ABSTRACT

Introduction. Although traumatic pneumocephalus is not uncommon, it rarely evolves into tension pneumocephalus (TP). Characterized by the presence of increasing amounts of intracranial air and concurrent appearance or worsening neurological symptoms, TP can be devastating if not recognized and treated promptly. We present two cases of traumatic TP and a concise review of literature on this topic.

Methods. Two cases of traumatic TP are presented. In addition, a literature search revealed 20 additional cases, of which 18 had sufficient information for inclusion. Literature cases were combined with the 2 reported cases and analyzed for demographics, mechanism of injury, symptoms, time to presentation (acute <72 hours; delayed ≥72 hours), diagnostic/treatment modalities, and outcomes.

Case reports and literature review. Twenty cases were analyzed (17 males, 3 females, median age 26, range 8-92 years). Presentation was acute in 13/20 and delayed in 7/20 patients. Injury mechanisms included motor vehicle collisions (6/20), assault/blunt trauma to the cranio-facial area (5), falls (4), and motorcycle/bicycle crashes (3). Common presentations included depressed mental status (10/20), CSF rhinorrhea (9), headache (8), and loss of consciousness (6). Computed tomography (CT) was utilized in 19/20 patients. Common underlying injuries were frontal bone/sinus fracture (9/20) and ethmoid fracture (5). Intracranial hemorrhage was seen in 5/20 patients and brain contusions in 4/20 patients. Nonoperative management was utilized in 6/20 patients. Procedural approaches included craniotomy (11/20), emergency burr hole (4), endoscopy (2), and ventriculostomy (2). Most patients responded to initial treatment (19/20). One early and one delayed death were reported.

Conclusions. Traumatic TP is rare, tends to be associated with severe cranio-facial injuries, and can occur following both blunt and penetrating injury. Early recognition and high index of clinical suspicion are important. Appropriate treatment results in improvement in vast majority of cases. CT scan is the diagnostic modality of choice for TP.

INTRODUCTION

Traumatic pneumocephalus – or abnormal presence of air in the cranial cavity following traumatic injury – occurs frequently. Its pathophysiology involves air entry into the cranial cavity following injury to the brain meninges.2 Tension pneumocephalus (TP) is a clinical entity characterized by continued build-up of air within the cranial cavity, leading to abnormal pressure exerted upon the brain and subsequent neurologic deterioration.3,4 The accumulation of intracranial air can be acute or delayed.5,6 Knowledge of risk factors, radiographic findings, and clinical signs/symptoms associated with TP is crucial to its prompt identification and treatment.4,5,7,8 Clinical diagnostic and treatment delays may result in poor neurologic outcome and mortality.1 Treatment may involve a combination of: (a) surgical removal of intracranial air; (b) supine or Trendelenburg positioning; (c) administration of 100% oxygen; (d) repair of the bone/dural defects; and (e) drain placement into the air-containing space. In this manuscript, the authors present two cases of traumatic TP and review additional 18 cases previously reported in the literature.

METHODS

Two cases of traumatic tension pneumocephalus are presented. In addition, a detailed literature search (PubMed, Google Scholar, ScientificCommons) revealed a total of 20 other traumatic pneumocephalus cases, of which 18 (Table 1) contained complete data that were sufficient for subsequent collection/analysis of the following variables: (a) patient age; (b) patient gender; (c) mechanism of injury; (d) primary injury associated with TP; (e) associated injuries; (f) signs and symptoms of TP; (g) therapeutic approach to TP; and (h) timing.

of clinical onset of TP. Cases reported in the literature were then combined with the 2 cases reported by our group and analyzed for demographics, mechanism of injury, symptoms, time to presentation (acute or presenting within 72 hours of injury versus delayed or presenting after the initial 72 hours post-injury), diagnostic and treatment modalities used, and outcomes.

