QUANTUM FIELD THEORY OVER $\mathbb{F}_q$

OLIVER SCHNETZ

Abstract. We consider the number $\bar{N}(q)$ of points in the projective complement of graph hypersurfaces over $\mathbb{F}_q$ and show that the smallest graphs with non-polynomial $\bar{N}(q)$ have 14 edges. We give six examples which fall into two classes. One class has an exceptional prime 2 whereas in the other class $\bar{N}(q)$ depends on the number of cube roots of unity in $\mathbb{F}_q$. At graphs with 16 edges we find examples where $\bar{N}(q)$ can be reduced to the number of points on a K3 in $\mathbb{P}^3$.

In an outlook we show that applying momentum space Feynman-rules over $\mathbb{F}_q$ lets the perturbation series terminate for renormalizable and non-renormalizable bosonic quantum field theories.

1. Introduction

Inspired by the appearance of multiple zeta values in quantum field theories [4], [16] Kontsevich informally conjectured in 1997 that for every graph the number of zeros of the graph polynomial (see Sect. [2.1] for a definition) over a finite field $\mathbb{F}_q$ is a polynomial in $q$ [15]. This conjecture puzzled graph theorists for quite a while. In 1998 Stanley proved that a dual version of the conjecture holds for complete as well as for ‘nearly complete’ graphs [17]. The result was extended in 2000 by Chung and Yang [8]. On the other hand, in 1998 Stembridge verified the conjecture by the Maple-implementation of a reduction algorithm for all graphs with at most 12 edges [18]. However, in 2000 Belkale and
Brosnan were able to disprove the conjecture (in fact the conjecture is maximally false in a certain sense) [2]. Their proof was quite general in nature and in particular relied on graphs with an apex (a vertex connected to all other vertices). This is not compatible with physical Feynman rules allowing only low vertex-degree (3 or 4). It was still a possibility that the conjecture works for ‘physical’ graphs where it originated from. Moreover, explicit counter-examples were not known.

We show that the first counter-examples to Kontsevich’s conjecture are graphs with 14 edges (all graphs with \( \leq 13 \) edges are of polynomial type). Moreover, these graphs are ‘physical’: Amongst all ‘primitive’ graphs with 14 edges in \( \phi^4 \)-theory we find six graphs for which the number \( \bar{N}(q) \) of points in the projective complement of the graph hypersurface (the zero locus of the graph polynomial) is not a polynomial in \( q \).

Five of the six counter-examples fall into one class that has a polynomial behavior \( \bar{N}(q) = P_2(q) \) for \( q = 2^k \) and \( \bar{N}(q) = P_{\neq 2}(q) \) for all \( q \neq 2^k \) with \( P_2 \neq P_{\neq 2} \) (although the difference between the two polynomials is minimal [Eqs. (2.31) – (2.35)]). Of particular interest are three of the five graphs because for these the physical period is known to be a weight 11 multiple zeta value [Eq. (2.44)]. The sixth counter-example is of a new kind. One obtains three mutually (slightly) different polynomials \( \bar{N}(q) = P_i(q), \ i = -1, 0, 1 \) depending on the remainder of \( q \) mod 3 [Eq. (2.36)].

At 14 edges the breaking of Kontsevich’s conjecture by \( \phi^4 \)-graphs is soft in the sense that after eliminating the exceptional prime 2 (in the first case) or after a quadratic field extension by cube roots of unity (leading to \( q = 1 \) mod 3) \( \bar{N}(q) \) becomes a polynomial in \( q \).

At 16 edges we find two new classes of counter-examples. One resembles what we have found at 14 edges by providing three different polynomials this time depending on the remainder of \( q \) mod 4 [Eq. (2.37)]. The result is of polynomial type after a quadratic field extension by fourth roots of unity (leading to \( q = 1 \) mod 4).

The second class is of an entirely new type. A formula for \( \bar{N}(q) \) can be given that entails a polynomial in \( q \) together with the number of points in the complement of a surface in \( \mathbb{P}^3 \) (Eqs. (2.38) – (2.43)). (The surface has been identified as a singular K3. In fact it is a Kummer surface with respect to the elliptic curve \( y^2 + xy = x^3 - x^2 - 2x - 1 \), corresponding to the weight 2 level 49 newform [6].) This implies that the motive of the graph hypersurface is of non-mixed-Tate type. The result was found by computer algebra using the reduction Thm. 2.8 which is proved with geometrical tools that lift to the Grothendieck ring of varieties \( K_0(\text{Var}_k) \). This allows us to state the result as a theorem in
the Grothendieck ring: The equivalence class of the graph hypersurface $X$ of graph Fig. 1(e) minus vertex 2 is given by the Lefschetz motive $\mathbb{L} = [\mathbb{A}^1]$ and the class $[F]$ of the singular degree 4 surface in $\mathbb{P}^3$ given by the zero locus of the polynomial

$$a^2b^2+a^2bc+a^2bd+a^2cd+ab^2c+abc^2+ab^2d+acd^2+bc^2d+c^2d^2,$$

namely (Thm. 2.19)

$$[X] = \mathbb{L}^{14} + \mathbb{L}^{13} + 4\mathbb{L}^{12} + 16\mathbb{L}^{11} - 8\mathbb{L}^{10} - 106\mathbb{L}^9 + 263\mathbb{L}^8 - 336\mathbb{L}^7 + 316\mathbb{L}^6 - 199\mathbb{L}^5 + 45\mathbb{L}^4 + 19\mathbb{L}^3 + [F]\mathbb{L}^2 + \mathbb{L} + 1.$$

Although Kontsevich’s conjecture does not hold in general, for physical graphs there is still a remarkable connection between $\bar{N}(q)$ and the quantum field theory period, Eq. (2.4). In particular, in the case that $\bar{N}(q)$ is a polynomial in $q$ (after excluding exceptional primes and finite-degree field extensions) we are able to predict the weight of the multiple zeta value from the $q^2$-coefficient of $\bar{N}$ (see Remark 2.10). Likewise, a non mixed-Tate $\mathbb{L}^2$-coefficient $[F]$ in the above equation could indicate that the (yet unknown) period of the corresponding graph is not a multiple zeta value.

In an outlook we make the attempt to define a perturbative quantum field theory over $\mathbb{F}_q$. We keep the algebraic structure of the Feynman-amplitudes, interpret the integrands as $\mathbb{F}_q$-valued functions and replace integrals by sums over $\mathbb{F}_q$. We prove that this renders many amplitudes zero (Lemma 3.1). In bonsonic theories with momentum independent vertex-functions only superficially convergent amplitudes survive. The perturbation series terminates for renormalizable and non-renormalizable quantum field theories. Only super-renormalizable quantum field theories may provide infinite (formal) power series in the coupling.

Acknowledgements. The author is grateful for very enlightening discussions with S. Bloch and F.C.S. Brown on the algebraic nature of the counter-examples. The latter carefully read the manuscript and made many valuable suggestions. More helpful comments are due to S. Rams, F. Knop and P. Müller. H. Frydrych provided the author by a C++ class that facilitated the counting in $\mathbb{F}_4$ and $\mathbb{F}_8$. Last but not least the author is grateful to J.R. Stembridge for making his beautiful programs publicly available and to have the support of the Erlanger RRZE Computing Cluster with its friendly and helpful staff.
2. Kontsevich’s Conjecture

2.1. Fundamental Definitions and Identities. Let $\Gamma$ be a connected graph, possibly with multiple edges and loops (edges connecting to a single vertex). We use $n$ for the number of edges of $\Gamma$.

The graph polynomial is a sum over all spanning trees $T$. Each spanning tree contributes by the product of variables corresponding to edges not in $T$,

$$\Psi_\Gamma(x) = \sum_{T: \text{span. tree}} \prod_{e \notin T} x_e.$$ 

The graph polynomial was introduced by Kirchhoff who considered electric currents in networks with batteries of voltage $V_e$ and resistance $x_e$ at each edge $e$ [14]. The current through any edge is a rational function in the $x_e$ and the $V_e$ with common denominator $\Psi_\Gamma(x)$. In a tree where no current can flow the graph polynomial is 1.

