Fluvial organic carbon cycling regulated by sediment transit time and mineral protection

Marisa Repasch12, Joel S. Scheingross3, Niels Hovius12, Maarten Lupker4, Hella Wittmann1, Negar Haghipour4, Darren R. Gröcke6, Oscar Orfeo7, Timothy I. Eglinton4 and Dirk Sachse1

Rivers transfer terrestrial organic carbon (OC) from mountains to ocean basins, playing a key role in the global carbon cycle. During fluvial transit, OC may be oxidized and emitted to the atmosphere as CO2 or preserved and transported to downstream depositional sinks. The balance between oxidation and preservation determines the amount of particulate OC (POC) that can be buried long term, but the factors regulating this balance are poorly constrained. Here, we quantify the effects of fluvial transit on POC fluxes along an ~1,300 km lowland channel with no tributaries. We show that sediment transit time and mineral protection regulate the magnitude and rate of POC oxidation, respectively. Using a simple turnover model, we estimate that annual POC oxidation is a small percentage of the POC delivered to the river. Modelling shows that lateral erosion into POC-rich floodplains can increase POC fluxes to downstream basins, thereby offsetting POC oxidation. Consequently, rivers with high channel mobility can enhance CO2 drawdown while management practices that stabilize river channels may reduce the potential for CO2 drawdown.

Earth’s habitability is regulated by atmospheric CO2 concentrations. Over geologic timescales, silicate weathering and terrestrial organic carbon burial drive atmospheric CO2 drawdown, while solid Earth degassing and organic carbon oxidation release CO2 to the atmosphere. Terrestrial organic carbon burial is facilitated by geomorphic processes such as erosion, which removes carbon from the terrestrial biosphere, and fluvial transit, which transfers organic particulate carbon (POC) to downstream depositional basins12. The amount of POC that can be buried long term is modulated by the balance between oxidation and preservation during fluvial transit, including time spent in transient storage in floodplains14. Predicting how fluvial transit regulates long-term POC burial, and ultimately atmospheric CO2 concentrations, requires an understanding of the feedbacks between geomorphic and geochemical processes governing sediment routing and POC decomposition56.

We hypothesize that the balance between fluvial POC oxidation and preservation (‘POC budget’) is controlled primarily by two factors: (1) fluvial transit time and (2) mineral protection of POC. First, fluvial transit time determines the residence time of POC in river systems12–14, and longer residence times facilitate POC oxidation. In coastal mountains with short (~10–100 km), steep rivers linking to the ocean, fluvial POC may be efficiently transferred to depositional31–19. In continental settings, fluvial transit lengths and times can exceed 105 km and 20 kyr11–12, respectively, and many large rivers have been characterized as net CO2 sources due to degassing from channels and floodplains14–18. Where measured, 14C ages of exported fluvial POC are an order of magnitude younger than clastic sediment transit times, indicating substantial POC turnover during lowland transit12,20. As POC oxidation is probably limited during in-river transport11, turnover must occur primarily during transient floodplain storage. However, sediment transit time data are scarce17, making it difficult to quantify the effect of sediment routing on the fluvial carbon budget.

A second possible control on POC turnover is the degree of coupling between clastic sediment and POC as stronger coupling reduces decomposition rates. Fluvial POC may travel as discrete particles or bound to minerals13,14, Reactive mineral phases, such as aluminium, iron and manganese oxhydroxides, may protect organic carbon from microbial degradation via cation-bridging reactions with phyllosilicates10 or ligand exchange on hydroxylated mineral surfaces10. This mineral association reduces POC turnover, and evidence of POC that has aged up to 104 yr30–32 suggests that this mechanism can be volumetrically important in river systems. However, the relative importance of organo–mineral complexes for preserving fluvial POC remains unclear10.

In this article, we trace organic matter through a river system with no tributaries for nearly 1,300 km to quantify the effects of sediment transit time and organo–mineral interactions on the fate of fluvial POC. Using existing fluvial sediment transit time estimates11, POC isotope measurements and secondary mineral data for actively transported sediment, we show that POC oxidation is regulated by both transit time and mineral protection. Our analysis allows us to develop a simple model to estimate POC turnover during fluvial transit, and we use this model to explore the geomorphic and geochemical drivers of fluvial organic carbon cycling.

