Gamow-Teller Strengths in $^{76}\text{Ge}$, $^{82}\text{Se}$, $^{90}\text{Zr}$, and $^{92}\text{Zr}$ from the Deformed Quasi-particle RPA (DQRPA)

Eunja Ha* and Myung-Ki Cheoun †

Department of Physics, Soongsil University, Seoul 156-743, Korea

(Dated: May 1, 2014)

We developed the deformed quasi-particle random phase approximation (DQRPA) to describe various properties of deformed nuclei and applied to the evaluation of the Gamow-Teller (GT) transition strength distributions whose experimental data can be extracted from the charge exchange reactions (CEXR). Our calculations started with the single-particle states calculated by the deformed axially symmetric Woods-Saxon potential. Pairing correlations of nucleons, neutron-neutron and proton-proton as well as neutron-proton pairing correlations, are explicitly taken into account at the deformed Bardeen Cooper Schriffer (BCS) theory leading to the quasi-particle concept. The ground state correlations and the two-particle and two-hole mixing states are included in the deformed QRPA. In this work, we use a realistic two-body interaction given by the Brueckner G-matrix based on the Bonn potential to reduce the ambiguity on the nucleon-nucleon interactions inside nuclei. We applied our formalism to the GT transition strengths for $^{76}\text{Ge}$, $^{82}\text{Se}$, $^{90}\text{Zr}$, and $^{92}\text{Zr}$, and compared to available experimental data. Our results are tested to the Ikeda sum rule, which is usually thought to be satisfied more or less even under the one-body current approximation without introducing the quenching factor, if high-lying excited states are properly taken into account as done in the present approach. The GT strength distributions turn out to be sensitive on the deformation parameter. We suggest most probable deformation parameters for the nuclei by adjusting GT strength distributions to the experimental data. In particular, many high-lying GT excited states beyond one nucleon threshold are confirmed in most of the GT strength of the nuclei considered in this work.

I. INTRODUCTION

In the core collapsing supernovae (SNe), medium and heavy elements are believed to be produced by the rapid and slow successive neutron capture reaction, dubbed as r-process and s-process, respectively. In these processes, many unstable neutron-rich nuclei are produced iteratively and decay to more stable nuclei at their turning points in the nuclear chart. These r- and s-processes play vital roles of understanding the nuclear abundances in the cosmos.

Since most of the nuclei produced in the processes are thought to be more or less deformed, we need to explicitly consider effects by the deformation in the nuclear structure and their reactions in the network calculations of the processes. One interesting process related to the deformed nuclei may be the rapid proton process (p-process), which is thought to be occurred on the binary star system composed of a neutron star and a companion star. Because of the strong gravitation on the neutron star surface, one expects hydrogen rich mass flow from the companion star. Since the high density and low temperature on the neutron star crust makes electrons degenerated, beta decays are usually Pauli blocked by the degeneration, which gives rise to the pycno-reactions. It means that neutron rich nuclei may become stable nuclei, while unstable nuclei may become stable in this situation.

Up to now, most conventional approaches to understand the nuclear structure are based on the spherical symmetry. In order to describe neutron-rich nuclei and their relevant nuclear reactions occurred in the nuclear processes, one needs to develop theoretical formalism including explicitly the deformation. Ref. exploited the Nilsson basis to the deformed quasi-particle random phase approximation (DQRPA). But the two-body interaction was derived from the effective separable force. The realistic two-body interaction derived from the realistic force is firstly exploited at Ref. only with neutron-neutron (nn) and proton-proton (pp) pairing interactions which have only isospin $T = 1$ and $J = 0$ interaction. But, to properly describe the deformed nuclei, the $T = 0$ and $J = 1$ pairing should be also taken into account because it is intimately related to the deformation by the $J = 1$ pairing.

In this work, we extend our previous QRPA based on the spherical symmetry to the DQRPA. The spherical QRPA has been exploited as a useful framework for describing the
nuclear reactions sensitive on the nuclear structure, such as $2\nu 2\beta$ and $0\nu 2\beta$ nuclear decay, of medium-heavy and heavy nuclei [6], where, as the mass number increases, the application of the shell model may have actual limits because of tremendous increase of configuration mixing due to the deformation. This paper is organized as follows. In Sec. II, we introduce detailed formalism for the DQRPA and the Gamow-Teller (GT) strength. Numerical results and related discussions are presented at Sec. III. Summary and conclusions are addressed at Sec. IV.

II. FORMALISM

A. Total Hamiltonian

We start from the following nuclear Hamiltonian

$$ H = H_0 + H_{\text{int}} , $$

$$ H_0 = \sum_{\alpha p, \alpha' p'} \epsilon_{\alpha p, \alpha' p'} c_{\alpha p, \alpha'}^\dagger c_{\alpha p, \alpha'} \quad (\alpha' = p, n) , $$

$$ H_{\text{int}} = \sum_{\alpha\beta\gamma\delta p, \beta'\gamma'\delta' p, \alpha'\beta'\gamma'\delta'} V_{\alpha p, \alpha' p' \beta p, \beta' p' \gamma p, \gamma' p, \epsilon_{\alpha p, \alpha' p'} c_{\alpha p, \alpha'}^\dagger c_{\beta p, \beta'}^\dagger c_{\gamma p, \gamma'}^\dagger c_{\delta p, \delta'}^\dagger , $$

where the interaction matrix $V$ is the anti-symmetrized interaction with the Baranger Hamiltonian [8] in which two $-\frac{1}{2}$ factors, from J and T coupling, are included, so that the $H_{\text{int}}$ in Eq. (1) is equivalent to the usual $H_{\text{int}} = \frac{1}{4} \sum_{\alpha\beta\gamma\delta p, \beta'\gamma'\delta' p, \alpha'\beta'\gamma'\delta'} V_{\alpha p, \alpha' p' \beta p, \beta' p' \gamma p, \gamma' p, \epsilon_{\alpha p, \alpha' p'} c_{\alpha p, \alpha'}^\dagger c_{\beta p, \beta'}^\dagger c_{\gamma p, \gamma'}^\dagger c_{\delta p, \delta'}^\dagger$. The Greek letters denote proton or neutron single particle states with the projection $\Omega$ of the total angular momentum on the nuclear symmetry axis and the parity $\pi$. The projection $\Omega$ is treated as the only good quantum number in the deformed basis. The $\rho_\alpha$ ($\rho_\alpha = \pm 1$) is the sign of the angular momentum projection $\Omega$ of the $\alpha$ state. The isospin of particles is denoted as a Greek letter with prime, while the isospin of quasi-particles is expressed as a Greek letter with double prime as shown later.

