Abstract

We derive an analytic expression for one-loop effective action of QCD+QED at zero and finite temperatures by using the Schwinger’s proper time method. The result is a nonlinear effective action not only for electromagnetic and chromo-electromagnetic fields but also the Polyakov loop, and thus reproduces the Euler-Heisenberg action in QED, QCD, and QED+QCD, and also the Weiss potential for the Polyakov loop at finite temperature. As applications of this “Euler-Heisenberg-Weiss” action in QCD+QED, we investigate quark pair productions induced by QCD+QED fields at zero temperature and the Polyakov loop in the presence of strong electromagnetic fields. Quark one-loop contribution to the effective potential of the Polyakov loop explicitly breaks the center symmetry, and is found to be enhanced by the magnetic field, which is consistent with the inverse magnetic catalysis observed in lattice QCD simulation.

I. INTRODUCTION

The very first stage in a high-energy heavy-ion collision is dominated by extremely strong chromo-electromagnetic (chromo-EM) fields reflecting colliding nuclei filled with high density gluons (color glass condensate). Such a state with strong fields is called a ‘glasma’ which is named since it is a transitional state between a color glass condensate (before the collision) and a quark-gluon plasma (QGP) [1]. The glasma is characterized by a field strength $F$ of the order of the saturation scale: $gF \sim Q_s^2$ (with $g$ being the QCD coupling). Notice that the saturation scale $Q_s$ is a semi-hard scale representing a typical transverse momentum of gluons in a colliding nucleus and can become large enough, at high energies, compared to light quark masses $Q_s \gg m_q$. Besides, it has been long known that heavy-ion collisions, with electrically charged nuclei, are accompanied by electromagnetic (EM) fields, but only recently it became seriously recognized that the strong EM fields could affect time evolution of heavy-ion collision events since the strength $F$ of the EM fields could be as large as or even greater than the non-perturbative QCD scale $\Lambda_{\text{QCD}}$, namely $eF \gtrsim \Lambda_{\text{QCD}}^2$ and thus $eF \gg m_q^2$ [2–5]. Since both the chromo-EM and EM fields created in heavy-ion collisions can be strong enough compared with the light quark masses, the effects of strong fields cannot be treated as perturbation (even though the coupling constants are small), but must be treated in a non-perturbative way. Then we expect nonlinear and non-perturbative phenomena associated with the strong fields to occur. Typical examples of such phenomena include particle productions (quarks, antiquarks and gluons) from these strong fields (the Schwinger mechanism), which must be a key towards understanding the formation of QGP.

While the (coherent) chromo-EM fields will disappear as the QGP is formed, the EM fields could survive longer due to Faraday’s law which works in the presence of a conducting medium [6, 7]. If the EM fields survive strong enough until the formation of QGP, and even until the end of QGP life time, we need to describe the QCD phase transition with the effects of strong EM fields taken into account. Notice that the effects of strong magnetic fields on thermodynamical or fundamental quantities of QGP can be investigated in lattice QCD simulations, and are indeed found to be large. For example, at zero temperature, lattice QCD simulations confirmed the ‘magnetic catalysis’ as predicted in several effective models [8–15] in which the value of chiral condensate increases with increasing magnetic field strength. On the other hand, at finite temperature, lattice QCD simulations almost
at the physical point concluded \[16, 17\] that the magnetic catalysis does not necessarily occur at all the temperature regions, but rather gets weakened and even shows opposite behavior with increasing temperature. Such behavior of the chiral condensate around the critical temperature is called ‘magnetic inhibition’ \[18\] or ‘inverse magnetic catalysis’, which eventually gives rise to decreasing critical temperature. For recent reviews on phase diagram of chiral phase transition in strong magnetic fields, see, e.g., \[20, 21\]. Furthermore, it is reported \[19\] that the (pseudo-)critical temperature of confinement-deconfinement phase transition (for the Polyakov loop) also decreases with increasing magnetic field. This is achieved by increasing Polyakov loop expectation values. Probably, these two phenomena are related to each other. However, so far, there is no clear explanation about the physical mechanism behind this (for recent attempts, see Refs. \[22, 23\] and \[24, 25\]).