A natural flume experiment

The Rio Bermejo in northern Argentina (Fig. 1) drains eastward from the Andes, delivering ~103 Mt yr–1 of sediment to the lowland basin11, ~92% of which is transported during the South American monsoon season (December–May) (Extended Data Fig. 1). The river flows ~1,270 km from the last tributary confluence at the mountain front (Rio San Francisco, river km 0) to the Rio Paraguay, with no notable tributaries, limited anthropogenic activity and negligible aquatic productivity due to high flow velocity and turbidity10 (Extended Data Fig. 2).

Fig. 1 | Overview of Rio Bermejo study area. a, Topographic map of the Rio Bermejo system. Blue arrows show $v_{\text{sed}}$ (km yr$^{-1}$) for four reaches between sampling points. $v_{\text{sed}}$ was determined for each reach from the measured accumulation of meteoric $^{10}$Be between upstream and downstream sampling points$^{34}$. b–d, Planet satellite images showing differences in morphology along the channel (downloaded from https://api.planet.com/) for river km 0–265 (b), river km 265–875 (c) and river km 875–1,267 (d). SRTM, Shuttle Radar Topography Mission.

From river km 0 to km 265, the river is braided and perched above the flood basin. The remaining ~1,000 km is a single-thread, meandering channel that migrates up to 30 m yr$^{-1}$ (ref. 34) (Fig. 1). While water can transit this system in ~14 days, sediment requires on average ~8,500 years, as determined by the net accumulation of $^{10}$Be in river sediment between river km 0 and 1,220 (ref 34). As a result of lateral channel migration, sediment experiences on average ~4.5 deposition–erosion episodes during lowland transit, each taking ~1,900 years (ref. 34). Averaged across all particle sizes, the downstream sediment transit velocity ($v_{\text{sed}}$) is ~0.15 km yr$^{-1}$. Due to local differences in channel morphodynamics, $v_{\text{sed}}$ varies along the channel, from ~0.59 km yr$^{-1}$ in the braided reach to ~0.1 km yr$^{-1}$ in the lower meandering reach (Fig. 1). In the following, we show that $v_{\text{sed}}$ is a first-order control on POC oxidation during fluvial transit.

Downstream evolution of POC composition

To evaluate how POC evolves during fluvial transit, we measured POC concentrations, stable ($^{13}$C/$^{12}$C) and radioactive ($^{14}$C) carbon isotopes and mineral specific surface area (SSA) of suspended sediment sampled from river depth profiles at six stations during monsoon season (Methods). To account for hydrodynamic sorting and characterize the bulk composition of the suspended load, we depth-integrated each profile, weighting individual sample measurements by suspended sediment and POC concentrations (Supplementary Table 1). At river km 0, the depth-integrated POC concentration ($\text{POC}_{\text{int}}$) was 0.18 ± 0.06%. Assuming $\text{POC}_{\text{int}}$ is constant during monsoon season and dry season changes are negligible, the mean annual headwater POC flux ($Q_{\text{hw}}$) is 1.85 ± 0.62 × 10$^{-10}$ tC yr$^{-1}$ (Methods). At river km 1,220, $\text{POC}_{\text{int}}$ increased to 0.28 ± 0.02%, yielding a mean annual POC export of 2.24 ± 0.16 × 10$^{-10}$ tC yr$^{-1}$ ($Q_{\text{out}}$). The difference between $Q_{\text{hw}}$ and $Q_{\text{out}}$ is +0.39 ± 0.10 × 10$^{-10}$ tC yr$^{-1}$, suggesting that, under modern conditions, lateral POC inputs exceed POC lost during transit.

$\text{POC}_{\text{int}}$ increased along the river’s braided reach to 0.30 ± 0.04%, while OC loading (mass of POC per unit SSA) remained constant at 0.21–0.23 mgC m$^{-2}$ (Fig. 2 and Supplementary Table 1). These diverging trends probably arise from selective deposition of coarse sediment with low POC (Extended Data Fig. 3). The OC loading decreased significantly in the meandering reach to ~0.13 mgC m$^{-2}$ due to lateral erosion of weathered floodplain sediment with high SSA. We further explored downstream POC transformations using stable and radiocarbon isotope measurements.