Therefore, the operator $c_{\alpha p, \alpha'}^\dagger (c_{\alpha p, \alpha'})$ in Eq.(1) stands for the usual creation (destruction) operator of the real particle in the state of $\alpha p\alpha'$ with the angular momentum projection $\Omega_\alpha$ and an isospin $\alpha'$, and $c_{\alpha p, \alpha'}^\dagger (= (-1)^{j_\alpha + m_\alpha} c_{-\alpha p, \alpha'})$ is the time reversed operator of $c_{\alpha p, \alpha'}$. Namely our intrinsic states are twofold-degenerate, i.e. $\Omega_\alpha$ state and its time-reversed state $-\Omega_\alpha$. $\epsilon_{\alpha p, \alpha'}$ means the single particle state energies.
In cylindrical coordinates, eigenfunctions of a single particle state and its time-reversed state in deformed Woods-Saxon potential are expressed as follows

$$|\alpha \rho = +1 > = \sum_{Nn_z} [b^{(+)}_{Nn_z \Omega_a} |N, n_z, \Lambda_a, \Omega_a = \Lambda_a + 1/2 > + b^{(-)}_{Nn_z \Omega_a} |N, n_z, \Lambda_a + 1, \Omega_a = \Lambda_a + 1 - 1/2 > ],$$

$$|\alpha \rho = -1 > = \sum_{Nn_z} [b^{(+)}_{Nn_z \Omega_a} |N, n_z, -\Lambda_a, \Omega_a = -\Lambda_a - 1/2 > - b^{(-)}_{Nn_z \Omega_a} |N, n_z, -\Lambda_a - 1, \Omega_a = -\Lambda_a - 1 + 1/2 > ],$$

where $N = n_\perp + n_z$ ($n_\perp = 2n_\rho + \Lambda$) is a major shell number, and $n_z$ and $n_\rho$ are numbers of nodes on the deformed harmonic oscillator wave functions in $z$ and $\rho$ direction, respectively. $\Lambda$ is the projection of the orbital angular momentum onto the nuclear symmetric axis $z$. The coefficients $b^{(+)}_{Nn_z \Omega}$ and $b^{(-)}_{Nn_z \Omega}$ are obtained by the eigenvalue equation of the total Hamiltonian in the Nilsson basis. The 2nd terms in Eq. (2) have the same projection $\Omega_a$ value as the 1st term, but retain another orbital angular momentum because of a flipped spin. The single particle states are used up to $5\hbar \omega$ for all nuclei, in the spherical limit. Single particle spectrum obtained by the deformed Woods Saxon potential is sensitive on the deformation parameter $\beta_2$ defined as

$$R(\theta) = R_0(1 + \beta_2 Y_{20}(\theta) + \beta_4 Y_{40}(\theta)) ,$$

where $R_0 = 1.2A^{1/3}$fm for the sharp-cut radius $R_0$ and $Y_{20}$ is spherical harmonics. The customary parameter $\epsilon = 3(\omega_\perp - \omega_3)/(2\omega_\perp + \omega_3)$ used in the deformed harmonic oscillator is related to as $\beta_2 \approx (2/3)\sqrt{4\pi/5} \epsilon$ at the leading order. We transform the Hamiltonian represented by real particles in Eq. (1) to the quasi-particle representation through the following Hartree Fock Bogoliubob (HFB) transformation,

$$a_{\alpha\alpha'}^{\dagger} = \sum_{\beta\beta'}(u_{\alpha\alpha'^{\dagger} \beta\beta'} + v_{\alpha\alpha'^{\dagger} \beta\beta'} c_{\beta\beta'}^{\dagger}) , \quad a_{\alpha\alpha'} = \sum_{\beta\beta'}(u_{\alpha\alpha'}^{\dagger} \beta\beta' c_{\beta\beta'} + v_{\alpha\alpha'}^{\dagger} \beta\beta' c_{\beta\beta'}^{\dagger}) .$$

The Hamiltonian, then, can be expressed in terms of the quasi-particles as follows

$$H' = H'_0 + \sum_{\alpha\alpha''} E_{\alpha\alpha''} a_{\alpha\alpha''}^{\dagger} a_{\alpha\alpha''} + H_{qp.int} .$$

Using the transformation of Eq. (4), finally we obtain the following HFB equation
\[
\left( \begin{array}{ccc}
\epsilon_p - \lambda_p & 0 & \Delta_{p\bar{p}} \\
0 & \epsilon_n - \lambda_n & \Delta_{n\bar{p}} \\
\Delta_{p\bar{p}} & \Delta_{n\bar{p}} & -\epsilon_p + \lambda_p & 0
\end{array} \right)
\left( \begin{array}{c}
u_{\alpha''p} \\
u_{\alpha'n} \\
v_{\alpha''p} \\
v_{\alpha'n}
\end{array} \right)
= E_{\alpha\alpha''}
\left( \begin{array}{c}
u_{\alpha''p} \\
u_{\alpha'n} \\
v_{\alpha''p} \\
v_{\alpha'n}
\end{array} \right),
\]

where \( E_{\alpha\alpha''} \) is the energy of a quasi-particle with the isospin quantum number \( \alpha'' \) in the state \( \alpha \). If we neglect \( \Delta_{np} \), this equation reduces to the standard Deformed BCS (DBCS) equation.

**B. Spherical and deformed wave functions for a single particle state**

Since various mathematical theorems regarding quantum numbers may not be easily used in the deformed basis, it is more convenient to play in the spherical basis. In addition, we exploit the G-matrix based on the Bonn potential in order to pin down plausible ambiguities on the nucleon-nucleon interaction inside a deformed nucleus. Since the G-matrix is calculated on the spherical basis, we need to represent the G-matrix in terms of the deformed basis. Here we present as to how to transform deformed wave functions to spherical wave functions.

The deformed harmonic oscillator wave function, \(|Nn_z\Lambda_\alpha \Omega_\alpha (= \Lambda_\alpha + \Sigma) >= |Nn_z\Lambda_\alpha > |\Sigma > \) in Eq. (2) can be expanded in terms of the spherical harmonic oscillator wave function \(|N_0l\Lambda > |\Sigma > \) as follows

\[
\sum A_{Nn_z\Lambda}^{N_0l, n_r} |N_0l\Lambda > |\Sigma > = \sum j C_{l\Lambda, \frac{1}{2} \Sigma}^{\Omega_\alpha} |N_0lj \Omega_\alpha > .
\]

Here the spatial overlap integral \( A_{Nn_z\Lambda}^{N_0l} = < N_0lj |Nn_z\Lambda > \) is calculated numerically in the spherical coordinate system. Roman letter indicates quantum numbers \((n_r,lj)\) of a nucleon state in a spherical basis, where \( n_r \) is the radial quantum number and \( l \) is the orbital angular momentum. \( C_{l\Lambda, \frac{1}{2} \Sigma}^{\Omega_\alpha} \) is the Clebsch-Gordan coefficient of the coupling of the orbital and spin angular momenta to total angular momentum with the projection \( \Omega_\alpha \). Therefore, the expansion can be simply written as

\[
|\alpha \Omega_\alpha > = \sum a B_{a}^{\alpha} |a \Omega_\alpha >,
\]

5
with the expansion coefficient summarized as \( B^\alpha_a = \sum_{Nn\Sigma} C^\alpha_{\alpha}' a_{\lambda\Omega} A^\alpha_{Nn\Lambda} b_{Nn\Sigma} \).