The graph polynomial is related by a Cremona transformation $x \mapsto x^{-1} := (x_e^{-1})_e$ to a dual polynomial built from the edges in $\Gamma$,

$$\bar{\Psi}_\Gamma(x) = \sum_{T: \text{span. tree}} \prod_{e \in T} x_e = \Psi_\Gamma(x^{-1}) \prod_e x_e.$$ 

The polynomial $\bar{\Psi}$ is dual to $\Psi$ in a geometrical sense: If the graph $\Gamma$ has a planar embedding then the graph polynomial of a dual graph is the dual polynomial of the original graph. Both polynomials are homogeneous and linear in their coordinates and for any simple graph we have

$$\Psi_\Gamma = \Psi_{\Gamma-1} x_1 + \Psi_{\Gamma/1}, \quad \bar{\Psi}_\Gamma = \Psi_{\Gamma/1} x_1 + \Psi_{\Gamma-1},$$

where $\Gamma - 1$ means $\Gamma$ with edge 1 removed whereas $\Gamma/1$ is $\Gamma$ with edge 1 contracted (keeping double edges). The degree of the graph polynomial equals the number $h_1$ of independent cycles of $\Gamma$ whereas $\deg(\bar{\Psi}) = n - h_1$.

In quantum field theory graph polynomials appear as denominators of period integrals

$$P_\Gamma = \int_0^\infty \cdots \int_0^\infty \frac{dx_1 \cdots dx_{n-1}}{\Psi_\Gamma(x)^2 |x_n = 1}$$

for graphs with $n = 2h_1$. The integral converges for graphs that are primitive for the Connes-Kreimer coproduct which is a condition that can easily be checked for any given graph (see Lemma 5.1 and Prop. 5.2 of [3]). If the integral converges, the graph polynomial may be replaced by its dual due to a Cremona transformation. A necessary and sufficient condition for a graph to be primitive is given in [3] (Prop. 5.2).
The polynomials $\Psi$ and $\bar{\Psi}$ have very similar (dual) properties. To simplify notation we mainly restrict ourself to the graph polynomial although for graphs with many edges its dual is more tractable and was hence used in [2], [8], [17], and [18].

The graph polynomial (and also $\bar{\Psi}$) has the following basic property

**Lemma 2.1.** Let $\Psi = a x_e x_{e'} + b x_e + c x_{e'} + d$ for some variables $x_e, x_{e'}$ and polynomials $a, b, c, d$, then

$$ad - bc = -\Delta^2_{e,e'}$$

for a homogeneous polynomial $\Delta_{e,e'}$ which is linear in its variables.

**Proof.** For the dual polynomial this is Theorem 2.8 in [18]. The result for $\Psi$ follows by a Cremona transformation, Eq. (2.2). $\square$

As a simple example we may take a cycle $C_3$ with 3 edges.

**Example 2.2.**

$$\Psi_{C_3}(x) = x_1 + x_2 + x_3, \quad \Delta_{1,2} = 1,$$

$$\bar{\Psi}_{C_3}(x) = x_1 x_2 + x_1 x_3 + x_2 x_3, \quad \Delta_{1,2} = x_3.$$

The dual of $C_3$ is a triple edge with graph polynomial $\bar{\Psi}_{C_3}$ and dual polynomial $\Psi_{C_3}$.

The zero locus of the graph polynomial defines an in general singular projective variety (the graph hypersurface) $X_\Gamma \subset \mathbb{P}^{n-1}$. In this article we consider the projective space over the field $\mathbb{F}_q$ with $q$ elements. Counting the number of points on $X_\Gamma$ means counting the number $N(\Psi_\Gamma)$ of zeros of $\Psi_\Gamma$. In this paper we prefer to (equivalently) count the points in the complement of the graph hypersurface.

In general, if $f_1, \ldots, f_m$ are homogeneous polynomials in $\mathbb{Z}[x_1, \ldots, x_n]$ and $N(f_1, \ldots, f_m)_{\mathbb{F}_q^n}$ is the number of their common zeros in $\mathbb{F}_q^n$ we obtain for the number of points $\bar{N}$ in the projective complement of their zero locus

$$\bar{N}(f_1, \ldots, f_m)_{\mathbb{P}\mathbb{F}_q^{n-1}} = |\{x \in \mathbb{P}\mathbb{F}_q^{n-1}| \exists i : f_i(x) \neq 0\}|$$

$$= \frac{q^n - N(f_1, \ldots, f_m)_{\mathbb{F}_q^n}}{q - 1}.$$

If $\bar{N}$ is a polynomial in $q$ so is $N$ (and vice versa). We drop the subscript $\mathbb{P}\mathbb{F}_q^{n-1}$ if the context is clear.

The duality between $\Psi$ and $\bar{\Psi}$ leads to the following Lemma (which we will not use in the following).
Lemma 2.3. The number of points in the complement of the graph hypersurface can be obtained from the dual surface of the graph and its minors. Namely,

\[(2.7) \quad \tilde{N}(\Psi_T) = \sum_{T,S} (-1)^{|S|} \tilde{N}(\Psi_{\Gamma/T-S})\]

where $T \cup S \subset E$ is a partition of an edge subset into a tree $T$ and an arbitrary edge set $S$ and $\Gamma/T - S$ is the contraction of $T$ in $\Gamma - S$.

Proof. The prove is given in [18] (Prop. 3.1) following an idea of [17].

Calculating $\tilde{N}(\Psi_T)$ is straight forward for small graphs. Following Ex. [2.2] we find that $\Psi_{C_3}$ has $q^2$ zeros in $\mathbb{F}_q^3$ (defining a hyperplane). Therefore $\tilde{N}(\Psi_{C_3}) = (q^3 - q^2)/(q-1) = q^2$. The same is true for $\tilde{\Psi}_{C_3}$, but here the counting is slightly more difficult. A way to find the result is to observe that whenever $x_2 + x_3 \neq 0$ we can solve $\tilde{\Psi}_{C_3} = 0$ uniquely for $x_1$. This gives $q(q-1)$ zeros. If, on the other hand, $x_2 + x_3 = 0$ we conclude that $x_2 = -x_3 = 0$ while $x_1$ remains arbitrary. This adds another $q$ solution such that the total is $q^2$.

A generalization of this method was the main tool in [18] basically only augmented by the inclusion-exclusion formula $\tilde{N}(fg) = \tilde{N}(f) + \tilde{N}(g) - \tilde{N}(f,g)$. We add coordinate rescalings to the toolbox and obtain the following proposition.

Proposition 2.4. Let $f_1, \ldots, f_m = f = f_{1\ldots m}$ be homogeneous polynomials in $\mathbb{Z}[x_1, \ldots, x_n]$. Then

\[(1) \quad \tilde{N}(f_1 f_2, f_{3\ldots m}) = \tilde{N}(f_1, f_{3\ldots m}) + \tilde{N}(f_2, f_{3\ldots m}) - \tilde{N}(f_1, f_2, f_{3\ldots m})_{\mathbb{F}_q^{n-1}}.\]

\[(2) \quad \tilde{N}(f_1, g_1 x_1 - g_0) = \tilde{N}(f_1, g_{1-1} x_1 - g_0) + h_k g_0 + h_{k-1} g_0 \cdots + h_0 g_0 \text{ be the resultant of } f_1 \text{ and } h = h_k x_1^k + h_{k-1} x_1^{k-1} + \ldots + h_0, \text{ and } \tilde{h} = h_k g_0 \text{ if } k > 0 \text{ while } \tilde{h} = h_0 \text{ if } k = 0. \text{ We have } (\tilde{f}_{2\ldots m} = (\tilde{f}_2, \ldots, \tilde{f}_m), \tilde{f}_{2\ldots m} = (\tilde{f}_2, \ldots, \tilde{f}_m))\]

\[(3) \quad \tilde{N}(f) = \tilde{N}(g_1, f_{2\ldots m})_{\mathbb{F}_q^{n-1}} + \tilde{N}(f_{2\ldots m})_{\mathbb{F}_q^{n-2}} - \tilde{N}(g_1, f_{2\ldots m})_{\mathbb{F}_q^{n-2}}.\]

\[(4) \quad \tilde{N}(f)_{\mathbb{F}_q} = \tilde{N}(g h, f)_{\mathbb{F}_q} + \tilde{N}(\hat{f})_{\mathbb{F}_q} - \tilde{N}(g h, \hat{f})_{\mathbb{F}_q}.\]
Proof. Inclusion-exclusion, Prop. 1.3, and Remark 1.4 of [18] together with Eq. (2.6) lead to (1) and (2). Equation (2.10) is another application of inclusion-exclusion. On \( gh \neq 0 \) the rescaling gives an isomorphism between the varieties defined by \( f \) and \( \tilde{f} \). Hence in \( \mathbb{F}_q^n \) we have \( N(f) = N(gh, f) + N(\tilde{f}|_{gh \neq 0}) \) and \( N(\tilde{f}|_{gh \neq 0}) = N(\tilde{f}) - N(gh, \tilde{f}) \). Translation to complements leads to the result. \( \square \)