The POC stable carbon isotope composition ($\delta^{13}$C_{POC}) for individual samples ranged from ~27.3‰ to ~24.9‰, and radiocarbon content (expressed as fraction modern, $F_{14}$C_{POC}) ranged from 0.78 to 0.94 (Fig. 2). All $\delta^{13}$C_{POC} and $F_{14}$C_{POC} values were within the compositional range of regional topsoil, vegetation and floodplain sediment (Fig. 2 and Extended Data Table 1), indicating that fluvial POC comprises a mixture of compounds ranging in age and turnover time. This is supported by $F_{14}$C values of refractory terrestrial leaf n-alkanes ($F_{14}$C_{POC}) in river sediment. $F_{14}$C_{POC} ranged from 0.74 to 0.86, significantly lower than $F_{14}$C_{POC} values for the same samples, suggesting that a fraction of fluvial POC derives from an older, preferentially preserved POC pool$^{35}$.

Within depth profiles, surface-water samples generally had higher POC concentrations, more positive $\delta^{13}$C_{POC} values and lower $F_{14}$C_{POC} values than samples collected >0.5 m below the surface (Fig. 2). In agreement, $F_{14}$C_{POC} values were generally lower for surface samples. These compositional differences reflect hydrodynamic sorting$^{36}$, where water-logged plant debris dominated POC at depth, and surface-water samples were concentrated in $^{13}$C-enriched POC associated with low-density mineral phases$^{25,26,38}$. With increasing transit distance along the meandering segment, surface-water POC became consistently more $^{13}$C enriched and $^{14}$C depleted, reflecting progressive addition of aged, mineral-associated POC. Bedload samples had low POC concentrations (Supplementary Table 1), suggesting that vertical exchange between bedload and suspended load has negligible effects on depth-integrated POC composition.

From river km 135 to 420, where $v_{\text{sed}}$ was highest, $\delta^{13}$C_{POC} remained constant, but $F_{14}$C_{POC} increased from 0.83 to 0.92 ($^{14}$C-age decrease of ~780 years) (Fig. 2). This may reflect mass loss of $^{14}$C-depleted sediment through selective deposition of coarse sand (including lithic fragments and petrogenic POC) and/or fresh organic matter addition. From river km 420 to 1,220, where $v_{\text{sed}}$ is low, $\delta^{13}$C_{POC} values increased from ~26.4 ± 0.3‰ to ~25.5 ± 0.3‰, and $F_{14}$C_{POC} values decreased from 0.92 to 0.86 (~510 years $^{14}$C-age increase).
These changes probably reflect entrainment of aged, $^{13}$C-enriched POC from floodplain deposits. These data are consistent with the idea that the time allowed for POC aging and transformation, as captured by sediment transit time, exerts a strong control over POC composition.

Complete POC turnover during floodplain storage would cause $^{14}$C values to increase downstream. The $^{13}$C-enrichment and apparent POC aging trends along the meandering reach (Fig. 2) suggest that some POC is preserved during floodplain storage, surviving multiple episodes of deposition and erosion. Below, we test the hypothesis that mineral protection limits POC turnover during fluvial transit.

Organ-metal complexation slows POC decomposition

To test whether organo–metal complexation slows POC turnover during fluvial transit, we measured acid-extractable metal concentrations in suspended sediment (Methods) as proxies for the abundance of reactive oxyhydroxide phases. Extractable [Al], [Fe], [Mg], [Mn] and SSA showed statistically significant correlations with $^{14}$CPOC (negative), $^{14}$Calk (negative) and $^{13}$CPOC (positive) (Fig. 3 and Extended Data Figs. 4 and 5). Samples with higher metal concentrations contained relatively older, $^{13}$C-enriched POC. All correlations between $^{14}$CPOC and metal concentrations are stronger than the correlation between $^{14}$CPOC and SSA, suggesting that organic compounds are not only adsorbed onto mineral surfaces but also bound to secondary minerals via complexation reactions. The $^{13}$C enrichment of mineral-stabilized POC may result from decomposition in the floodplain and/or preferential reaction of minerals with $^{13}$C-enriched organic compounds. These data suggest that organo–mineral complexes developed during transient floodplain storage help stabilize biospheric POC (POC$_{bio}$), in agreement with our hypothesis, and can therefore increase the probability of long-term POC$_{bio}$ burial.