The DBCS Eq. (6) is solved by using the Brueckner G-matrix calculated from the realistic Bonn CD potential for the nucleon-nucleon interaction in the following way. The pairing potentials \( \Delta_p, \Delta_n \) and \( \Delta_{pn} \) in Eq. (6) are calculated as

\[
\Delta_{\alpha\alpha p} = -\frac{1}{2(2a+1)^{1/2}} \sum_{Jc} g_{\text{pair}}(g_{\text{pair}}^p) F_{a\alpha}^{J0} G_{\gamma c}(aacc, J)(2c+1)^{1/2}(u_{1p}^* v_{1p} + u_{2c}^* v_{2c}) ,
\]

where \( F_{a\alpha}^{J0} = B_{a0} B_{\beta} C_{\alpha\alpha\beta}^J (K' = \Omega_\alpha + \Omega_\beta) \) is introduced for the transformation to the deformed basis of G-matrix. Here \( K' \), which is a projection number of the total angular momentum \( J \) onto the \( z \) axis, is selected \( K' = 0 \) at the BCS stage because we consider the pairings of the quasi-particles at \( \alpha \) and \( \bar{\alpha} \) states. \( \Delta_{\alpha\alpha n} \) is the same as Eq. (9) with replacement of \( n \) by \( p \). In order to renormalize the G-matrix, strength parameters, \( g_{\text{pair}}^p \), \( g_{\text{pair}}^n \) and \( g_{\text{pair}}^{pn} \) are multiplied to the G-matrix [5] by adjusting the pairing potentials to the empirical pairing potentials, \( \Delta_{\alpha\alpha p}^{\text{emp}}, \Delta_{\alpha\alpha n}^{\text{emp}} \) and \( \Delta_{\alpha\alpha pn}^{\text{emp}} \). The empirical pairing potentials of protons (neutrons) and neutron-proton are evaluated by the following symmetric five term formula for the neighboring nuclei

\[
\Delta_{\alpha\alpha p}^{\text{emp}} = \frac{1}{8} [M(Z + 2, N) - 4M(Z + 1, N) + 6M(Z, N) - 4M(Z - 1, N) + M(Z - 2, N)] ,
\]

\[
\Delta_{\alpha\alpha n}^{\text{emp}} = \frac{1}{8} [M(Z, N + 2) - 4M(Z, N + 1) + 6M(Z, N) - 4M(Z, N - 1) + M(Z, N - 2)] ,
\]

\[
\Delta_{\alpha\alpha pn}^{\text{emp}} = \pm \frac{1}{4} \{2[M(Z, N + 1) + M(Z, N - 1) + M(Z - 1, N) + M(Z + 1, N)] - [M(Z + 1, N + 1) + M(Z - 1, N + 1) + M(Z - 1, N - 1) + M(Z + 1, N - 1)] - 4M(Z, N) \} ,
\]

where \(+(-)\) stands for even(odd) mass nuclei. As for masses in Eqs. (10) \~ (12), we use empirical masses. For the neutron-rich nuclei far from the stability region, the masses are still unknown. We, thus, are going to use the values from the extrapolation or the values derived from the liquid-drop model, \( \Delta \approx 12A^{-1/2}\text{MeV} \). More exact mass measurement of the exotic nuclei from the penning trap [10, 11] are greatly helpful for these empirical parameters.
C. Description of an excited state by the DQRPA

We take the ground state of a target even-even nucleus as the DBCS vacuum for a quasi-particle. In the following, we show how to generate an excited state in a deformed compound nucleus. Since the deformed nuclei have two different frames, the laboratory and the intrinsic frame, we need to consider the relationship of the two frames. The GT excited state in the intrinsic frame of even-even nuclei, which is described by operating a phonon operator to the BCS vacuum $Q_{m,K}^{\dagger}|QRPA>$, can be transformed to the wave function in the laboratory frame by using the Wigner function $D_{MK}(\phi, \theta, \psi)$ as follows

$$|1M(K), m> = \sqrt{\frac{3}{8\pi^2}}D_{M-K}^1(\phi, \theta, \psi)Q_{m,K}^{\dagger}|QRPA> \quad \text{(for } K = 0),$$ \hfill (13)

$$|1M(K), m> = \sqrt{\frac{3}{16\pi^2}}[D_{MK}^1(\phi, \theta, \psi)Q_{m,K}^{\dagger}$$

$$+(-1)^{1+K}D_{M-K}^1(\phi, \theta, \psi)Q_{m,-K}^{\dagger}]|QRPA> \quad \text{(for } K = \pm 1),$$

where $M(K)$ is a projection of the total angular momentum onto the $z$ (the nuclear symmetry) axis. Of course, the $K$ is accepted as only a good quantum number in deformed nuclei. The QRPA phonon creation operator $Q_{m,K}^{\dagger}$ acting on the ground state is given as

$$Q_{m,K}^{\dagger} = \sum_{\rho, \alpha \rho' \beta' \rho''} [X_{(\alpha \rho' \beta' \rho'' K)}^{m} A_{(\alpha \rho' \beta' \rho'' K)}^{(\alpha \rho' \beta' \rho'' K)} - Y_{(\alpha \rho' \beta' \rho'' K)}^{m} \tilde{A}_{(\alpha \rho' \beta' \rho'' K)}].$$ \hfill (14)

with pairing creation and annihilation operators comprising two quasi-particles defined as

$$A_{(\alpha \rho' \beta' \rho'' K)}^{(\alpha \rho' \beta' \rho'' K)} = a_{\alpha \rho'}^{\dagger} a_{\beta' \rho''}^{\dagger}, \quad \tilde{A}_{(\alpha \rho' \beta' \rho'' K)} = a_{\beta' \rho''} a_{\alpha \rho'},$$ \hfill (15)

where bar denotes a time-reversal state for a given state. The quasi-particle pairs in two-particle states, $\alpha$ and $\bar{\beta}$, are chosen by the selection rules $\Omega_{\alpha} - \Omega_{\beta} = K$ and $\pi_{\alpha} \pi_{\beta} = 1$. If we switch off the $np$ pairing, Eq. (14), which includes charge conserving and non-conserving cases, reduces to the phonon operator in Ref. [4].