In practice, one first tries to eliminate variables using (1) and (2). If no more progress is possible (3) is the next best chance to proceed (see the proof of Thm. 2.19). In this case it may be convenient to work with non-homogeneous polynomials in affine space. One can always swap back to projective space by

\[
\tilde{N}(f)_{\mathbb{P}_q^{n-1}} = \tilde{N}(f|_{x_1=0})_{\mathbb{P}_q^{n-2}} \quad N(f|_{x_1=1})_{\mathbb{P}_q^{n-1}}.
\]

This equation is clear by geometry. Formally, it can be derived from Eq. (2.10) by the transformation \( x_i \mapsto x_ix_1 \) for \( i > 1 \) leading to \( \tilde{f} = f|_{x_1=1} \).

In the case of a single polynomial \( f = f \) we have the following corollary:

**Corollary 2.5.** Fix a variable \( x_k \). Let \( f = f_1 x_k + f_0 \) be homogeneous, with \( f_1, f_0 \in \mathbb{Z}[x_1, \ldots, x_k, \ldots, x_n] \). If \( \deg(f) > 1 \) then

\[
\tilde{N}(f) = q\tilde{N}(f_1, f_0)_{\mathbb{P}_q^{n-2}} - \tilde{N}(f_1)_{\mathbb{P}_q^{n-2}}.
\]

If \( f \) is linear in all \( x_k \) and \( 0 < \deg(f) < n \) then \( \tilde{N}(f) \equiv 0 \mod q \).

**Proof.** We use Eq. (2.9) for \( f_1 = f \). Because \( \deg(f) > 1 \) neither \( f_1 \) nor \( f_0 \) are constants \( \neq 0 \) in the first term on the right hand side. Hence, a point in the complement of \( f_1 = f_0 = 0 \) in \( \mathbb{P}_q^{n-1} \) has coordinates \( x \) with \( (x_2, \ldots, x_n) \neq 0 \). Thus \( (x_2 : \ldots : x_n) \) are coordinates in \( \mathbb{P}_q^{n-2} \) whereas \( x_1 \) may assume arbitrary values in \( \mathbb{F}_q \). The second term in Eq. (2.9) is absent for \( m = 1 \) and we obtain Eq. (2.12). Moreover, modulo \( q \) we have \( \tilde{N}(f) = -\tilde{N}(f_1)_{\mathbb{P}_q^{n-2}} \). We may proceed until \( f_1 = h \) is linear yielding \( \tilde{N}(f) = \pm\tilde{N}(h)_{\mathbb{P}_q^{n-\deg(f)}} = \pm q^{n-\deg(f)} \equiv 0 \mod q \), because \( \deg(f) < n \). \( \square \)

In the case of two polynomials \( f_1, f_2 \) we obtain a result analogous to Lemma 2.3 in [18]:

**Corollary 2.6.** Fix a variable \( x_k \). Let \( f_1 = f_{11}x_k + f_{10}, f_2 = f_{21}x_k + f_{20} \) be homogeneous, with \( f_{11}, f_{10}, f_{21}, f_{20}, \in \mathbb{Z}[x_1, \ldots, x_k, \ldots, x_n] \). If \( \deg(f_1) > 1, \deg(f_2) > 1 \) then

\[
\tilde{N}(f_1, f_2) = q\tilde{N}(f_{11}, f_{10}, f_{21}, f_{20}) + \tilde{N}(f_{11}f_{20} - f_{10}f_{21}) - \tilde{N}(f_{11}, f_{21})_{\mathbb{P}_q^{n-2}}.
\]
If $f_1, f_2$ are linear in all their variables, $f_{11}f_{20} - f_{10}f_{21} = \pm \Delta^2$, $\Delta \in \mathbb{Z}[x_1, \ldots, x_n]$ for all choices of $x_k$, $0 < \deg(f_1), 0 < \deg(f_2)$, and $\deg(f_1f_2) < 2n - 1$ then $\bar{N}(f_1, f_2) \equiv 0 \mod q$.

Proof. Double use of Eq. (2.9) and Eq. (2.8) lead to

\[\bar{N}(f_1, f_2) = \bar{N}(f_{11}, f_{10}, f_{21}, f_{20})_{\mathbb{F}_q^n} - \bar{N}(f_{11}f_{20} - f_{10}f_{21})_{\mathbb{F}_q^n} - \bar{N}(f_{11}, f_{21})_{\mathbb{F}_q^{n-2}}.\]

If $\deg(f_1) > 1$, $\deg(f_2) > 1$ we obtain Eq. (2.13) in a way analogous to the proof of the previous corollary.

If $f_{11}f_{20} - f_{10}f_{21} = \pm \Delta^2$ and $\deg(f_1f_2) < 2n - 1$ then $\deg(\Delta) < n - 1$ and the second term on the right hand side is $0 \mod q$ by Cor. 2.5. We obtain $\bar{N}(f_1, f_2) \equiv -\bar{N}(f_{11}, f_{21})_{\mathbb{F}_q^{n-2}} \mod q$. Without restriction we may assume that $d_1 = \deg(f_1) < d_2 = \deg(f_2)$ and continue eliminating variables until $f_{11} \in \mathbb{F}_q^n$. In this situation Eq. (2.14) leads to

\[\bar{N}(f_1, f_2) \equiv \pm[\bar{N}(1)_{\mathbb{F}_q^{n-d_1}} + \bar{N}(\Delta)_{\mathbb{F}_q^{n-d_1-1}} - \bar{N}(1)_{\mathbb{F}_q^{n-d_1-1}}] \mod q.
\]

Still $0 < \deg(\Delta) = (d_2 - d_1 + 1)/2 < n - d_1$ such that the middle term vanishes modulo $q$. The first and the third term add up to $q^{n-d_1} \equiv 0 \mod q$ because $d_1 < n - 1$.

We combine both corollaries with Lemma 2.1 (Eq. (2.16) is basically Thm. 2.4 in [18]).

Corollary 2.7. Let $f = f_{11}x_1x_2 + f_{10}x_1 + f_{01}x_2 + f_{00}$ be homogeneous with $f_{11}, f_{10}, f_{01}, f_{00} \in \mathbb{Z}[x_3, \ldots, x_n]$. If $\deg(f) > 2$ and $f_{11}f_{00} - f_{10}f_{01} = -\Delta_{12}^2$, $\Delta_{12} \in \mathbb{Z}[x_3, \ldots, x_n]$ then

\[\bar{N}(f) = q^2\bar{N}(f_{11}, f_{10}, f_{01}, f_{00}) + q[\bar{N}(\Delta_{12}) - \bar{N}(f_{11}, f_{01}) - \bar{N}(f_{11}, f_{10})] + \bar{N}(f_{11})_{\mathbb{F}_q^{n-3}}.\]

If $f$ is linear in all its variables, if the statement of Lemma 2.7 holds for $f$ and any choice of variables $e, e'$, and if $0 < \deg(f) < n - 1$ then $\bar{N}(f) \equiv 0 \mod q^2$. In particular $\bar{N}(\Psi_{11}) = 0 \mod q^2$ for every simple graph with $h_1 > 0$.