We can investigate these two aspects, namely the nonlinear and non-perturbative dynamics of strong fields (including particle production) and the phase transition under strong external fields, within a single framework of an effective action. So far, effective actions for QED and QCD in various external conditions have been extensively explored. First of all, Euler and Heisenberg derived a non-linear effective action for constant EM fields at electron’s one-loop level, known as the Euler-Heisenberg (EH) action \[26\]. Later Schwinger reproduced the same action in a field theoretical manner, which is so-called the Schwinger’s proper time method \[27\]. The EH action at finite temperatures is computed in imaginary time formalism \[28, 29\] as well as in real time formalism \[30, 31\]. Furthermore, an analog of the EH action in QCD (for chromo-EM fields) has been evaluated too within a similar method at zero and finite temperatures \[32-41\]. Lastly, the most recent progress was to compute the EH action at zero temperature when both the EM and chromo-EM fields are present, which was done by one of the authors and B.V. Galilo and S.N. Nedelko independently \[42, 43\]. The author of Ref. \[43\] used this effective action to investigate the QCD vacuum (gluon condensate) in the presence of strong magnetic fields. Though all of these are about the effective action for strong fields and chromo-EM condensates, it should be possible to include the Polyakov loop at finite temperatures. Indeed, an effective action for the Polyakov loop at the one loop level was computed by N. Weiss \[44, 45\] also within the Schwinger’s proper time method. In the present paper, we are going to derive an analog of the EH effective action in QCD+QED at finite temperatures with the Polyakov loops included. Thus, the result may be collectively called the “Euler-Heisenberg-Weiss action”.
Our result is also a generalization of the one obtained by H. Gies [41] who computed an
effective action for the Polyakov loop and the chromo-electric field.

The paper is organized as follows. In the next section, we will derive the effective action for
QCD+QED at finite temperatures by using the Schwinger’s proper time method. Variables
of the effective action are the EM and chromo-EM fields as well as the Polyakov loop, and
one can reproduce the previous results (the EH action with QCD+QED fields, the Weiss
potential, etc.) in various limits. Then, we discuss some applications of our effective action
in section III. First, we investigate quark-antiquark pair production in QCD+QED fields
at zero temperature. We obtain the quark production rate in the presence of QCD+QED
fields which allows us to study the quark pair production with arbitrary angle between the
EM and chromo-EM fields. Next we study an effective potential for the Polyakov loop
with electromagnetic fields. We find that the magnetic field enhances the explicit center
symmetry breaking while the electric field reduces it. This indicates that the (pseudo)-
critical temperature of confinement-deconfinment phase transition decreases (increases) with
increasing magnetic (electric) field. Finally, we conclude our study in section IV.

II. ONE-LOOP EFFECTIVE ACTION FOR QCD+QED AT FINITE TEMPERATURE

In this section, we derive the one-loop effective action for QCD+QED at finite tempera-
tures. The effective action will be a function of chromo-EM and EM fields as well as the
temporal component of the gluon field which gives the Polyakov loop. Notice that both the
strong fields and the temporal component of the gluon field can be treated as background
fields so that the background field method is applicable. We will take quantum fluctuations
around the background fields up to the second order in the action, and integrate them in
the path integral. This corresponds to computing the action in the one-loop level.

We shall begin with the four-dimensional QCD action of SU($N_c$) gauge group with $N_f$
flavor quarks interacting with EM fields:

$$
S_{\text{QCD+QED}} = \int d^4 x \left\{ -\frac{1}{4} F_{\mu\nu}^a F^{a\mu\nu} - \frac{1}{4} f_{\mu\nu} f^{\mu\nu} + \bar{q} (i \gamma_{\mu} D_{\mu} - M_q) q \right\},
$$

(1)

where the covariant derivative contains gluon fields$^1$ $A_{\mu}^a (a = 1, \cdots, N_c^2 - 1)$ and U(1) gauge