**CASE REPORT #1**

An 8-year-old male was admitted to the hospital after being struck by a motor vehicle. During the initial trauma evaluation, he was found to have slight facial deformities and abdominal tenderness. Computed tomography (CT) demonstrated the presence of multiple skull fractures, including right mastoid fracture (Figure 1A-D). His other injuries included a grade II splenic laceration with no evidence of intravenous contrast extravasation. He was admitted to the surgical intensive care unit (SICU) for observation. The following morning, the patient was found to have dilated and minimally responsive pupils bilaterally. He also experienced several episodes of bradycardia (lowest recorded heart rate of 28 beats/minute). He had no other focal neurologic findings (his Glasgow Coma Score [GCS] remained between 14 and 15), with the only major subjective complaint being significant headache. The patient underwent an urgent repeat CT of the brain, which demonstrated a marked increase in the volume of pneumocephalus, no intra- or extra-axial hemorrhage, and stable multiple skull fractures (Figure 1E-F). The patient, who was initially maintained with 30-degree head elevation, was now re-positioned in flat configuration and high-flow oxygen was administered via face mask. His bradycardic episodes resolved after this positional change and his pupillary dilation resolved over the period of approximately 18 hours. Therapy directed at TP was continued for three days, after which his activity was liberalized without any recurrent symptoms. The patient was doing well on three-month follow-up [Glasgow Outcome Score (GOS) of 5, GCS of 15, no focal neurological deficits].

**CASE REPORT #2**

A twenty-year-old man was brought to the trauma evaluation area following a high-speed motor vehicle collision. He sustained massive injuries to his midface after striking the steering wheel. His initial GCS was 14 (Motor 6, Verbal 5, Eyes 3) upon hospital arrival. The initial CT of the head and face demonstrated a small to moderate pneumocephalus, brain contusions, as well as multiple facial fractures (Figure 2B), with slight midline shift and the classic appearance of the “Mount Fuji” sign (Figure 2C). No other obvious causes for such rapid deterioration (i.e., opioid administration, rapidly expanding intracranial hematoma, or other traumatic injuries) were noted. The patient was taken to the operating room for repair of a dural tear as well as fixation of multiple facial fractures. Postoperative CT scan demonstrated resolution of the preoperative pathologic findings (Figure 2D). The patient gradually recovered over a period of 3 weeks and was discharged to a rehabilitation facility with a GCS of 13 and GOS of 3. On three-month follow up, the patient was ambulatory, with GCS of 15, GOS of 4, and continued neurologic improvement.

**REVIEW OF LITERATURE**

A total of 20 tension pneumocephalus reports were identified. Of those, 18 were suitable for inclusion and further comparisons. Cases outlined by the authors were then added to those identified from the literature search, for a total of 20 patients. There were 17 males and 3 females (median age 26, range 8-92 years). Presentation was acute in 13/20 and delayed in 7/20 patients. Injury mechanisms included motor vehicle collisions (6/20),

parallel those for a cerebrospinal fluid leak. It is important to identify the site where the communication between the air cavity and the external environment occurs. If the site can be identified, the passage should be sealed off, thereby decreasing the possibility of worsening or recurrent pneumocephalus. Effective therapy of TP via a controlled decompression using a closed water-seal drainage system has also been described.

Tension pneumocephalus is a neurosurgical emergency, and as such, its early identification is crucial. Diagnostically, Ishiwata al described the appearance of the "Mount Fuji" sign in a series of patients with tension pneumocephalus. The presence of such "Mount Fuji" sign (Figures 1F & 2B-C) on head CT in trauma patients should be considered a critical finding, and its presence should prompt immediate patient evaluation and appropriate re-appraisal of the therapeutic plan. To diagnose TP, the CT findings should correlate with clinical signs of neurologic deterioration. In the early 1980s, an attempt was made to explain the mass effect of pneumocephalus based on the volume of gas. It has been proposed that the volume of air as little as 65 mL is sufficient enough to produce tension pneumocephalus.

Subsequent to this finding, however, other authors found no substantial difference between the volume of air and the occurrence of tension pneumocephalus. After both clinical and imaging findings are appropriately recognized and correlated, definitive treatment is initiated. Reported treatment options for tension pneumocephalus include a combination of: (a) drilling of burr holes; (b) criocytomia; (c) needle aspiration; (d) ventriculostomy placement; (e) Administration of 100% oxygen; and (f) closure of dural defect(s). Careful monitoring for clinical deterioration, as well as serial CT scanning of the brain, is recommended.

CONCLUSIONS
Post-traumatic tension pneumocephalus is rare, tends to be associated with severe cranial and facial injuries, and can be present following both blunt and penetrating mechanisms of injury. Early recognition and high index of clinical suspicion are important and prompt treatment results in improvement in vast majority of cases. Computed tomography is the gold standard for diagnosis of this condition.