A model for POC oxidation during fluvial transit

Our data provide evidence for POC oxidation, fluvial recruitment of young biomass via lateral channel migration and POC preservation by organo–mineral complexation during fluvial transit. In the following we use these findings to estimate the POC budget of the Rio Bermejo, as regulated by sediment transit time and mineral protection.

We calculated the annual Rio Bermejo POC oxidation flux by defining a relationship between $v_{sed}$ and POC decomposition rate. We assume that POC travels with clastic sediment at $v_{sed}$ because we found water-logged plant organic matter at all water depths, and POC reactivity is described by a decomposition rate constant ($k$, $1$ yr$^{-1}$) (Methods). Linking $v_{sed}$ and $k$, the characteristic channel length ($x_c$) over which the fluvial POC load is turned over (depleted) is:

$$x_c = \frac{v_{sed}}{k} \quad (1)$$

Then the number of POC turnover cycles ($n_c$) during transit along a river system of length $L$ is:

![Figure 2](image-url)
Finally, the annual POC oxidation flux ($Q_{\text{ox}}$) resulting from fluvial transit of the mean annual headwater POC load ($\text{POC}_{\text{in}}$, tC) over transit time $t$ is:

$$Q_{\text{ox}} = n_c \times \text{POC}_{\text{flx}}$$

(3)

We assume geomorphic steady state, where mean POC and $\chi_c$ are constant over ~10^4 yr transit timescales. This also assumes POC is spatially constant, such that we underestimate POC oxidation if the POC load increases in downstream reaches. Fluvial POC contains numerous carbon pools ranging in source, age and decomposition rate. For simplicity, we divided fluvial POC into two pools: (1) fast-cycling discrete organic particles, POC$_{\text{fast}}$, and (2) slow-cycling mineral-associated POC, POC$_{\text{slow}}$ (4). We assume each POC pool is homogeneous and decomposition rates are constant, although this is rarely the case in nature.

Annually, the Rio Bermejo receives ~1.85 × 10^4 tC POC via erosion in the headwaters ($\text{POC}_{\text{in}}$). According to a Bayesian endmember isotope mixing model, 47% ± 10% of this load behaves as POC$_{\text{slow}}$ and 53% ± 17% as POC$_{\text{fast}}$ (Methods and Extended Data Table 2). For these two pools, we estimated $\chi$ using radiocarbon data, following Torn et al. (Methods). For POC$_{\text{fast}}$, we set the turnover time to ~17 years, which is the modelled ecosystem turnover time in the subtropical Rio Bermejo region, yielding $k_{\text{fast}}$ $\approx$ 6 × 10^{-2} yr$^{-1}$ (Methods and Extended Data Table 3). For POC$_{\text{slow}}$, we utilized n-alkane F$^{14}$C$_{\text{alk}}$ data because of their recalcitrance and association with secondary minerals. As a conservative estimate of POC$_{\text{slow}}$ oxidation, we used the lowest F$^{14}$C$_{\text{alk}}$ value (0.74), yielding $k_{\text{slow}}$ $\approx$ 3.4 × 10^{-4} yr$^{-1}$ (turnover time of ~2,900 years) (Methods).

Using equations (1–3), we estimated separate oxidation fluxes for POC$_{\text{slow}}$ and POC$_{\text{fast}}$ during an 8,500 yr fluvial transit along the ~1,270 km lowland Rio Bermejo (Methods). POC turnover varies significantly along the Rio Bermejo (Extended Data Table 4). With lower transit velocity (increased storage time), the meandering reach is the locus of turnover, with a POC turnover length scale ($\chi$) nearly an order of magnitude shorter than in the braided reach (Fig. 4). This highlights the control of channel morphodynamics on the fate of POC in lowland rivers.

Along the full channel length, $\chi_f$ for POC$_{\text{fast}}$ is 2 ± 1 km, resulting in $n_f$ of 520 ± 160 (Fig. 4). By contrast, $\chi_c$ for POC$_{\text{slow}}$ is 430 ± 190 km, resulting in $n_c$ of 3.0 ± 0.9. Since the Rio Bermejo sediment load experiences ~4.5 deposition–erosion cycles along this pathway, POC$_{\text{slow}}$ must be coupled to the clastic sediment trajectory, while POC$_{\text{fast}}$ is decoupled from it. During ~8,500 yr transit between the mountain front and Rio Paraguay, turnover results in $Q_{\text{out}}$ of 30.4 (+23.8 to 17.0) tC yr$^{-1}$ for POC$_{\text{slow}}$ and 6.050 (+4410 to 3210) tC yr$^{-1}$ for POC$_{\text{fast}}$, suggesting that ~2–6% of POC$_{\text{in}}$ is oxidized annually during fluvial transit.