---

$^1$ Throughout the paper, we use $a, b, c$ (and $h$) for adjoint color indices $(a, b, c = 1, \cdots, N_c^2 - 1)$, $i$ for
fields $a_\mu$ as

$$D_\mu = \partial_\mu - ig A_\mu^a T^a - ie Q_q a_\mu ,$$

(2)

and gluon and EM field strength tensors are given by $F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + gf^{abc} A_\mu^b A_\nu^c$ and $f_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu$, respectively. In this paper, we treat the EM fields just as background fields, and assume that the field strengths are constant so that $\partial f = 0$. We abbreviated color, flavor and spinor indices of the quark field in Eq. (1). Mass and charge matrices of quarks are given by $M_q = \text{diag}(m_{q_1}, m_{q_2}, \cdots, m_{q_{N_f}})$ and $Q_q = \text{diag}(Q_{q_1}, Q_{q_2}, \cdots, Q_{q_{N_f}})$. As for the gluon field, we apply the background field method and decompose the gluon field into a slowly varying background field $A_\mu^a$ and a quantum fluctuation $\tilde{A}_\mu^a$ as

$$A_\mu^a = A_\mu^a + \tilde{A}_\mu^a .$$

(3)

Here we employ the covariantly constant field as a background field, which obeys the following condition [46–48]:

$$D_\rho^{ac} F_{\mu\nu}^c = 0 ,$$

(4)

where the covariant derivative $D_\rho$ is defined only with respect to the gluon background field:

$$D_\rho^{ac} = \partial_\rho \delta^{ac} + gf^{abc} A_\rho^b ,$$

(5)

and $F_{\mu\nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + gf^{abc} A_\mu^b A_\nu^c$. From the condition (4), the field strength tensor $F_{\mu\nu}^a$ can be factorized as $F_{\mu\nu}^a = F_{\mu\nu} n^a$, where $n^a$ is a unit vector in color space, normalized as $n^a n^a = 1$, whereas $F_{\mu\nu}$ expresses the magnitude of the chromo-EM field. We further assume that $F$ is very slowly varying, satisfying $\partial F = 0$, which allow us to obtain the analytic expression of the EH action for QCD, just as in QED. Both $F_{\mu\nu}$ and $n^a$ are space-time independent. The background field $A_\mu^a$ is proportional to the color unit vector $n^a$ as

$$A_\mu^a = A_{\mu} n^a ,$$

(6)

and the field strength tensor $F_{\mu\nu}$ has an Abelian form, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$. This background field (6) indeed satisfies the condition (4). By using the background field and the quantum fluctuation, the full gluon field strength tensor can be decomposed as

$$F_{\mu\nu}^a = F_{\mu\nu} n^a + (D_\rho^{ac} \tilde{A}_\nu^c - D_\rho^{ac} \tilde{A}_\mu^c) + gf^{abc} \tilde{A}_\mu^b \tilde{A}_\nu^c .$$

(7)

