 1257184 issued by JPL/Caltech. KS thanks the JPL Center for Long-Wavelength Astrophysics for support.

Fig. 1.— IRAC images of the central 6′ × 6′ of the RN NGC 7023, at 4.5 μm (top) and 8.0 μm (bottom). NGC 7023 spectra show that the IRAC 4.5 μm filter is continuum emission and the IRAC 8.0 μm filter is primarily AEF emission. Both observations were made with the 12 s High Dynamic Range mode, consisting of a 1.2 s exposure for observing bright field stars, followed by a 10.4 s exposure for detecting the low surface brightness nebular emission. Even in this mode, the central star, HD 200775, is saturated in both images. North is up; east is to the left.

Fig. 2.— MIPS image of the central ∼12′ × ∼10′ of NGC 7023, at 24 μm (top), and IRAC image of the central ∼3′ × ∼3′ region, at 3.6 μm (bottom). We illustrate how the IRS slits overlay different parts of the central regions of our 3.6 μm IRAC image, which is our highest spatial resolution Spitzer image. We extracted and combined SL2 and SL1 spectra at eight spatial locations. Spectrum S1 (42″ W 8″ N) is closest to the star and spectrum S8 (38″ W 58″ N) is farthest from the star. We extracted LL2 spectra at seven spatial positions. Offsets range from 25″ E 19″ S (spectrum L1) to 49″ W 36″ N (spectrum L7). Spectrum L3 is HD 200775. Position A (the intersection of SL and LL) and Position B (the slit location for SH) are marked. North is up; east is to the left.

Fig. 3.— (a) Combined 5 – 33 μm normalized spectrum (R = 60 – 130) of Position A in NGC 7023 (top). We combined SL2 (5.1 – 7.6 μm; red), SL1 (7.5 – 15.1 μm; green), LL2 (14.0 – 21.1 μm; magenta), and LL1 (20.9 – 32.9 μm; blue) spectra. No scaling was done between SL2 and SL1. LL2 and LL1 were multiplied by factors of order ∼2–3, after scaling by the beam size, in order to match SL1. (b) Normalized SH spectrum (9.9 – 19.4 μm; R = 600) of Position B in NGC 7023 (bottom), extracted from the entire entrance slit (4″7 × 11″3). The spectrum is a composite of eleven orders, with substantial overlap between each. Relative uncertainty in the flux calibration between orders is ∼7%. Adjacent orders are shown in contrasting colors.

Fig. 4.— Long-slit SL (R = 60 – 130) spectra of NGC 7023. We extracted and combined SL2 (second order; 5.1 to 7.6 μm) and SL1 (first order; 7.5 to 15.1 μm) spectra at eight spatial locations, with a 7″2 × 3″6 box. No scaling was done; SL1 and SL2 agree well at overlapping wavelengths. The absolute flux uncertainty in SL is 25%. The y-axis is flux density (Jy). The panel for each of the spectra S1 (bottom), S2, S3, S4, S5, S6, S7, and S8 (top) is labeled with the offset of the spectrum, from HD 200775, in arcsec, and the wavelengths of the H2 lines 0–0 S(5) 6.91 μm, 0–0 S(3) 9.66 μm, and 0–0 S(2) 12.28 μm are marked (vertical lines).
Fig. 5.— Long-slit LL2 (14.0 – 21.1 μm; R = 60 – 130) spectra of NGC 7023, extracted at seven spatial positions, each with a 15′′.3 × 10′′.6 box. The y-axis is flux density (Jy). The absolute flux uncertainty in LL2 is 25%. The panel for each of the spectra L1 (bottom), L2, L3, L4, L5, L6, and L7 (top) is labeled with the offset of the spectrum, from HD 200775, in arcsec, and the wavelength of the H$_2$ line 0–0 S(1) 17.03 μm is marked (vertical line). Spectrum L3 is HD 200775.