**Controls on the fluvial POC budget**

Our data show that sediment transit time and mineral protection are primary controls on the fate of fluvial POC during source-to-sink transit. Our model for POC turnover allows quantification of the respective roles of these two governing mechanisms. Here we define a transit time-dependent fluvial POC budget:

$$Q_{\text{out}} - Q_{\text{in}} = Q_{\text{lat}} - (n_c \times f_{\text{fast}} \times \text{POC}_{\text{in}} + n_f \times f_{\text{fast}} \times \text{POC}_{\text{in}}))$$

(4)

The last term on the right side of equation (4) represents the total annual POC $Q_{\text{in}}$, encompassing POC$_{\text{slow}}$ and POC$_{\text{fast}}$ turnover.
during transit, where \( f \) is the fraction of POC_{slow} or POC_{fast} contributing to POC_{total}. \( Q_{lat} \) represents POC delivered via tributaries or lateral erosion. Whether \( Q_{out} - Q_{hw} \) is positive or negative determines whether fluvial transit results in net CO\(_2\) drawdown or release, respectively. Our estimates for the Rio Bermejo, \( Q_{out} \approx 2.24 \times 10^5 \) tC yr\(^{-1} \) > \( Q_{hw} \approx 1.85 \times 10^5 \) tC yr\(^{-1} \), suggest that additional POC is sequestered from the floodplain during transit. Given \( Q_{ox} \approx 6.08 \times 10^3 \) tC yr\(^{-1} \), equation (4) can be solved for \( Q_{lat} \approx 4.58 \times 10^4 \) tC yr\(^{-1} \), resulting from lateral erosion into floodplain forests. This agrees with estimates from measured channel migration rates and net primary productivity (Methods). \( Q_{ox} \) is nearly an order of magnitude greater than \( Q_{lat} \), more than offsetting oxidative POC loss.

Using equation (4), we test the sensitivity of the fluvial POC budget by varying environmental boundary conditions for the Rio Bermejo. \( Q_{ox} \) is linearly proportional to \( v_{sed} \) and \( k \) (equations (2–4)). Holding all else constant, decreasing \( v_{sed} \) by an order of magnitude (mean transit time of \( \approx 85 \) kyr) would increase \( Q_{ox} \) by one order of magnitude, but such a long transit time is unrealistic for this system. Removing mineral protection (100% POC_{fast}) would increase \( Q_{ox} \) by one order of magnitude, reducing the potential for long-term burial. Doubling \( k \) for POC_{fast} would result in net CO\(_2\) release, but such high decomposition rates are realistic only under warmer and wetter conditions. These tests suggest that modern conditions in the Rio Bermejo do not cause significant oxidation relative to the amount of POC exported annually. Drastic changes in boundary conditions are required to oxidize more POC than is preserved. However, the key variables here are linked in complex ways by climate, hydrology, vegetation, tectonics and even anthropogenic disturbance\(^47\), and associated feedbacks may be important.

At a global scale, \( v_{sed} \) and \( k \) vary across different climatic and tectonic settings. Using equations (1–4), we estimated carbon budgets for the Amazon (tropics) and Mackenzie (Arctic) rivers, where \( Q_{out} \), \( k \) and \( v_{sed} \) are known. In the Amazon, where POC_{fast} turnover is fast, <10 years (refs. \(^{10,46}\)), and \( v_{sed} \approx 0.21 \) km yr\(^{-1} \) (ref. \(^{48}\)), \( \approx 13\% \) of the POC load is oxidized, but \( Q_{ox} \approx 1 \) MtC yr\(^{-1} \) augments POC export to the ocean.