Two-body wave functions in deformed basis are calculated from the spherical basis as follows

$$|\alpha\beta> = \sum_{abJ} F_{aa'\beta' b}^{JK} |ab, JK>,$$ \hfill (16)

where 2-body wave function in the spherical basis is given as $|ab, JK> = \sum_{\Omega_a, \Omega_b} C_{J a \Omega_a, J b \Omega_b}^{\alpha \beta} |a\Omega_a> |b\Omega_b>$, and the transformation coefficient is calculated as $F_{aa'\beta' b}^{JK} =$
\[ B^\alpha_a \ B^\beta_b (-1)^{j_\beta-\Omega_\beta} \ C^{JK}_{J_a \Omega_{a,j_\beta-\Omega_\beta}} \] which has a phase factor \((-1)^{j_\beta-\Omega_\beta}\) arising from the time-reversed states \(\tilde{\beta}\). \(B^\alpha_a\) is defined below Eq.(8).

Our QRPA equation in deformed basis is given as follows

\[
\begin{pmatrix}
A^{1111}_{a,\beta\gamma\delta}(K) & A^{1112}_{a,\beta\gamma\delta}(K) & A^{1111}_{a,\beta\gamma\delta}(K) & B^{1111}_{a,\beta\gamma\delta}(K) & B^{1111}_{a,\beta\gamma\delta}(K) \\
A^{2211}_{a,\beta\gamma\delta}(K) & A^{2222}_{a,\beta\gamma\delta}(K) & A^{2211}_{a,\beta\gamma\delta}(K) & B^{2211}_{a,\beta\gamma\delta}(K) & B^{2211}_{a,\beta\gamma\delta}(K) \\
A^{1211}_{a,\beta\gamma\delta}(K) & A^{1222}_{a,\beta\gamma\delta}(K) & A^{1211}_{a,\beta\gamma\delta}(K) & B^{1211}_{a,\beta\gamma\delta}(K) & B^{1211}_{a,\beta\gamma\delta}(K) \\
- B^{1111}_{a,\beta\gamma\delta}(K) & - B^{1222}_{a,\beta\gamma\delta}(K) & - B^{1111}_{a,\beta\gamma\delta}(K) & - A^{1112}_{a,\beta\gamma\delta}(K) & - A^{1112}_{a,\beta\gamma\delta}(K) \\
- B^{2211}_{a,\beta\gamma\delta}(K) & - B^{2222}_{a,\beta\gamma\delta}(K) & - B^{2211}_{a,\beta\gamma\delta}(K) & - A^{2211}_{a,\beta\gamma\delta}(K) & - A^{2211}_{a,\beta\gamma\delta}(K) \\
- B^{1211}_{a,\beta\gamma\delta}(K) & - B^{1222}_{a,\beta\gamma\delta}(K) & - B^{1211}_{a,\beta\gamma\delta}(K) & - A^{1211}_{a,\beta\gamma\delta}(K) & - A^{1211}_{a,\beta\gamma\delta}(K)
\end{pmatrix}
\]

\[
\begin{pmatrix}
\tilde{X}^m_{(\gamma\delta K)} \\
\tilde{X}^m_{(\gamma\delta K)} \\
\tilde{X}^m_{(\gamma\delta K)} \\
\tilde{Y}^m_{(\gamma K)} \\
\tilde{Y}^m_{(\gamma K)} \\
\tilde{Y}^m_{(\gamma K)}
\end{pmatrix}
\begin{pmatrix}
\tilde{X}^m_{(\alpha K)} \\
\tilde{X}^m_{(\alpha K)} \\
\tilde{X}^m_{(\alpha K)} \\
\tilde{Y}^m_{(\alpha K)} \\
\tilde{Y}^m_{(\alpha K)} \\
\tilde{Y}^m_{(\alpha K)}
\end{pmatrix}
\times
\begin{pmatrix}
\hbar \Omega^m_K \\
\hbar \Omega^m_K \\
\hbar \Omega^m_K \\
\hbar \Omega^m_K \\
\hbar \Omega^m_K \\
\hbar \Omega^m_K
\end{pmatrix}
\]

where 1 and 2 denote quasi-protons and quasi-neutrons. The amplitudes \(X_{\alpha\alpha''\beta\beta''}\) and \(Y_{\alpha\alpha''\beta\beta''}\), which stand for forward and backward going amplitudes from state \(\alpha\alpha''\) to \(\beta\beta''\), are related to \(\tilde{X}_{\alpha\alpha''\beta\beta''} = \sqrt{2} \sigma_{\alpha\alpha''\beta\beta''} X_{\alpha\alpha''\beta\beta''}\) and \(\tilde{Y}_{\alpha\alpha''\beta\beta''} = \sqrt{2} \sigma_{\alpha\alpha''\beta\beta''} Y_{\alpha\alpha''\beta\beta''}\), where \(\sigma_{\alpha\alpha''\beta\beta''} = 1\) if \(\alpha = \beta\) and \(\alpha'' = \beta''\), otherwise \(\sigma_{\alpha\alpha''\beta\beta''} = \sqrt{2} \ \text{[5]}\). The A and B matrices are given by

\[
A^{\alpha''\beta''}_{a,\beta, \gamma'\delta'}(K) = \left( E_{\alpha\alpha''} + E_{\beta\beta''} \right) \delta_{\alpha'\gamma'} \delta_{\alpha''\delta''} - \sigma_{\alpha\alpha''\beta\beta''} \sigma_{\gamma'\delta''}
\]

\[
\times \left[ g_{pp} \left( u_{\alpha\alpha''} u_{\beta\beta''} u_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} v_{\delta'\delta''} \right) V^K_{a,\beta', \gamma''} + g_{ph} \left( u_{\alpha\alpha''} u_{\beta\beta''} u_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} u_{\delta'\delta''} \right) V^K_{a,\delta', \gamma''} + g_{ph} \left( u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} v_{\delta'\delta''} \right) V^K_{\gamma', \delta''} \right],
\]

\[
B^{\alpha''\beta''}_{a,\beta, \gamma'\delta'}(K) = - \sigma_{\alpha\alpha''\beta\beta''} \sigma_{\gamma'\delta''}
\]