Fundamental color indices ($i = 1, \cdots, N_c$), $\mu, \nu, \alpha, \beta$ for Lorentz indices, and $f$ for flavor indices ($f = 1, \cdots, N_f$).
Applying the background gauge for the quantum fluctuation,
\[ \mathcal{D}_{\mu}^{ac} \tilde{A}_\mu^c = 0 , \]  
we get the gauge fixed action in the presence of EM fields,
\[ S_{\text{QCD+QED}} = \int d^4x \left\{ -\frac{1}{4} \{ F_{\mu\nu} n^a + (\mathcal{D}_{\mu}^{ac} \tilde{A}_\nu^c - \mathcal{D}_{\nu}^{ac} \tilde{A}_\mu^c) + gf^{abc} \tilde{A}_b^\mu \tilde{A}_c^\nu \}^2 - \frac{1}{2\xi} (\mathcal{D}_{\mu}^{ac} \tilde{A}_\mu^c)^2 \right. \\
\left. - \bar{c}^a (\mathcal{D}_\mu D^\mu)^{ac} c^c + \bar{q} (i\gamma_\mu D^\mu - M_q) q - \frac{1}{4} f_{\mu\nu} f^{\mu\nu} \right\} , \]  
where \( c \) is the ghost field and \( \xi \) is the gauge parameter. Notice that one of the covariant derivative in the ghost kinetic term \( D_{\mu}^{ac} \) and the one in the quark kinetic term \( D_\mu \) defined in Eq. (2) contain all the gauge fields. The effective action for the background fields \( \mathcal{A}_\mu \) and \( a_\mu \) can be obtained through the functional integral as
\[ \exp \left( iS_{\text{eff}}[\mathcal{A}_\mu, a_\mu] \right) \equiv \int \mathcal{D}\tilde{A} \mathcal{D}c \mathcal{D}\bar{c} \mathcal{D}q \mathcal{D}\bar{q} \exp \left( i \int d^4x S_{\text{QCD+QED}} \right) . \]  
We perform the functional integral with fluctuations taken up to second order. This corresponds to evaluating the one-loop diagrams as shown in Fig. 1. The gluon, ghost, and quark loop integrations can be separately done and one respectively finds
\[ \int \mathcal{D}\tilde{A} \exp \left\{ \int d^4x \left[ -\frac{i}{2} \tilde{A}^{a\mu} \left[ -(\mathcal{D}^2)^{oc} g_{\mu\nu} - 2gf^{abc} F_{\mu\nu}^b \right] \tilde{A}^{c\nu} \right] \right\} = \det \left[ -(\mathcal{D}^2)^{ac} g_{\mu\nu} - 2gf^{abc} F_{\mu\nu}^b \right]^{-\frac{1}{2}} , \\
\int \mathcal{D}c \mathcal{D}\bar{c} \exp \left\{ i \int d^4x c^a \left[ -(\mathcal{D}^2)^{ac} \right] c^c \right\} = \det \left[ -(\mathcal{D}^2)^{ac} \right]^{+1} , \\
\int \mathcal{D}q \mathcal{D}\bar{q} \exp \left\{ i \int d^4x \bar{q} \left( i\gamma_\mu \mathcal{D}^\mu - M_q \right) q \right\} = \det \left[ i\gamma_\mu \mathcal{D}^\mu - M_q \right]^{+1} . \]  
Here we have taken the Feynman gauge, \( \xi = 1 \). In the quark one-loop contribution, the covariant derivative \( \mathcal{D}_\mu \) contains both of the background fields \( \mathcal{A}_\mu \) and \( a_\mu \):
\[ \mathcal{D}_\mu = D_\mu - ieQ_q a_\mu \]
\[ = \partial_\mu - ig A_\mu^a T^a - ieQ_q a_\mu . \]  
On the other hand, the gluon and ghost one-loop contributions contain \( D_{\mu}^{ac} \) and \( F_{\mu\nu}^a \) which only depend on the gluon background field \( \mathcal{A}_\mu \). This is of course because the gluon and ghost fields do not have electric charge and thus cannot interact with EM fields. Since these contributions are the same as in the pure Yang-Mills (YM) theory, we may call these the YM part.
FIG. 1: Typical loop diagrams contributing to the effective action. The field $A$ contains both the chromo-EM fields and the Polyakov loop.

So far, we have not specified the background field $A_\mu$, but it can contain both the chromo-EM fields and the Polyakov loop. Let us briefly explain how the Polyakov loop is described within our framework. In the pure Yang-Mills theory at finite temperature, there is a confinement-deconfinement transition whose order parameter is given by the Polyakov loop. It is defined by the (closed) Wilson line along the imaginary time ($\tau$) direction:

$$\Phi(\vec{x}) = \frac{1}{N_c} \text{Tr} \mathcal{P} \exp \left\{ ig \int_0^\beta d\tau A^a_\tau(\tau, \vec{x}) T^a \right\},$$