Proof. Eq. (2.16) is a combination of Eqs. (2.12) and (2.13). The second statement is trivial for $\deg(f) = 1$ and straightforward for $\deg(f) = 2$ usingCors. 2.5 and 2.6. To show it for $\deg(f) > 2$ we observe that modulo $q^2$ the second term on the right hand side of Eq. (2.16) vanishes due to Cor. 2.5 while the third and fourth term vanish due to Cor. 2.6. We thus have $\bar{N}(f) \equiv \bar{N}(f_{11})_{\mathbb{F}_q^{n-3}} \mod q^2$ and by iteration we reduce the statement to $\deg(f) = 2$. Any simple non-tree graph fulfills the conditions of the corollary by Lemma 2.1. □
Theorem 2.8. Let \( \Gamma \) be a simple graph with vertex-connectivity \( \geq 2 \). Then

\[
\bar{N}(\Psi_\Gamma) = q^{n-1} + O(q^{n-3}),
\]

\[
\bar{N}(\Psi_\Gamma) \equiv 0 \mod q^2.
\]

If \( \Gamma \) has a 3-valent vertex \( v \) with attached edges 1,2,3 then \((\Gamma - 1/23)\) means edge 1 removed, edges 2,3 contracted, etc.)

\[
\bar{N}(\Psi_\Gamma) = q^3\bar{N}(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}, \Psi_{\Gamma-2/13}, \Psi_{\Gamma/123})
\]

\[-q^2\bar{N}(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}, \Psi_{\Gamma-2/13})|_{_{PF_q}}^{n-4}.
\]

gives the number of points in the projective complement of the graph hypersurface in terms of graph polynomials of minors. Alternatively, with

\[
\Delta_{12} = \Psi_{\Gamma-123}x_3 + \Delta,
\]

\[
\Delta = \frac{\Psi_{\Gamma-1/23} + \Psi_{\Gamma-2/13} - \Psi_{\Gamma-3/12}}{2} \in \mathbb{Z}[x_4, \ldots, x_n],
\]

we have

\[
\bar{N}(\Psi_\Gamma) = q\bar{N}(\Psi_{\Gamma/3})|_{_{PF_q}}^{n-2} + q\bar{N}(\Delta_{12})|_{_{PF_q}}^{n-3} - q^2\bar{N}(\Delta)|_{_{PF_q}}^{n-4}.
\]

In particular,

\[
\bar{N}(\Psi_\Gamma) \equiv q\bar{N}(\Delta_{12})|_{_{PF_q}}^{n-3} \equiv q^2\bar{N}(\Psi_{\Gamma-123}, \Delta)|_{_{PF_q}}^{n-4} \mod q^3.
\]

If, additionally, there exists an edge 4 such that edges 2,3,4 form a triangle we have

\[
\delta = \frac{\Psi_{\Gamma-123/4} + \Psi_{\Gamma-24/13} - \Psi_{\Gamma-34/12}}{2} \in \mathbb{Z}[x_5, \ldots, x_n]
\]

and

\[
\bar{N}(\Psi_\Gamma) = q(q-2)\bar{N}(\Psi_{\Gamma-2/3})|_{_{PF_q}}^{n-3}
\]

\[
+ q(q-1)[\bar{N}(\Psi_{\Gamma-123}) + \bar{N}(\Psi_{\Gamma-24/3})] + q^2\bar{N}(\Psi_{\Gamma-2/43})|_{_{PF_q}}^{n-4}
\]

\[
+ q^2[\bar{N}(\Psi_{\Gamma-1234}) + \bar{N}(\Psi_{\Gamma-123/4}) - \bar{N}(\Psi_{\Gamma-1234}, \delta) - \bar{N}(\Psi_{\Gamma-123/4}, \delta) - (q-2)\bar{N}(\delta)]|_{_{PF_q}}^{n-5}.
\]

Proof. From the definition it is clear that the graph polynomial can factorize only if the graph has vertex-connectivity \( \leq 1 \). Hence, \( \Psi_\Gamma \) is irreducible and \( \bar{N}(\Psi_\Gamma)|_{_{PF_q}} = q^{n-1} + O(q^{n-2}). \) For the projective complement we obtain Eq. (2.17) while \( \bar{N}(\Psi_\Gamma) \equiv 0 \mod q^2 \) is Cor. 2.7

Every spanning tree has to reach \( v \). Hence \( \Psi_\Gamma \) can not have a term proportional to \( x_1x_2x_3 \). Similarly, the coefficients of \( x_1x_2, x_1x_3, \) and
$x_2x_3$ have to be equal to the graph polynomial of $\Gamma - 123$. Hence $\Psi_\Gamma$ has the following shape

$$\Psi_{\Gamma-123}(x_1x_2+x_1x_3+x_2x_3) + \Psi_{\Gamma-1/23}x_1 + \Psi_{\Gamma-2/13}x_2 + \Psi_{\Gamma-3/12}x_3 + \Psi_{\Gamma/123},$$

From this we calculate $\Delta_{12}$ to

$$\Delta_{12}^2 = (\Psi_{\Gamma-123}x_3 + \Delta)^2 - \Delta^2 + \Psi_{\Gamma-1/23}\Psi_{\Gamma-2/13} - \Psi_{\Gamma-123}\Psi_{\Gamma/123},$$

with Eq. (2.20) for $\Delta$ and non-zero $\Psi_{\Gamma-123}$ (because $\Gamma$ is simple, two-connected). The left hand side of the above equation is a square by Lemma 2.1 which leads to Eq. (2.19) plus

$$\Psi_{\Gamma-123}\Psi_{\Gamma/123} - \Psi_{\Gamma-1/23}\Psi_{\Gamma-2/13} = -\Delta^2$$

(which is Eq. (2.5) for $\Gamma/3$). This leads to

$$\Psi_{\Gamma-1/23}\Psi_{\Gamma-2/13} \equiv \Delta^2 \mod \Psi_{\Gamma-123}.$$

Substitution of Eq. (2.20) into 4-times Eq. (2.25) leads to

$$\Psi_{\Gamma-3/12} \equiv \Psi_{\Gamma-2/13} \mod (\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}),$$

where $(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23})$ is the ideal generated by $\Psi_{\Gamma-123}$ and $\Psi_{\Gamma-1/23}$.

A straight forward calculation eliminating $x_1, x_2, x_3$ using Eq. (2.16) and Prop. 2.4 (one may modify the Maple-program available on the homepage of J.R. Stembridge to do this) leads to

$$N(\Psi_\Gamma) = q^3N(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}, \Psi_{\Gamma-2/13}, \Psi_{\Gamma-3/12}, \Psi_{\Gamma/123})$$

$$+ q^2[-N(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}, \Psi_{\Gamma-2/13}, \Psi_{\Gamma-3/12})$$

$$+ N(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23}, \Psi_{\Gamma-2/13}) + N(\Psi_{\Gamma-1/23}, \Delta)$$

$$-N(\Psi_{\Gamma-123}, \Psi_{\Gamma-2/13}) - N(\Psi_{\Gamma-123}, \Psi_{\Gamma-1/23})]_{PF_n^q}.$$  

From this equation one may drop $\Psi_{\Gamma-3/12}$ by Eq. (2.27). Now, replacing $\Delta$ by $\Delta^2$ and Eq. (2.20) with inclusion-exclusion (2.8) proves Eq. (2.18).

Alternatively, we may use Eqs. (2.12) and (2.16) together with Eq. (2.19) to obtain Eq. (2.21). By Cor. 2.7 we have $N(\Psi_{\Gamma/3})$, $N(\Psi_{\Gamma-123}) \equiv 0 \mod q^2$ and by Cor. 2.3 we have $\bar{N}(\Delta) \equiv 0 \mod q$ which makes Eq. (2.22) a consequence of Eqs. (2.12) and (2.21).

The claim in case of a triangle $2,3,4$ follows in an analogous way from Eq. (2.18): With the identities

$$\Psi_{\Gamma-123} = \Psi_{\Gamma-1234}x_4 + \Psi_{\Gamma-123/4}, \quad \Psi_{\Gamma-1/23} = \Psi_{\Gamma-123/4}x_4,$$

$$\Psi_{\Gamma-2/13} = \Psi_{\Gamma-24/13}x_4 + \Psi_{\Gamma-2/134}, \quad \Psi_{\Gamma/123} = \Psi_{\Gamma-2/134}x_4,$$

which follow from the definition of the graph polynomial we use Prop. 2.4 and

$$\Psi_{\Gamma-1234}\Psi_{\Gamma-2/134} - \Psi_{\Gamma-123/4}\Psi_{\Gamma-24/13} = -\delta^2.$$
which is analogous to Eq. (2.25) to prove Eq. (2.24).