\[
\times \left[ - g_{pp} \left( u_{\alpha\alpha''} u_{\beta\beta''} u_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} v_{\beta\beta''} u_{\gamma'\gamma''} u_{\delta'\delta''} \right) V^K_{a,\beta', \gamma''} + g_{ph} \left( u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} u_{\beta\beta''} u_{\gamma'\gamma''} u_{\delta'\delta''} \right) V^K_{a,\delta', \gamma''} + g_{ph} \left( u_{\alpha\alpha''} v_{\beta\beta''} v_{\gamma'\gamma''} u_{\delta'\delta''} + u_{\alpha\alpha''} u_{\beta\beta''} v_{\gamma'\gamma''} u_{\delta'\delta''} \right) V^K_{\gamma', \delta''} \right],
\]
\[ V^K_{\alpha \beta, \gamma \delta} = \sum_J \sum_{abcd} F^{JK}_{\alpha \alpha \beta \beta} F^{JK}_{\gamma \gamma \delta \delta} G(abcd, J), \quad (20) \]

\[ V^K_{\alpha \delta, \gamma \beta} = \sum_J \sum_{abcd} F^{JK'}_{\alpha \alpha \delta \delta} F^{JK'}_{\gamma \gamma \beta \beta} G(adcb, J), \]

\[ V^K_{\alpha \gamma, \delta \beta} = \sum_J \sum_{abcd} F^{JK}_{\alpha \alpha \gamma \gamma} F^{JK}_{\delta \delta \beta \beta} G(acdb, J). \]

where \( F^{JK'}_{\alpha \alpha \delta \delta} = B^\alpha_a B^\beta_b C^{JK'}_{\alpha \alpha \beta \beta} \) with non-zero \( K' = \Omega_{\alpha} + \Omega_{\beta} \), and \( u \) and \( v \) coefficients are determined from deformed HFB calculation with the pairing strength \( g_{\text{pair}}^n, g_{\text{pair}}^p \) and \( g_{\text{pair}}^{np} \) adjusted to the empirical pairing gaps \( \Delta_{nn}, \Delta_{pp} \) and \( \Delta_{np} \), respectively. \( E_{\alpha \alpha''} \) indicates the quasi-particle energy of the state \( \alpha \) with the quasi-particle isospin \( \alpha'' \). The \( G(F) \) matrices are two body particle-particle (hole) matrix elements obtained as solutions of the Bethe-Goldstone equation from the Bonn potential \[12\]. If we do not consider the np pairing correlations, the A and B matrices can be expressed in the following simple form, which is the same as those of Saleh \[4\],

\[ A^{nm, \nu \nu'}_{\alpha \beta, \gamma \delta}(K) = (E_{\alpha p} + E_{\beta n}) \delta_{\alpha \gamma} \delta_{\nu \nu'} \delta_{\beta \delta} \delta_{nn'} \]

\[ -2 \left[ g_{pp}(u_{\alpha p} u_{\beta n} u_{\gamma p'} u_{\delta n'} + v_{\alpha p} v_{\beta n} v_{\gamma p'} v_{\delta n'}) \right] V^K_{\alpha \beta, \gamma \delta} \]

\[ + g_{ph}(u_{\alpha p} u_{\beta n} u_{\gamma p'} u_{\delta n'} + v_{\alpha p} v_{\beta n} v_{\gamma p'} v_{\delta n'}) \right] V^K_{\alpha \beta, \gamma \delta}, \quad (21) \]

\[ B^{nm, \nu \nu'}_{\alpha \beta, \gamma \delta}(K) = -2 \left[ -g_{pp}(u_{\alpha p} u_{\beta n} v_{\gamma p'} v_{\delta n'} + v_{\alpha p} v_{\beta n} u_{\gamma p'} u_{\delta n'}) \right] V^K_{\alpha \beta, \gamma \delta} \]

\[ + g_{ph}(u_{\alpha p} u_{\beta n} v_{\gamma p'} v_{\delta n'} + v_{\alpha p} v_{\beta n} u_{\gamma p'} u_{\delta n'}) \right] V^K_{\alpha \beta, \gamma \delta}. \quad (22) \]

D. Description of Gamow-Teller Transition

The \( \beta^{\pm} \) decay operator, \( \hat{\beta}^{\pm}_{1\mu} \), is defined in the intrinsic frame as

\[ \hat{\beta}^{-}_{1\mu} = \sum_{\alpha \beta \rho \sigma} \langle \alpha \rho | \tau^+ \sigma | \beta \sigma \rangle \hat{c}_{\alpha \beta}, \quad \hat{\beta}^{+}_{1\mu} = (\hat{\beta}^{-}_{1\mu})^\dagger = (-\mu)^\dagger \hat{\beta}^{-}_{1,-\mu}, \quad (23) \]

in which the \( \hat{\beta}^{\pm}_{1\mu} \) transition operators are related with those in the laboratory system \( \hat{\beta}^{\pm}_{M} \) operator as follows

\[ \hat{\beta}^{\pm}_{M} = \sum_{\mu} D^{\dagger}_{M\mu}(\phi, \theta, \psi) \hat{\beta}^{\pm}_{1\mu}. \quad (24) \]
The $\beta^\pm$ transition amplitudes from the ground state of an initial nucleus to the excited state, the one phonon state in a final nucleus, are expressed by

$$< 1(K), m | \hat{\beta}_K^\pm | Q R P A >$$

$$= \sum_{\alpha'\rho_\alpha, \beta'\rho_\beta} N_{\alpha'\rho_\alpha, \beta'\rho_\beta} < \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > [ u_{\alpha\alpha'} v_{\alpha'\rho_\alpha} X_{\alpha\beta'\rho_\beta} + v_{\alpha\alpha'} u_{\alpha'\rho_\alpha} Y_{\alpha\beta'\rho_\beta}, K ]$$

$$< 1(K), m | \hat{\beta}_K^\pm | Q R P A >$$

$$= \sum_{\alpha'\rho_\alpha, \beta'\rho_\beta} N_{\alpha'\rho_\alpha, \beta'\rho_\beta} < \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > [ u_{\alpha\alpha'} v_{\alpha'\rho_\alpha} Y_{\alpha\beta'\rho_\beta} + v_{\alpha\alpha'} u_{\alpha'\rho_\alpha} X_{\alpha\beta'\rho_\beta}, K ]$$

where $| Q R P A >$ denotes the correlated QRPA ground state in the intrinsic frame and the normalization factor is given as $N_{\alpha'\rho_\alpha, \beta'\rho_\beta} (J) = \sqrt{1 - \delta_{\alpha\beta} \delta_{\alpha'\beta'}} (1 + \delta_{\alpha\beta} \delta_{\alpha'\beta'})$. The Wigner functions are disappeared by using the orthogonality of two Wigner functions from the operator and the excited state, respectively. This form is also easily reduced to the results by proton-neutron DQRPA without the $np$ pairing

$$< 1(K), m | \hat{\beta}_K^\pm | Q R P A >$$

$$= \sum_{\alpha'\rho_\alpha, \beta'\rho_\beta} < \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > [ u_{\alpha'\rho_\alpha} Y_{\alpha'\beta'\rho_\beta} + v_{\alpha'\rho_\alpha} u_{\alpha'\rho_\alpha} X_{\alpha'\beta'\rho_\beta}, K ].$$