**Fig. 4 | Variability in \( v_{sed} \) and POC turnover along the channel.**

- **a**, Mean \( v_{sed} \) for the four study reaches bound by the sediment sampling locations.
- **b**, \( x_i \), for the four study reaches.
- **c**, Cumulative \( n_i \), that occur during transit along the Rio Bermejo.
- **d**, Cumulative amount of POC oxidized during transit along the river. All are plotted against distance downstream along the channel from the last tributary confluence at the Andean mountain front. Bold lines represent mean values, and shaded areas represent the range of uncertainty.
the ocean. In the Mackenzie River, where POC\textsubscript{oc} turnover is slow, >70 years (ref. 46), and \textit{v}_{\text{oc}} is \textasciitilde 0.09 km yr\textsuperscript{-1}, <1% of the POC load is oxidized, indicating efficient source-to-sink transit and potential CO\textsubscript{2} drawdown on burial in the Beaufort Sea\textsuperscript{9}. These analyses suggest that lateral erosion into vegetated floodplains enhances CO\textsubscript{2} drawdown if POC recruited from the lowlands is buried long term. River engineering, particularly the construction of artificial levees and groins that reduce lateral mobility, can significantly reduce Q\textsubscript{oc} (ref. 47), thereby decreasing potential CO\textsubscript{2} drawdown. Dams may also increase POC oxidation by increasing source-to-sink transit times. Applying this model to rivers globally may yield more robust estimates of river–atmosphere carbon fluxes, advancing our understanding of the global carbon cycle.

Methods

River sediment sampling. We collected 24 river suspended sediment samples from the Rio Bermejo between 13 and 25 March 2017, during the peak of the South American monsoon season (December to May), with 75th–85th percentile water discharge conditions (over a 50 yr gauging record) (673 to 1,079 m³ s⁻¹) (Argentina National System of Hydrologic Information, https://snih.hidricosargentina.gob.ar/). Suspended sediment flux data indicate that 92% of the annual suspended sediment load is transported during monsoon season, suggesting our samples are representative of the majority of POC transported by the Rio Bermejo. We sampled river water from depth profiles (two to five sampling depths depending on total water depth) at four locations along the mainstream Rio Bermejo, one location on the Rio Bermejo 10 km upstream of the Rio San Francisco confluence, and one location on the Rio San Francisco 15 km upstream from the confluence (Fig. 1). River water was sampled by boat using a weighted eight-litre horizontal sampling bottle. Sediment was recovered by filtering the water under pressure through 0.22 μm polyethersulfone 100 μm filter paper in a custom filtration device. Four bedload samples were collected with a weighted mesh net. Sediment was dried in an oven at 40°C and subsequently disaggregated and homogenized with mortar and pestle. Suspended sediment concentrations were calculated as dry sediment mass normalized by the sampled water volume.

POC concentrations and isotope measurements. For bulk organic carbon analyses, sediment samples were powdered in a disc mill, and inorganic carbon was removed following Galè et al.¹⁰. Sediment was decarbonated by leaching in 4% HCl solution, discarding the supernatant, rinsing with deionized water and drying before measurement. Grain size and SSA measurements. Grain size and SSA were measured on ~10 mg aliquots of river sediment using a Horiba LA-950 laser particle size analyser. Before measurement, we added 1.5 ml sodium metaphosphate dispersion agent to each sample and shook samples on an overhead shaker for ~24 hours.

Bayesian isotope mixing model—MixSIAR. To determine the relative contributions of different OC sources to riverine POC, we used a three-endmember Bayesian isotope mixing model constrained by bulk POC 8C and F14C data for the endmembers. Input to the model included the mean and standard deviation of measured isotopic values for sample sets of leaf litter (n = 6), floodplain sediment (n = 51) and topsoil (n = 17) (Extended Data Table 2). We calculated the fractional contribution of each endmember to all suspended sediment sample ‘mixtures’ using the R package MixSIAR.²⁷ We ran the MixSIAR model with an uninformative prior, making no initial assumptions about the source contributions to the samples. The Markov chain Monte Carlo method was performed with 1 x 10⁶ iterations, burn-in of 5 x 10⁵ iterations, thinning factor of 500 and three chains. For each river sediment sample, this analysis yielded three posterior distributions, which contained the full range of possible fractional contributions of the three OC sources. We calculated the mean and standard deviation of the posterior distribution for each sample to obtain the most probable values (Extended Data Table 3). We combined the leaf litter and topsoil values to represent the proportion of POCbio in each sample and used the floodplain sediment values to represent POCfast. We estimated the proportions of these two pools for all suspended sediment samples, and then calculated the depth-integrated mean contributions of POCbio and POCfast at the headwaters, resulting in 0.53 ± 0.17 and 0.47 ± 0.10, respectively. We calculated the mean annual Qs, of POCbio and POCfast, as the product of these values and the mean annual headwater POC flux.