Every primitive $\phi^4$-graph comes from deleting a vertex in a 4-regular graph. Hence, for these graphs Eqs. (2.18) – (2.22) are always applicable. In some cases a 3-valent vertex is attached to a triangle. In this case it is best to apply Prop. 2.4 to Eq. (2.24) although this equation is somewhat lengthy (see Thm. 2.19).

Note that Eq. (2.22) gives quick access to $\bar{N}(\Psi_{\Gamma}) \mod q^3$. In particular, we have the following corollary.

**Corollary 2.9.** Let $\Gamma$ be a simple graph with $n$ edges and vertex-connectivity $\geq 2$. If $\Gamma$ has a 3-valent vertex and $2h_1(\Gamma) < n$ then $\bar{N}(\Psi_{\Gamma}) \equiv 0 \mod q^3$.

**Proof.** We have $\deg(\Psi_{\Gamma-123}) = h_1 - 2$ and $\deg(\Delta) = h_1 - 1$ in Eq. (2.22), hence $\deg(\Psi_{\Gamma-123}) + \deg(\Delta) < n - 3$. By the Ax-Katz theorem [1], [13] we obtain $N(\Psi_{\Gamma-123}, \Delta) \mod q^3 \equiv 0 \mod q$ such that the corollary follows from Eq. (2.6). □

If $2h_1 = n$ we will be able to trace $\bar{N} \mod q^3$ by following a single term in the reduction algorithm (details will be published in [6]): Because in the rightmost term of Eq. (2.22) the sum over the degrees equals the number of variables we can apply Eq. (2.13) while keeping only the middle term on the right hand side. Modulo $q$ the first term vanishes trivially whereas the third term vanishes due to the Ax-Katz theorem. As long as $f_{11}f_{20} - f_{10}f_{21}$ factorizes we can continue using Eq. (2.13) which leads to the ‘denominator reduction’ method in [5], [7], see Eq. (2.25).

In the next subsection we will see that $\bar{N}(\Psi_{\Gamma}) \mod q^3$ starts to become non-polynomial for graphs with 14 edges (and $2h_1 = n$) whereas higher powers of $q$ stay polynomial (see Result 2.18). On the other hand $\bar{N} \mod q^3$ is of interest in quantum field theory. It gives access to the most singular part of the graph polynomial delivering the maximum weight periods and we expect the (relative) period Eq. (2.4) amongst those. Moreover, $\Delta_{12}^2$ [as in Eq. (2.22)] is the denominator of the integrand after integrating over $x_1$ and $x_2$ [5].

For graphs that originate from $\phi^4$-theory we make the following observations:

**Remark 2.10.** Let $\Gamma$ be a 4-regular graph minus one vertex, such that the integral Eq. (2.4) converges. Let $c_2(f, q) \equiv \bar{N}(f) / q^2 \mod q$ for $f$ the graph polynomial $\Psi_{\Gamma}$ or its dual $\bar{\Psi}_{\Gamma}$. We make the following empirical observations:

(1) $c_2(\Psi_{\Gamma}, q) \equiv c_2(\bar{\Psi}_{\Gamma}, q) \mod q$. 
(2) If $\Gamma'$ is a graph with period $P_{\Gamma'} = P_{\Gamma}$ [Eq. (2.4)] then $c_2(\Psi_{\Gamma}, q) \equiv c_2(\Psi_{\Gamma'}, q) \mod q$.

(3) If $c_2(\Psi_{\Gamma}, q) = c_2$ is constant in $q$ then $c_2 = 0$ or $-1$.

(4) If $c_2(\Psi_{\Gamma}, p^k)$ becomes a constant $c_2$ after a finite-degree field extension and excluding a finite set of primes $p$ then $c_2 = 0$ or $c_2 = -1$.

(5) If $c_2 = -1$ (even in the sense of (4)) and if the period is a multiple zeta value then it has weight $n - 3$, with $n$ the number of edges of $\Gamma$.

(6) If $c_2 = 0$ and if the period is a multiple zeta value then it may mix weights. The maximum weight of the period is $\leq n - 4$.

(7) One has $c_2(\Psi_{\Gamma}, q) \equiv \tilde{N}(\Delta_{e,e'})/q \mod q$ for any two edges $e, e'$ in $\Gamma$ (see Eq. (2.22) for the definition of $\Delta$). An analogous equivalence holds for the dual graph polynomial $\tilde{\Psi}_{\Gamma}$ which is found to give the same $c_2 \mod q$ by observation (1).

Proof of the first statement in (7). By the arguments in the paragraph following Cor. 2.9 we can eliminate variables starting from $\tilde{N}(\Delta_{e,e'})$ keeping only one term mod $q^2$. In [5] it is proved that one can always proceed until five variables (including $e, e'$) are eliminated leading to the ‘5-invariant’ of the graph. This 5-invariant is invariant under changing the order with respect to which the variables are eliminated. This shows that $\tilde{N}(\Delta_{e,e'}) = \tilde{N}(\Delta_{f,f'}) \mod q^2$ for any four edges $e, e', f, f'$ in $\Gamma$. The equivalence in (7) follows from Eq. (2.22) and the fact that $\Gamma$ has four 3-valent vertices. In fact, every ‘primitive’ graph has at least four 3-valent vertices such that observation (7) holds for those graphs in general. □

By the proven part of (7) we know that ‘denominator reduction’ [5] of a primitive graph $\Gamma$ gives $\tilde{N}(\Gamma) \mod q^3$: If a sequence of edges leads to a reduced denominator $\psi$ in $m$ (non-reduced) variables we have

\[
\tilde{N}(\psi) \equiv (-1)^m \tilde{N}(\psi)_{PP_q^{m-1}}, \text{ if } m \geq 1, \\
\tilde{N}(\psi) \equiv -\tilde{N}(\psi), \text{ if } \psi \in \mathbb{Z},
\]

where $\tilde{N}(z)$ for $z \in \mathbb{Z}$ is 1 if $\gcd(z, q) = 1$ and 0 otherwise. This explains observations (3) and (4) for ‘denominator reducible’ graphs (for which there exists a sequence of edges, such that $\psi \in \mathbb{Z}$). In this situation observations (5) and (6) are proved in [5]. Moreover, for a class of not too complicated graphs (6) can be explained by means of étale cohomology and Lefschetz’s fixed-point formula [9].

Of particular interest will be the case when $\tilde{N}$ is a polynomial in $q$. In this situation we have the following statement.
Lemma 2.11. For homogeneous $f_1, \ldots, f_m$ let $\bar{N}(f_1, \ldots, f_m)_{\mathbb{P}^{n-1}_q} = c_0 + c_1 q + \ldots + c_{n-1} q^{n-1}$ be a polynomial in $q$. We obtain for the local zeta-function $Z_q(t)$ of the projective zero locus $f_1 = \ldots = f_m = 0$,

$$Z_q(t) = \prod_{k=0}^{n-1} (1 - q^k t)^{c_k}.$$ 

By rationality of $Z_q$ \cite{10} we see that all coefficients $c_k$ are integers, hence $\bar{N} \in \mathbb{Z}[q]$.

Proof. A straightforward calculation using Eq. (2.6) shows that $Z_q(t) = \exp(\sum_{k=1}^\infty N_{\mathbb{P}^n_q} t^k / k)$ leads to Eq. (2.29). \qed

We end this subsection with the following remark that will allow us to lift some results to general fields (see Thm. 2.19).

Remark 2.12. All the results of this subsection are valid in the Grothendieck ring of varieties over a field $k$ if $q$ is replaced by the equivalence class of the affine line $[\mathbb{A}_k^1]$.

Proof. The results follow from inclusion-exclusion, cartesian products, $\mathbb{F}_q$-fibrations which behave analogously in the Grothendieck ring. \qed

2.2. Methods. Our main method is Prop. 2.4 applied to Thm. 2.8. Identities (1) and (2) of Prop. 2.4 have been implemented by J.R. Stembridge in a nice Maple worksheet which is available on his homepage. Stembridge’s algorithm tries to partially eliminate variables and expand products in a balanced way (not to generate too large expressions). But, actually, it turned out to be more efficient to completely eliminate variables and expand all products once the sequence of variables is chosen in an efficient way. Thm. 2.8 reflects this strategy by providing concise formulae for completely eliminating variables that are attached to a vertex (and a triangle). A good sequence of variables will be a sequence that tries to complete vertices or cycles. Such a sequence is related to \cite{5} by providing a small ”vertex-width”. So, in fact, the author modified Stembridge’s algorithms to work in a less intelligent way.