Here single particle matrix elements of $< \alpha' | p | \sigma_K | \beta' | n | \rho_\beta >$ can be expressed in deformed basis

$$< \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > = \delta_{\alpha'\Omega_{\rho_\alpha, n}} \rho_\alpha \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(+)} b_{N_{n z} n_{\rho_\beta}}^{(-)} - b_{N_{n z} n_{\rho_\alpha}}^{(-)} b_{N_{n z} n_{\rho_\beta}}^{(+)}.$$  

$$< \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > = - \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n+1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(+)} b_{N_{n z} n_{\rho_\beta}}^{(-)} (\rho_\alpha = \rho_\beta = +1)$$

$$= + \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n+1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(-)} b_{N_{n z} n_{\rho_\beta}}^{(+)} (\rho_\alpha = \rho_\beta = -1)$$

$$= - \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n-1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(-)} b_{N_{n z} n_{\rho_\beta}}^{(+)} (\rho_\alpha = +1, \rho_\beta = -1),$$

$$< \alpha' | p | \sigma_K | \beta' | n | \rho_\beta > = \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n-1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(-)} b_{N_{n z} n_{\rho_\beta}}^{(+)} (\rho_\alpha = \rho_\beta = +1)$$

$$= - \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n-1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(+)} b_{N_{n z} n_{\rho_\beta}}^{(-)} (\rho_\alpha = \rho_\beta = -1)$$

$$= + \sqrt{2} \delta_{\alpha'\Omega_{\rho_\alpha, n+1}} \sum_{N_{n z}} b_{N_{n z} n_{\rho_\alpha}}^{(+) n_{\rho_\beta}^{(+)}} (\rho_\alpha = +1, \rho_\beta = -1).$$
To compare our theoretical results to the experimental data, the GT(±) strength functions and their running sums (total strengths) are calculated as

\[ B_{GT}^-(m) = \sum_{K=0,\pm 1} |<1(K), m|\hat{\beta}_K^-|| QRPA >|^2, \quad (30) \]

\[ B_{GT}^+(m) = \sum_{K=0,\pm 1} |<1(K), m|\hat{\beta}_K^+|| QRPA >|^2, \]

\[ S_{GT}^- = \sum_{K=0,\pm 1} \sum_m |<1(K), m|\hat{\beta}_K^-|| QRPA >|^2, \quad (31) \]

\[ S_{GT}^+ = \sum_{K=0,\pm 1} \sum_m |<1(K), m|\hat{\beta}_K^+|| QRPA >|^2. \]

E. Ikeda Sum Rule

Numerical results for total GT(±) strengths, \( S_{GT}^- \) and \( S_{GT}^+ \), in Eq. (31) are investigated through the Ikeda sum-rule (ISR), which is known to be satisfied more or less independently of the constructed excited states by any nuclear models,

\[ S_{GT}^- - S_{GT}^+ = 3(N - Z). \quad (32) \]

The ISR within the Deformed QRPA, denoted as ISR II, is given by

\[ (S_{GT}^- - S_{GT}^+)_{ISR \; II} = \sum_{K=0,\pm 1} \sum_m |<1(K), m|\hat{\beta}_K^-|| QRPA >|^2 - |<1(K), m|\hat{\beta}_K^+|| QRPA >|^2 \]

\[ = \sum_{K=0,\pm 1} \sum_m \sum_{\alpha_p \rho_\alpha, \beta_n \rho_\beta} |<\alpha_p \rho_\alpha |\tau^+ \sigma_K|\beta_n \rho_\beta >|^2 (u_{\alpha_p} v_{\beta_n}^2 - v_{\alpha_p} u_{\beta_n}^2)(X_{\alpha_p,\beta_n,K}^m)^2 - (Y_{\alpha_p,\beta_n,K}^m)^2. \quad (33) \]

If we use the closure relation for the excited states, the ISR which we denote as ISR I is shown to be easily calculated as follows

\[ (S_{GT}^- - S_{GT}^+)_{ISR \; I} = \sum_{K=0,\pm 1} \sum_{\alpha_p \rho_\alpha, \beta_n \rho_\beta} |<\alpha_p \rho_\alpha |\tau^+ \sigma_K|\beta_n \rho_\beta >|^2 (v_{\beta_n}^2 - v_{\alpha_p}^2) \]. \quad (34) \]

Since we use the limited particle model space in deformed basis under the one-body current without the \( \Delta \) excitation, the above sum rule is a bit broken, but it may be used to test our
nuclear model and their numerical calculations as shown in our numerical results. On the other hand, the ISR in spherical basis is easily shown to satisfy the ISR as follows

\[
S_{GT}^- - S_{GT}^+ = \sum_{apbn} |<ap|\tau^+\sigma|bn>|^2(v_n^2 - v_p^2)
\]

\[
= \sum_{apbn} (2j_a + 1)(2j_b + 1)\delta_{na nb}\delta_{la lb} \left\{ \begin{array}{ccc}
\frac{1}{2} & \frac{1}{2} & 1 \\
\frac{1}{2} & j_a & j_b \\
& l_a & l_b \\
\end{array} \right\} (v_n^2 - v_p^2)
\]

\[
= 3 \sum_{bn} (2j_b + 1)v_n^2 - 3 \sum_{ap} (2j_a + 1)v_p^2 = 3(N - Z).
\]

**III. RESULTS**

We calculated the Gamow-Teller (GT) strength, \(B_{GT}^\pm\), in Eq. (30), for \(^{76}\)Ge, \(^{82}\)Se, \(^{90}\)Zr, and \(^{92}\)Zr within the DQrpa. Those nuclei are selected to represent medium-heavy nuclei which have experimental GT strength data deduced from CERXs. Since the GT strength distributions turn out to be sensitive on the deformation parameter, \(\beta_2\) in Eq.(3), we exploited various values of the deformation parameter, \(|\beta_2| \leq 0.3\), as the default values. For the pairing interaction, the strength parameters \(g^{pa}_{pair}\) and \(g^{p}_{pair}\) in Eq.(9), which are introduced to renormalize the finite Hilbert model particle space, are adjusted to reproduce the empirical pairing gaps through symmetric five term formula Eqs.(10)-(12) \[5\]. Corresponding values of the deformation parameter \(\beta_2\), theoretical and empirical pairing gaps are tabulated in Table I with the ISR I and II in Eqs.(33) and (34). It is a remarkable point that theoretical ISR results are well satisfied, and nearly independent of the deformation parameter, \(\beta_2\), as required in the sum rule. Of course, the percentage depends on the particle model space. If the single particle states are used up to \(6\hbar\omega\) for all nuclei in the spherical limit, the ISR values could be satisfied within 1% error.