where $\beta = 1/T$ is the inverse temperature and $\mathcal{P}$ stands for a path-ordered product along the imaginary time direction. Indeed, $\langle \Phi \rangle \to 0$ ($\langle \Phi \rangle \neq 0$) corresponds to a confining (deconfined) phase since the negative logarithm of the expectation value of the Polyakov loop can be identified with a free energy of a static quark (a vanishing value of the Polyakov loop implies that the energy of a single quark state is infinity). These two phases are distinguished by the center symmetry. The gauge fields at finite temperature are not necessarily periodic in the direction of imaginary time and can have ambiguity related to the center subgroup $Z_{N_c}$ of the gauge symmetry SU($N_c$). This residual symmetry is called the center symmetry and the theory is invariant under gauge transformations which differ at $\tau = 0$ and $\tau = \beta$. 

7
a center element of the gauge group. The Polyakov loop $\Phi$ transforms as $\Phi \rightarrow e^{2\pi i n/N_c} \Phi$ ($n = 0, 1, 2, \ldots, N_c - 1$). Thus, the values of $\Phi$ distinguish the center symmetric (confining) phase and the center broken (deconfined) phase. Dynamical quarks, however, explicitly break the center symmetry. Therefore in QCD, the Polyakov loop should be understood as an approximated order parameter. Still, we can compute an effective action for the Polyakov loop and discuss how a phase transition occurs when external parameters such as temperature are varied.

An effective action for the Polyakov loop in the pure Yang-Mills theory was obtained by N. Weiss [44] in the following way. Working in what we now call the “Polyakov gauge” for a time-independent field $A_0^a(\vec{x}) = \phi(\vec{x})\delta^a_3$ in the SU(2) case, he performed functional integral with respect to fluctuations around the field $\phi(\vec{x})$. This procedure is nothing but the one we explained above where we treated the gluon field $A_\mu^a$ as a background $\bar{A}_\mu^a$ with a fluctuation around it. Besides, as far as we consider a spatially homogeneous and time-independent order parameter $\bar{A}_4^a$, we can have both the Polyakov loop and the chromo-EM fields at the same time. We divide the background field into the constant part and the coordinate dependent part as $A_\mu^a(x) = \bar{A}_\mu^a + \hat{A}_\mu^a(x)n^a$. The second term gives the real (physical) chromo-EM fields so that $F_{\mu\nu}^a = \partial_\mu A_\nu^a(x) - \partial_\nu A_\mu^a(x) = (\partial_\mu \bar{A}_\nu(x) - \partial_\nu \bar{A}_\mu(x))n^a$, while the first constant term $\bar{A}_\mu^a$ does not. We want to treat both the chromo-EM fields and the Polyakov loop, and the latter is described at finite temperature. In order to have both, we specify the transformation of the temporal component of the background field $A_0^a(x)$ under the Wick rotation of the coordinate, $x_0 \rightarrow -ix_4 = -i\tau$ and $x_i \rightarrow x_i$ ($i = 1, 2, 3$), as follows: $A_0^a(x) = \bar{A}_0^a + \hat{A}_0(x)n^a \rightarrow i\bar{A}_4^a + \hat{A}_0(x)n^a$. In this way, the first term gives the Polyakov loop defined in Eq. (13), while the second term remains unchanged to give the real chromo-EM fields. We work in the Polyakov gauge for $\bar{A}_4^a$ [44]:

$$\bar{A}_4^a = \bar{A}_4 \delta^a_3, \quad \partial_4 \bar{A}_4 = 0, \quad (14)$$

which does not conflict with the covariant constant condition in Eq. (4). Notice that we use this gauge with $\delta^a_3$ even for the SU($N_c$) case, and the color unit vector $n^a$ introduced in Eq. (6) should be understood as $n^a = \delta^a_3$ at finite temperature.\footnote{Still, we keep the expression $n^a$ because we will discuss the case at zero temperature.} Following Ref. [44], we
also introduce a dimensionless field \( C \) as

\[
C = \frac{g A_1}{2\pi T},
\]

so that the Polyakov loop is simply given as

\[
\Phi = \cos(\pi C) \quad \text{for } \text{SU}(2),
\]

\[
\Phi = \frac{1}{3} \left\{ 1 + 2\cos(\pi C) \right\} \quad \text{for } \text{SU}(3).
\]