Method 2.13. Choose a sequence of edges $1, 2, \ldots, n$ such that every sub-sequence $1, 2, \ldots, k$ contains as many complete vertices and cycles as possible. Start from Thm. 2.8 (if possible). Pick the next variable in the sequence that can be eliminated completely (if any) and apply Prop. 2.4 (2). Factor all polynomials. Expand all products by Prop. 2.4 (1). Continue until no more variables can be eliminated completely (because no variable is linear in all polynomials).
Next, apply the above algorithm to each summand. Continue until Prop. 2.4 (2) can no longer be applied (because no variable is linear in any polynomial).

Finally (if necessary), try to use Prop. 2.4 (3) to modify a polynomial in such a way that it becomes linear in (at least) one variable. If successful continue with the previous steps.

In most cases (depending on the chosen sequence of variables) graphs with up to 14 edges reduce completely and the above method provides a polynomial in \( q \). Occasionally one may have to stop the algorithm because it becomes too time-consuming. This depends on Maple’s ability to factorize polynomials and to handle large expressions.

But working over finite fields we do not have to quit where the algorithm stops: We can still count for small \( q \). A side effect of the algorithm is that it eliminates many variables completely before it stops. This makes counting significantly faster. If \( \bar{N} \) is a polynomial, by Eq. (2.17) we have to determine the coefficients \( c_2, c_3, \ldots, c_{n-3} \). We can do this for \( n = 14 \) edges by considering all prime powers \( q \leq 16 \). By Lemma 2.11 the coefficients have to be integers. Conversely, if interpolation does not provide integer coefficients we know that \( \bar{N} \) cannot be a polynomial in \( q \). For graphs with 14 edges this is a time consuming though possible method even if hardly any variables were eliminated.

D. Doryn used a similar method to prove (independently) that one of the graphs obtained from deleting a vertex from Fig. 1(a) is a counterexample to Kontsevich’s conjecture [9].

We implemented a more efficient polynomial-test that uses the fact that the coefficients are not only integers but have small absolute value. This determines the coefficients by the Chinese-Remainder-Theorem if \( \bar{N} \) is known for a few small primes. For graphs with 14 edges it was sufficient to use \( q = 2, 3, 5, \) and 7 because the coefficients are two-digit integers (and test the result with \( q = 4 \)). For graphs with 16 edges we had additionally to count for \( q = 11 \).

Method 2.14. Select a set of small primes \( p_1, p_2, \ldots, p_k \). Evaluate \( d_2(i) = \bar{N}(p_i)/p_i^2 \) for these primes. Determine the smallest (by absolute value) common representatives \( c_2 \) of \( d_2(i) \mod p_i \) (usually take the smallest one and maybe the second smallest if it is not much larger than the smallest representative). For each of the \( c_2 \) calculate \( d_3(i) = (d_2(i) - c_2)/p_i \). Proceed as before to obtain a set of sequences \( c_2, c_3, \ldots, c_{n-1} \). If for one of the sequences one has \( d_n(i) = 0 \) for all \( i \) and \( \text{[see Eq. (2.17)]} \) \( c_{n-2} = 0, c_{n-1} = 1 \) (and the set of sequences was not too large) then it is likely that \( \bar{N}(q) \) is a polynomial in \( q \), namely \( c_2q^2 + c_3q^3 + \ldots + c_{n-3}q^{n-3} + q^{n-1} \mod (q - p_1)(q - p_2) \cdots (q - p_k) \).
If \( \bar{N} \) is a polynomial with coefficients \( c_i \) such that \( |c_i| < p_1 p_2 \cdots p_k / 2 \) then it is determined uniquely by the smallest representative for each \( c_i \).

Note that one can use the above method to either test if \( \bar{N}(q) \) is a polynomial in \( q \) (this test may occasionally give a wrong answer in both directions) or to completely determine a polynomial \( \bar{N}(q) \) with a sufficient number of primes counted.

Normally, one would use the smallest primes, but because (as we will see in the next subsection) \( p = 2 \) may be an exceptional prime it is useful to try the method without \( p = 2 \) if it fails when \( p = 2 \) is included. Similarly one may choose certain subsets of primes (like \( q = 1 \mod 3 \)) to identify a polynomial behavior after finite field extensions.

Because only few primes are needed to apply this method it can be used with no reduction beyond Thm. 2.13 for graphs with up to 16 edges. Calculating modulo small primes is fast in C++ and counting can easily be parallelized which makes this Method a quite practical tool.

The main problem is to find a result for \( \bar{N}(q) \) if it is not a polynomial in \( q \). It turned out that for \( \phi^4 \)-graphs with 14 edges the deviation from being polynomial can be completely determined mod \( q^3 \). This is no longer true for graphs with 16 edges, but at higher powers of \( q \) we only find terms that we already had in graphs with 14 edges (see Result 2.18). Therefore a quick access to \( \bar{N}(q) \) mod \( q^3 \) is very helpful.

Method 2.15. Determine \( c_2(q) \equiv \bar{N}(q)/q^2 \mod q \) using Eq. (2.22) together with Eq. (2.13) [or Eq. (2.28)] and Remark 2.10.

Afterwards check if \( \bar{N}(q)/q^2 - c_2(q) \) is a polynomial in \( q \).

In practice it is often useful to combine the methods. Typically one would first run Method 2.13. If it fails to deliver a complete reduction one may apply Method 2.15 to determine its polynomial discrepancy and eventually Method 2.14 to determine the result.

2.3. Results. First, we applied our methods to the complete list of graphs with 13 edges that are potential counter-examples to Kontsevich’s conjecture. This list due to the 1998 work by Stembridge and it is available on his homepage. We found that for all of these graphs \( \bar{N} \) is a polynomial in \( q \). This extends Stembridge’s result [18] from 12 to 13 edges.

Result 2.16. Kontsevich’s conjecture holds for all graphs with \( \leq 13 \) edges.
Figure 1. 4-regular graphs that deliver primitive $\phi^4$-graphs by the removal of a vertex. Every such $\phi^4$-graph is a counter-example to Kontsevich’s conjecture. Graphs (a) – (c) give a total of six non-isomorphic counter-examples with 14 edges. Graphs (d), (e) provide another seven counter-examples with 16 edges. The graph hypersurface of (e) minus any vertex entails a degree 4 non-mixed-Tate two-fold (a K3). The graphs are taken from [16] where they have the names $P_{7,8}$, $P_{7,9}$, $P_{7,11}$, $P_{8,40}$, and $P_{8,37}$, respectively. See Eqs. (2.31) – (2.43) for the results.

Second, we looked at all graphs with 14 edges that originate from primitive $\phi^4$-graphs [graphs with finite period Eq. (2.4)]. These graphs come as 4-regular graphs with one vertex removed. They have $n = 2h_1$ edges, four of which are 3-valent whereas all others are 4-valent. A complete list of 4-regular graphs that lead to primitive $\phi^4$-graphs with up to 16 edges can be found in [16].

Result 2.17. Kontsevich’s conjecture holds for all primitive $\phi^4$-graphs with 14 edges with the exception of the graphs obtained from Figs. 1(a) – (c) by the removal of a vertex.
The counter-examples Fig. 1(a) – (c) fall into two classes: One, Figs. 1(a), (b) with exceptional prime 2, second, Fig. 1(c) with a quadratic extension. These counter-examples are the smallest counter-examples to Kontsevich’s conjecture by Result 2.16.

Next, we tested the power of our methods to primitive $\phi^4$-graphs with 16 edges. We were scanning through the graphs with Method 2.15 to see whether we find some new behavior. Only in the last five graphs of the list in [16] we expect something new. We were able to pin down the result for graphs coming from Fig. 1(d), (e). Figure 1(d) features a fourth root of unity extension together with an exceptional prime 2 whereas Fig. 1(e) leads to a degree 4 surface in $\mathbb{P}^3$ which is non-mixed-Tate.