The single particle state energies adopted from the deformed Woods Saxon potential naturally depends on the parameter \(\beta_2\). In the cylindrical Woods-Saxon potential, the nuclear and spin-orbit terms are \[7\]

\[V(l) = -\frac{V_0}{1 + \exp(l/a)}, \quad V_{so} = -\lambda(h/2mc)^2\nabla V(l)(\sigma \times p),\]

where \(l = l(r; r_0, \beta_2, \beta_4)\) is the distance function of a given point \(r\) to the nuclear surface represented by Eq. \[3\], and \(a\) and \(\lambda\) is the diffuseness parameter and the strength of spin-orbit potential, respectively. The deformation of nuclei may be conjectured to come from
macroscopic phenomena, for example, the core polarization, the high spin states and so on. Microscopic reasons may be traced to the tensor force in nucleon-nucleon interaction, which is known to account for the shell evolution according to the recent systematic shell model calculations [13, 14]. For example, $T = 0, J = 1$ pairing, which is associated with the $^3S_0$ tensor force, may lead to the deformation contrary to the spherical $T = 1, J = 0$ pairing. Therefore, the deformation parameters adopted in this work may include implicitly and effectively such effects, because the single particle states from the deformed Wood Saxon potential show a strong dependence on the $\beta_2$ [15].

The deformation parameter $\beta_2$ may help us to conjecture the nuclear shape through the intrinsic quadrupole moment, $Q = \sqrt{16\pi/5(3/4\pi)}AR_0^2\beta_2$, where $R_0 = 1.2A^{1/3}$fm for the sharp-cut radius $R_0$ [16, 17]. In experimental side, the deformation parameter $\beta_2$ can be extracted from the E2 transition probability, $Q = \sqrt{16\pi B(E2)/5e^2}$. Since we do not have yet enough E2 data to be exploited in the nuclei considered here to our knowledge, we refer to theoretical results by the relativistic mean field theory (RMF) [18]. But the sign of the $\beta_2$ is sometimes still uncertain and also the coexistence of prolate and oblate shapes are also possible. In this work, such coexistence and $\beta_4$ deformation are not taken into account.

In the DQRPA stage, we took the particle-hole and particle-particle strength parameters, $g_{ph}$ and $g_{pp}$ in Eqs.(18)-(19) as 1.0 for for the four nuclei. Actually $g_{ph}$ might be determined from the Gamow Teller Giant Resonance (GTGR), while fine tunings of $g_{pp}$ are usually performed for the double beta decay [5]. In this work, we fix them because the GT strength distributions are not so sensitive on those values.

Since the nuclei considered here are expected to have large energy gaps between proton and neutron spaces, we considered only the $nn$ and $pp$ pairing correlation although the formalism is presented generally. For example, in the neutron-rich nuclei of importance in the r-process, the $np$ pairing may not contribute so much. But for the p-process, the $np$ pairing could be more important than in the neutron-rich nuclei because of the adjacent energy gaps of protons and neutrons. The calculations for the neutron-deficient nuclei in p-process are in progress by the explicit inclusion of the $np$ pairing correlations.

In the following, we show the GT strength distribution in terms of the $\beta_2$ parameter, as a function of excited energy of parent nucleus. Therefore, experimental data, which were usually measured w.r.t. the the ground state of daughter nuclei, are presented by subtracting the empirical Q values from the measured data.

13
In Figs. 1 and 2, we show the GT(–) strength of $^{76}$Ge as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{76}$Ge, whose Q value is 0.9233 MeV. The uppermost two panels are the experimental data from the $^{76}$Ge(p,n)$^{76}$As reaction at 134.4 MeV \[19\], which show a strong GT state peak around 12 MeV. Fig. 1 represent the calculated GT strength with prolate shapes, $\beta_2 = 0.1 \sim 0.3$, and Fig. 2 is for oblate shapes, $\beta_2 = -0.1 \sim -0.3$. The GT strength distributions are widely scattered owing to deformation.

In particular, the results for $\beta_2 = 0.3$ nicely reproduce the peak on the high-lying excited GT states around 12 MeV. Therefore, the redistribution of the GT strength by the deformation is not a simple wide scattering, but should be understood as the redistribution well matched to the high-lying excited states to be confirmed in the experiments. Our $\beta_2$ value is consistent with the prolate shape suggested by the RMF calculation, whose value was $\beta_2 = 0.157$ \[18\] a bit smaller than the present value.

The GT(–) strength, B(GT–), on $^{82}$Se is presented, in Fig. 3, as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{82}$Se (whose Q value is 0.092 MeV) for $\beta_2 = \pm 0.1 \sim \pm 0.2$. The uppermost panel of Fig. 3 is the experimental data from the $^{82}$Se(p,n)$^{82}$Br reaction at 134.4 MeV \[19\]. Particularly, the strong strength on the high-lying excited GT state around 12 MeV is neatly reproduced by the $\beta_2 = 0.2$ at (c) panel. For a reference, the $\beta_2$ value from the RMF is 0.133 \[18\]. Our theoretical calculations address a possibility of another peak beyond 15 MeV.

The forward GT amplitudes $X_{\alpha\alpha'\beta\beta'}$, for three highest GT transition peaks at 10.08 and 12.99 MeV in (c) panel of Fig. 3, are shown in Fig. 4. Main transitions turn out to come from the $(312 3/2) \rightarrow (303 5/2)$ at 10.08 MeV, and $(303 5/2) \rightarrow (303 7/2)$ transition at 12.99 MeV, respectively. They are thought to result from the 2p-2h configuration mixing stemming from the deformation around the Fermi surface.