Calculating decomposition rate constants. We calculated a characteristic decomposition rate, k, for POCfast and POCslow. We estimated k for POCfast and POCslow, following the method of Torn et al.⁴⁵:

\[ k = \frac{\Delta \times f^{14}C}{\Gamma - f^{14}C} \] (5)

where k is the 14C-decay constant (1.21 x 10⁻⁹ yr⁻¹) and F14C is a representative fraction modern value for the POC pool of interest. The turnover time corresponding to the POC pool is simply 1/k, resulting in short turnover times for fast decomposition rates and long turnover times for slow decomposition rates⁴⁶. By selecting just one characteristic 14C value to input into equation (5), we assume that the entire POC pool being modelled decomposes at the same rate through time. To determine the POCfast turnover time, we used radiocarbon data from the Rio Bermejo catchment. Leaf litter samples had a mean F14C value of 1.00 (Extended Data Table 2), indicating modern carbon and suggesting a turnover time <50 years. Total ecosystem turnover times were estimated at a global scale by Carvalhais et al.⁴⁷, and the ecosystem turnover time for the subtropical Rio Bermejo region was modelled at 170 years. We used this turnover time to determine a characteristic decomposition rate of 0.06 yr⁻¹ for POCfast. This is six times faster than, but of the same magnitude as, other estimates made for POCbio in the literature (for example, Torres et al.²²). Where turnover times for POCbio are estimated, mineral-bound POCbio is included in this estimate, while we consider only free, labile POC in the fast-cycling pool.

Validating the modelled lateral POC influx. Balancing the Rio Bermejo carbon budget (equation (4)) revealed that the lateral influx of floodplain POC significantly influences the strength of the carbon sink. We estimated the possible lateral influx of POC into the Rio Bermejo from the floodplain due to lateral channel migration (Qlat) as:

\[ Q_{lat} = m_s \times L \times NPP \] (6)

where ms is the mean lateral channel migration rate (m yr⁻¹), L is the total channel length (m) and NPP is the net primary productivity of floodplain biomass (kg C m⁻²). Lateral channel migration rates for the Rio Bermejo range from 0 to 30 m yr⁻¹, averaging 14.9 ± 6.2 m yr⁻¹. The length of the lowland segment of the Rio Bermejo is 1,267 km. We calculated the mean NPP for the lowland portion of the Rio Bermejo catchment (east of the mountain front) using the MODIS MOD17A3H V6 annual NPP product for the year 2014 (500 m pixel resolution). The mean NPP for the 78,700 km² area was 3,623 ± 4,373 kg C m⁻². Applying equation (6) gives Qlat = 6.84 ± 2.85 x 10⁵ tC yr⁻¹, which agrees well with our model estimate of 4.58 ± 10⁵ tC yr⁻¹ derived from the equation (4).

Data availability

The data supporting the findings of this study are available at the PANGAEA data repository. Data for Rio Bermejo suspended sediment samples can be accessed at
Organic geochemical data for Rio Bermejo topsoil, leaf litter and floodplain sediment can be accessed at https://doi.pangaea.de/10.1594/PANGAEA.925616.

Acknowledgements
We thank M. Strecker for support through the StRATEGy international research training group (Deutsche Forschungsgemeinschaft (DFG) grant STR 373/34-1 (M.R. and D.S.). We are grateful for assistance from D. Montlaçon for compound-specific radiocarbon and surface-area measurements, the ETH Laboratory of Ion Beam Physics for AMS support, N. Golombek for sample preparation, and R. Szupiany and R. Lopez for field assistance.

Author contributions
M.R., J.S.S., N.Hovius and D.S. designed the study and contributed to data interpretation and model development. M.R. and J.S.S. collected and processed samples, with help from D.S., N.Hovius and H.W. H.W. provided analytical assistance for reactive metal extraction and measurement. M.L., N.Haghipour and T.I.E. provided radiocarbon measurements. D.R.G. provided stable carbon isotope measurements. M.R. analysed the data, produced the figures and authored the manuscript (with significant input from J.S.S., N.Hovius, D.S. and M.L.). All co-authors reviewed, commented on and approved the manuscript.