**Result 2.18.** All graphs coming from Fig. 1 by removal of a vertex are counter-examples to Kontsevich’s conjecture (six with 14 edges, seven with 16 edges). We list $\bar{N}(\Psi)/q^2$, the number of points in the projective complement of the graph hypersurface divided by $q^2$. The second expression [in brackets] contains the result $\bar{N}(\Psi)/q^2$ for the dual graph hypersurface.

In the following $\bar{N}(2) = \bar{N}(2)_{\mathbb{F}_{q^2}} = 0$ if $q = 2^k$ and 1 otherwise, $\bar{N}(a^2+ab+b^2) = \bar{N}(a^2+ab+b^2)_{\mathbb{F}_{q^2}} = q - \{1, 0, -1\}$ if $q \equiv 1, 0, -1$ mod 3, $\bar{N}(a^2+b^2) = \bar{N}(a^2+b^2)_{\mathbb{F}_{q^2}} = q - \{1, 0, -1\}$ if $q \equiv 1, 0$ or 2, -1 mod 4, respectively, and

$$f = f(a, b, c, d) = a^2b^2 + a^2bc + a^2bd + a^2cd + ab^2c + abc^2 + abcd + abd^2 + acd^2 + bc^2d + c^2d^2.$$

\[ [q^{13} - 5q^{10} - 11q^9 + 13q^8 + 81q^7 - 210q^6 + 290q^5 - 329q^4 + 269q^3 - 90q^2 - [24 + 2\tilde{N}(2)]q + \tilde{N}(f)_{\mathbb{F}_q^4}] \]

Interestingly, the period Eq. (2.4) associated to Fig. 1(a), Eqs. (2.31) – (2.33), has been determined by ‘exact numerical methods’ as weight 11 multiple zeta value [16], namely
\[ P_{7,8} = \frac{22383}{20} \zeta(11) - \frac{4572}{5} [\zeta(3)\zeta(5, 3) - \zeta(3, 5, 3)] - 700\zeta(3)^2\zeta(5) + 1792\zeta(3) \left( \frac{27}{80} \zeta(5, 3) + \frac{45}{64} \zeta(5)\zeta(3) - \frac{261}{320} \zeta(8) \right), \]

where \( \zeta(5, 3) = \sum_{i>j} i^{-5}j^{-3} \) and \( \zeta(3, 5, 3) = \sum_{i>j>k} i^{-3}j^{-5}k^{-3} \). So, a multiple zeta period does not imply that \( \tilde{N} \) is a polynomial in \( q \). The converse may still be true: If \( \tilde{N} \) is a polynomial in \( q \) then the period (2.4) is a multiple zeta value. It would be interesting to know if the period of Fig. 1(e) is a multiple zeta value, but regretfully this is beyond the power of the present ‘exact numerical methods’ used in [4] and [16].

Most of the above results were found applying the counting Method 2.14 at some stage. We mainly used the prime-powers \( q = 2, 3, 4, 5, 7, 8, \) and 11. The counting for \( q = 8 \) and \( q = 11 \) for graphs with 16 edges (using Eq. (2.18) or similar equations for the dual graph polynomial and in case of an extra triangle) were performed on the Erlanger RRZE Computing Cluster.
Resorting to the counting Method 2.14 is not necessary for most graphs with 14 edges. Eqs. (2.21) and (2.24) of Thm. 2.8 are powerful enough to determine the results by pure computer-algebra. But in some cases finding good sequences can be time consuming and the 14-edge results had been found by the author prior to Eqs. (2.21) and (2.24). The results have been checked by pure computer-algebra for Fig. 1(a) minus vertex 2, 3, 4, or 5 [Eq. (2.32)] and Fig. 1(e) minus vertex 2 or 4 [Eq. (2.39)] because the latter may be of interest exhibiting a presumably non-mixed-Tate surface in $\mathbb{P}^3$. In connection with Remark 2.12 we can state the following theorem:

**Theorem 2.19.** Let $\Gamma$ be the graph of Fig. 1(e) minus vertex 2 (or minus vertex 4) and $X$ its graph hypersurface in $\mathbb{P}^{15}$ defined by the vanishing locus of graph polynomial $\Psi_\Gamma$. Let $[X]$ be the image of $X$ in the Grothendieck ring $K_0(\text{Var}_k)$ of varieties over a field $k$, let $L = [\mathbb{A}_k]$ be the equivalence class of the affine line, and $1 = [\text{Spec } k]$. With $[F]$ the image of the (singular) zero locus of $f$ [given by Eq. (2.30)] in $\mathbb{P}^3$ we obtain the identity

$$[X] = L^{14} + 4L^{12} + 16L^{11} - 8L^{10} - 106L^9 + 263L^8 - 336L^7$$

$$+ 316L^6 - 199L^5 + 45L^4 + 19L^3 + [F]L^2 + L + 1.$$  

(2.45)

**Proof.** By Remark 2.12 and translation from complements to hypersurfaces in projective space Eq. (2.45) is equivalent to Eq. (2.39).

To prove Eq. (2.39) we use Eq. (2.24) in Thm. 2.8 with edges 1, 2, 3, 4 corresponding to (1,3), (1,4), (1,5), (4,5) (edge (1,3) connects vertex 1 with vertex 3 in Fig. 1(e), etc.). Terms without $\delta$ in Eq. (2.24) refer to minors of $\Gamma$. The most complicated of these is the first one which has 14 edges and is isomorphic to Fig. 1(a) minus vertex 2. This minor has again a triangle with a 3-valent vertex such that Eq. (2.24) applies to it. Having two edges less than $\Gamma$ it is relatively easy to calculate $\tilde{N}$ for this minor by Method 2.13 with the result given in Eq. (2.32) [use e.g. the sequence (1,3), (1,4), (1,5), (4,5), (3,9), (3,8), (5,8), (5,9), (4,6), (6,8), (7,8), (4,7), (6,9), (7,9)]. The other minors have 13 edges or less. They give polynomial contributions to $\tilde{N}(\Psi_\Gamma)$ by Result 2.16. These are easy to determine.

The first of the three terms containing $\delta$ in Eq. (2.24) can be reduced by Method 2.13 using the sequence (4,7), (4,6), (3,7), (3,9), (6,9), (6,10), (9,10), (7,10), (7,8), (8,9), (5,8), (5,10). With the Maple 9.5-implementation used by the author (a modified version of Stembridge’s programs) it takes somewhat less than a day on a single core to produce the result which is the polynomial $q^{11} + q^{10} - q^9 - 6q^8 - 7q^7 + 51q^6 - 95q^5 + 101q^4 - 59q^3 + 11q^2 + 4q$. 

The third term with \(\delta\) is much simpler and produces 
\[q^{11} - 2q^9 - 10q^8 + 28q^7 - 25q^6 + 13q^5 - 18q^4 + 27q^3 - 16q^2 - N(2)q\]
within two minutes using the sequence (4,6), (6,9), (6,10), (9,10), (4,7), (3,9), (3,7), (5,10), (7,10), (7,8), (8,9), (5,8). Interestingly it cancels the \(\bar{N}(2)\)-dependence coming from the 14-edge minor, Eq. (2.32).

Only the second term with \(\delta\) contains the degree 4 surface in \(\mathbb{P}^3\). Eliminating variables according to the sequence (3,7), (3,9), (4,7), (4,6), (6,9), (6,10), (9,10), (5,10), (5,8), (8,9), (7,10), (7,8) (if possible) leaves us (after about one day of computer algebra) with a degree 5 threefold and two simpler terms which add to an expression polynomial in \(q\) after applying a rescaling, Eq. (2.10), to one of them. The threefold depends on the variables \(x_{5,10}, x_{5,8}, x_{8,9}, x_{7,10}, x_{7,8}\) corresponding to the last five edges of the sequence. To simplify the threefold we first go to affine space using Eq. (2.11) with \(x_1 = x_{7,8}\). Afterwards we rescale \(x_{5,10}\) and \(x_{7,10}\) by the factor \(x_{5,8}x_{8,9} + x_{5,8} + x_{8,9}\) to obtain a degree 4 two-fold. We decided to apply another rescaling, namely \(x_{7,10} \mapsto x_{7,10}(x_{8,9} + 1)/x_{8,9}\), to eliminate powers of 3 from the two-fold that otherwise would have appeared after going back to projective space using Eq. (2.11) backwards. The variables \(a, b, c\) in Eq. (2.30) correspond to \(x_{5,10}, x_{8,9}, x_{7,10}\), respectively. The variable \(d\) is introduced by homogenizing the polynomial. □

Counting \(\bar{N}(f)_{\mathbb{P}^3}\) mod \(p\) for all primes \(< 10000\) we observe the following behavior: (This result is an immediate consequence of the fact that \(F\) is a Kummer surface [6].)