Figs. 5 and 6 show the GT(±) strength on $^{90}$Zr as a function of the excitation energy $E_{ex}$ w.r.t. $^{90}$Zr, whose Q values for GT(±) are 6.111 and 2.280 MeV, respectively. The uppermost panels (a) stand for the experimental data on GT(–) and GT(+) deduced from the $^{90}$Zr(p,n)$^{90}$Nb reaction $^{90}$Zr(n,p)$^{90}$Y at 293 MeV \[20\], respectively. Panels (c)∼(d) are the results by the DQRPA for two different prolate and oblate $\beta_2$ values. For a reference, in panel (b), we show results by the spherical QRPA \[5, 21\]. The ISR is almost satisfied at each $\beta_2$ value for both B(GT(±)). If we recollect that the experimental GT(–) (GT(+)') strengths on the high-lying states around 30 $\sim$ 38 MeV (17 $\sim$ 25 MeV) include the contributions by
the isovector spin monopole (IVSM) which are not considered in the present calculation, our spherical QRPA (SQRPA) (b) and DQRPA (c) for $\beta_2 = 0.1$ results seem to be consistent with the data.

It means that the $^{90}\text{Zr}$ is thought to be near to a spherical shape, i.e. almost spherical. But the DQRPA results by $\beta_2 = 0.1$ are consistent with the data. Since our DQRPA is based on the intermediate deformation, the extension to small $\beta_2$ values may not be a proper treatment, if we understand that the angular momentum projection $\Omega_j$ may have angular momenta higher than $j$, and may go back to different $j$ values in the $\beta_2 = 0$ limit. One more interesting point is that almost spherical nuclei, such as $^{90}\text{Zr}$, did not show the high-lying GT(–) excited states appeared on $^{76}\text{Ge}$ and $^{82}\text{Se}$. The high-lying states at the GT(+) transition is also neatly explained as shown at (c) in Fig.6.

Fig.7 show the GT(–) strength of $^{92}\text{Zr}$ as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{92}\text{Zr}$, whose Q value is 2.005 MeV. The uppermost panel (a) of Fig.7 represent the experimental $B(\text{GT}^-)$ values extracted from $^{92}\text{Zr}(p,n)^{92}\text{Nb}$ reaction at 26MeV, which energy was too low to expect high-lying excited states. Excitation energies observed in this reaction are located below 9 MeV. Panels (b) is the our results for $\beta_2 = 0.1$.

IV. SUMMARY AND CONCLUSION

To describe deformed nuclei, we performed the deformed axially symmetric Woods-Saxon potential, the deformed BCS, and the deformed QRPA with realistic two-body interaction calculated by Brueckner G-matrix based on Bonn CD potential. Results of the Gamow-Teller strength, $B(\text{GT}^\pm)$, for $^{76}\text{Ge}$, $^{82}\text{Se}$, $^{90}\text{Zr}$, and $^{92}\text{Zr}$ show that the deformation effect leads to a fragmentation of the GT strength into high-lying GT excited states, in particular, on $^{76}\text{Ge}$ and $^{82}\text{Se}$ which GT data were already measured at the charge exchange reaction experiments by the 134.4 MeV proton beam. Those states are shown to be properly explained by the deformation effects.

These high-lying excited GT states may affect seriously relevant nuclear reactions, particularly for neutrino-induced reactions, exploited in the nucleosynthesis because the emitted neutrinos from the proto-neutron star may have a high energy tail up to tens of MeV energy range. Since the experiments relate to the neutrino reaction on such a high energy would be a very challenging task in the present neutrino factories, the extraction of the high-lying GT
states from charge exchange reactions could be very useful for understanding the neutrino reaction in the cosmos, if we recollect that the GT transitions are main components for the neutrino-induced reaction.

More systematic analysis of deformed nuclei by our DQRPA are under progress by including light nuclei characterized by the shell evolution or the inversion island. In the light nuclei or neutron-deficient nuclei, which may have small energy gaps between protons and neutrons and small N-Z values, the neutron-proton pairing correlations could definitely affect nuclear $\beta^+$ decays and Ikeda sum rule. Therefore GT(+) strength distribution data on the nuclei could be a stringent test of nuclear models.

FIG. 1: (Color online) Gamow-Teller strength distributions $B(GT^-)$ on $^{76}$Ge as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{76}$Ge. Experimental data denoted as filled (red) points in the uppermost panels are deduced from the $^{76}$Ge(p,n) reaction at 134.4 MeV [19]. In each panel, we indicate $\beta_2 = 0.1 \sim 0.3$ for prolate shapes.
FIG. 2: (Color online) The same as in Fig. 1 but for oblate shapes, $\beta_2 = -0.1 \sim -0.3$. 
FIG. 3: (Color online) Gamow-Teller strength distributions $B(GT^-)$ on $^{82}$Se as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{82}$Se. Experimental data denoted as filled (red) points in the uppermost panels are deduced from the $^{82}$Se(p,n) reaction at 134.4 MeV [19]. In each panel, we indicate $\beta_2$. 
FIG. 4: Forward amplitudes $X$ of the two highest GT strengths in (c) panel of Fig.3 at 10.08 and 12.99 MeV w.r.t. the ground state of $^{82}\text{Se}$ among the GT transition configuration mixing. Transition (3 1 3 3/2, 3 0 3 5/2) is the only physical component to the GT state at 10.08 MeV and (3 0 3 5/2, 3 0 3 7/2) transition at 12.99 MeV.
FIG. 5: (Color online) Gamow-Teller strength distributions \( B(\text{GT}^-) \) on \(^{90}\text{Zr}\) as a function of the excitation energy \( E_{\text{ex}} \) w.r.t. the ground state of \(^{90}\text{Zr}\). Experimental data denoted as filled (red) points in the uppermost panels are deduced from the \(^{90}\text{Zr}(p,n)\) reaction at 293 MeV [20]. In each panel, we indicate \( \beta_2 \). The energy regions of IVSM excitation are around 30 ~ 38 MeV in panel (a).
FIG. 6: (Color online) Gamow-Teller strength distributions $B(\text{GT}^+)$ on $^{90}\text{Zr}$ as a function of the excitation energy $E_{ex}$ w.r.t. the ground state of $^{90}\text{Zr}$. The filled (red) circles in the uppermost panels are deduced from the $^{90}\text{Zr}(n,p)$ reaction at 293 MeV [20]. In each panel, we indicate $\beta_2$. The energy regions of IVSM excitation are around $17 \sim 25$ MeV in panel (a).
FIG. 7: (Color online) Gamow-Teller strength distributions $B(\text{GT}^-$) on $^{92}\text{Zr}$ as a function of the excitation energy $E_{\text{ex}}$ w.r.t. the ground state of $^{92}\text{Zr}$. Experimental data denoted as filled (red) points in the uppermost panels are deduced from the $^{92}\text{Zr}(p,n)^{92}\text{Nb}$ reaction at 26 MeV [22]. In each panel, we indicate $\beta_2$.