**Result 2.20.** For \(p > 2\) we have 
\(\bar{N}(f)_{\mathbb{P}^3} \equiv 28k(p)^2 \mod p\) with \(k(p) = 0\) if \(p = 7\) or \(p \equiv 3, 5, 6 \mod 7\) (\(−7\) is not a square in \(\mathbb{F}_p\)) and \(k(p) \in \{1, 2, \ldots, [\sqrt{p/7}]\}\) otherwise. We have (confirmed to 4 digits)
\[
(2.46) \quad \sup_{p} \frac{7k(p)^2}{p} = 1.
\]

Equation (2.46) gives us a hint that the surface \(f = 0\) can not be reduced to a curve (or a finite field extension) because from the local zeta-function and the Riemann hypothesis for finite fields we know [11] that the number of points on a projective non-singular curve of genus \(g\) over \(F_q\) is given by \(q + 1 + \alpha\) with \(|\alpha| \leq 2g\sqrt{q}\). Thus, modulo \(q\) this number is relatively close to 0 for large \(q\). We can not see such a behavior in Eq. (2.46).

We expect that the graphs derived from \(P_{8,38}, P_{8,39}, P_{8,41}\) in [16] also lead to 16-edge graphs which are counter-examples to Kontsevich’s conjecture none of which being expressible in terms of exceptional primes and finite field extensions. By an argument similar to the one above it
seems that the graph hypersurfaces of these graphs reduce to varieties of dimension $\geq 2$. The (likely) absence of curves was not expected by the author.

3. Outlook: Quantum Fields over $\mathbb{F}_q$

In this section we try to take the title of the paper more literally. The fact that the integrands in Feynman-amplitudes are of algebraic nature allows us to make an attempt to define a quantum field theory over a finite field $\mathbb{F}_q$. Our definition will not have any direct physical interpretation. In particular, it should not be understood as a kind of lattice regularization. In fact, the significance of this approach is unclear to the author.

We start from momentum space. The parametric space used in the previous section is not a good starting point because it is derived from momentum or position space by an integral transformation that does not translate literally to finite fields.

We work in general space-time dimension $d$ and consider a bosonic quantum field theory with momentum independent vertex-functions. A typical candidate of such a theory would be $\phi^k$-theory for any integer $k \geq 3$. In momentum space the ‘propagator’ (see [12]) is the inverse of a quadric in $d$ affine variables. Normally one uses $Q = |p|^2 + m^2$, where $|p|$ is the euclidean norm of $p \in \mathbb{R}^d$ and $m$ is the mass of the particle involved. One may use a Minkowskian metric (or any other metric) as well.

The denominator of the integrand in a Feynman amplitude is a product of $n$ quadrics $Q_i$ for a graph $\Gamma$ with $n$ (interior) edges. The momenta in these propagators are sums or differences of $h_1$ momentum vectors, with $h_1$ the number of independent cycles of $\Gamma$. The Feynman-amplitude of $\Gamma$ has the generic form

$$A(\Gamma) = \int_{\mathbb{R}^{dh_1}} d^d p_1 \cdots d^d p_{h_1} \frac{1}{\prod_{i=1}^n Q_i(p)}.$$

The asymptotical behavior of the differential form on the right hand side for large momenta is $\sim |p|^c$, where

$$c = dh_1 - 2n$$

is called the ‘superficial degree of divergence’ (if $h_1 > 0$). It is clear that (at least) graphs with $c \geq 0$ are ill-defined and need regularization. From these amplitudes $A(\Gamma)$ we can construct a correlation function as sum over certain classes of graphs weighted by the order of the
automorphism group,

\[
\Pi = \sum_{\Gamma} g^{\mid\Gamma\mid} A(\Gamma) / |\text{Aut}(\Gamma)|, \tag{3.3}
\]

where \( g \) is the coupling and \( |\Gamma| \) is an integer that grows with the size of \( \Gamma \) (like \( h_1 \)). The correlation function demands renormalization to control the regularization of the single graphs. For a renormalizable quantum field theory all graphs \( \Gamma \) in the sum have the same superficial degree of divergence. In a super-renormalizable theory (at low dimensions \( d \)) the divergence becomes less for larger graphs, whereas the converse is true for a non-renormalizable theory (like quantum gravity).

Working over a finite field it seems natural to replace the integral in Eq. (3.1) by a sum

\[
A(\Gamma)_{\mathbb{F}_q} = \sum_{p \in \mathbb{F}_q^{dh_1}, Q_i(p) \neq 0} \frac{1}{\prod_{i=1}^{n} Q_i(p)}. \tag{3.4}
\]

The amplitude is well-defined (whereas \( |\text{Aut}(\Gamma)| \) in the denominator of Eq. (3.3) causes problems for small \( q \)). It is zero in many cases.

**Lemma 3.1.** Let \( \Gamma \) be a graph with \( n \) edges, \( h_1 > 0 \) independent cycles and superficial degree of divergence \( c \). If \( q > 2 \) then

\[
A(\Gamma)_{\mathbb{F}_q} = 0 \text{ if } (q-1)c + 2n > 0. \tag{3.5}
\]

**Proof.** For all \( x \in \mathbb{F}_q^\times \) we have \( x^{q-1} = 1 \). Hence the amplitude (3.4) can be written as

\[
A(\Gamma)_{\mathbb{F}_q} = \sum_{p \in \mathbb{F}_q^{dh_1}} \prod_{i=1}^{n} Q_i(p)^{q-2} \tag{3.6}
\]

where the restriction to non-zero \( Q_i \) can be dropped for \( q > 2 \). The right hand side is a polynomial in the coordinates of the \( p_i \) of degree \( 2n(q-2) \). On the other hand we have (we use \( 0^0 := 1 \))

\[
\sum_{x \in \mathbb{F}_q} x^k = \begin{cases} -1 & \text{if } 0 < k \equiv 0 \mod (q-1) \\ 0 & \text{else} \end{cases} \tag{3.7}
\]

which is obvious if one multiplies both sides of the equation by any \( 1 \neq y^k \in \mathbb{F}_q^\times \) [if \( k \neq 0 \mod (q-1) \)]. In particular, the sum over a polynomial in \( x \) vanishes unless the polynomial has a minimum degree \( q-1 \). In case of \( dh_1 \) variables we need a minimum degree \( dh_1(q-1) \). The right hand side of (3.6) does not have this minimum degree if \( 2n(q-2) < dh_1(q-1) \) which by Eq. (3.2) gives Eq. (3.5). \( \square \)
We see that only superficially convergent graphs (with \( c < 0 \)) can give a non-zero amplitude. The complexity of the graph is limited by \( q - 1 \) times the degree of convergence. This means for the three possible scenarios of quantum field theory:

1. If the quantum field theory is non-renormalizable then \( c \) becomes positive for sufficiently large graphs. All correlation functions are polynomials in the coupling \( g \) of universal \((q\)-independent) maximum degree.

2. If the quantum field theory is renormalizable then \( c \) is constant for all graphs that contribute to the correlation function. The correlation function becomes a polynomial in the coupling with degree that may grow with \( q \). If the correlation function has \( c \geq 0 \) only the tree level (with \( h_1 = 0 \)) contributes.

3. If the quantum field theory is super-renormalizable then \( c \) becomes negative for sufficiently large graphs. In this case all correlation functions may be infinite (formal) power series.

It is interesting to observe that finite fields give an upside down picture to normal quantum field theories. The most problematic non-renormalizable quantum field theories give the simplest results whereas the most accessible super-renormalizable theories may turn out to be the most complicated ones over finite fields. In between we have the renormalizable quantum field theories that govern the real world.

Another theme of interest could be an analogous study of \( p \)-adic quantum field theories.