\section{A. Yang-Mills part of effective action}

Now, we consider the Yang-Mills part (gluon and ghost contributions) of the one-loop effective action. In the one-loop level, the effect of EM fields is not included in gluon and ghost loops, since these do not directly interact with EM fields. From Eq. (11), the effective actions of gluon and ghost parts are respectively given as

\[
iS_{\text{gluon}} \equiv \ln \det \left[ -(D^2)^{ac} g_{\mu\nu} - 2gf^{abc} F_{\mu\nu}^b \right]^{-\frac{1}{2}},
\]

\[
iS_{\text{ghost}} \equiv \ln \det \left[ -(D^2)^{ac} \right]^{+1}.
\]

Let us first explore the gluon part (17). By using the proper time integral\footnote{We use the following identity

\[
\ln(\hat{M} - i\delta) = \frac{1}{\epsilon} - \frac{\epsilon}{\Gamma(\epsilon)} \int_0^\infty \frac{ds}{s^{1-\epsilon}} e^{-s(M-\delta)}
\]

in the limit \( \epsilon \to 0 \) and \( \delta \to 0 \). We ignore the first divergent term since it does not depend on the fields.}, the gluon part of the effective action can be rewritten in the following form (the limit \( \epsilon, \delta \to 0 \) is always implicit and should be taken after the calculation):

\[
iS_{\text{gluon}} = -\frac{1}{2} \text{Tr} \ln \left[ -(D^2)^{ac} g_{\mu\nu} - 2gf^{abc} F_{\mu\nu}^b \right]
\]

\[
= \int d^4x \left( \frac{\epsilon}{2} \sum_{h=1}^{N^2-1} \int_0^\infty d\tau \langle x| e^{-i(D^2 g_{\mu\nu} + 2ig_{\nu} F_{\mu\nu} - i\delta s)|x\rangle}
\]

\[
= \int d^4x \left( \frac{\epsilon}{2} \sum_{h=1}^{N^2-1} \int_0^\infty d\tau \langle x| e^{-\delta s} \left\{ e^{-i(2g_{\nu} a)s} + e^{-i(-2g_{\nu} a)s} + e^{-i(ig_{\nu} b)s} + e^{-i(-2ig_{\nu} b)s} \right\}
\]

\[
\times \langle x| e^{-i(D^2 g_{\mu\nu})s}|x\rangle \right).
\]

While the capital trace “Tr” in the first line is taken with respect to colors, Lorentz indices, and coordinates, “tr” in the second line is only for Lorentz indices. Also in the second line,
we have introduced real quantities \( v_h (h = 1, \ldots, N_c^2 - 1) \) that are eigenvalues of a hermitian matrix \( V^{ac} \equiv i f^{abc} n^b \) (i.e., \( V^{ac} \varphi^c = v_h \varphi^a \)), and Lorentz-invariant quantities \( a, b \) defined by

\[
a \equiv \frac{1}{2} \sqrt{\mathcal{F}^4 + (\mathcal{F} \cdot \tilde{\mathcal{F}})^2 + \mathcal{F}^2}, \quad b \equiv \frac{1}{2} \sqrt{\mathcal{F}^4 + (\mathcal{F} \cdot \tilde{\mathcal{F}})^2 - \mathcal{F}^2},
\]

with the dual field strength tensor \( \tilde{\mathcal{F}}^{\mu \nu} = \frac{1}{2} \epsilon^{\mu \nu \alpha \beta} \mathcal{F}_{\alpha \beta} \) (or equivalently, by \( a^2 - b^2 = \frac{1}{2} \mathcal{F}^2 \) and \( ab = \frac{1}{4} \mathcal{F} \cdot \tilde{\mathcal{F}} \)). The covariant derivative is defined as \( D_{\mu} v_h = \partial_{\mu} - i g v_h A_{\mu} \). The calculation up to now is in fact the same as in the case at zero temperature which was done in Ref. [43]. At finite temperature, however, one needs to be careful in evaluating the matrix element \( \langle x | e^{-i(-D_{\mu} v_h) s^\mu} | x \rangle \). Namely, it can be now written as the Matsubara summation:

\[
\langle x | e^{-i(-D_{\mu} v_h) s^\mu} | x \rangle = iT \sum_{n=-\infty}^{\infty} \int \frac{d^3 p}{(2\pi)^3} e^{-p_a X^{\alpha \beta}_h (is^\alpha) p_{\beta}} e^{-Y_h(is)} \bigg|_{p_0 = ig v_h A_4 - i 2\pi n T},
\]

where the functions \( X^{\alpha \beta}_h (s) \) and \( Y_h (s) \) have been defined as

\[
X^{\alpha \beta}_h (s) = \left[ (g v_h \mathcal{F})^{-1} \tan(g v_h \mathcal{F} s) \right]^{\alpha \beta}, \quad Y_h (s) = \frac{1}{2} \text{tr} \ln \cos(g v_h \mathcal{F} s).
\]

In the presence of the Polyakov loop \( \bar{A}_4 \), the periodic boundary condition of the gluon in the imaginary time direction is modified. Then, the Matsubara frequency is shifted by the Polyakov loop as in Eq. (21). Performing the three dimensional momentum integral and applying the Poisson resummation [49], one can obtain the matrix element in terms of \( a \) and \( b \) as

\[
\langle x | e^{-i(-D_{\mu} v_h) s^\mu} | x \rangle = -\frac{i g v_h a s}{16\pi^2 \sin(g v_h a s) \sinh(g v_h b s)} \left[ 1 + 2 \sum_{n=1}^{\infty} e^{\frac{h(s) n^2}{4T} - \frac{g v_h \bar{A}_4}{T} n} \right],
\]

where

\[
h(s) = \frac{b^2 - c^2}{a^2 + b^2} g v_h a \cot(g v_h a s) + \frac{a^2 + c^2}{a^2 + b^2} g v_h b \coth(g v_h b s),
\]

with

\[
c^2 = (u_\alpha \mathcal{F}^{\alpha \mu})(u_\beta \mathcal{F}^{\beta \mu}).
\]

The vector \( u^\mu \) is the heat-bath four vector, which is \((1, 0, 0, 0)\) in the rest frame of the heat bath. The first (second) term in Eq. (23) corresponds to the zero (finite) temperature
contribution. The gluon part of the effective action is then given as

\[ iS_{\text{gluon}} = -\frac{i^{1+\epsilon}}{32\pi^2} \int d^4x \sum_{h=1}^{N^2-1} \int_0^\infty \frac{ds}{s^{3-\epsilon}} e^{-\delta s} \left\{ e^{-i(2gv_a)s} + e^{-i(2gv_a)s} + e^{-i(igv_b)s} + e^{-i(-2igv_b)s} \right\} \]

\[ \times \frac{gv_h a_s}{\sin(gv_h a_s) \sinh(gv_h b_s)} \left[ 1 + 2 \sum_{n=1}^{\infty} e^{\frac{b(s)}{4T^2}} n^2 \cos \left( \frac{gv_h \bar{A}_4}{T} n \right) \right]. \]  

Similarly, we obtain the ghost part as,

\[ iS_{\text{ghost}} = -\frac{i^{1+\epsilon}}{32\pi^2} \int d^4x \sum_{h=1}^{N^2-1} \int_0^\infty \frac{ds}{s^{3-\epsilon}} e^{-\delta s} \left\{ 2 \right\} \]

\[ \times \frac{gv_h a_s}{\sin(gv_h a_s) \sinh(gv_h b_s)} \left[ 1 + 2 \sum_{n=1}^{\infty} e^{\frac{b(s)}{4T^2}} n^2 \cos \left( \frac{gv_h \bar{A}_4}{T} n \right) \right]. \]  

In both parts, the first terms in the square brackets are the results at zero temperature and agree with the known results [43]. As discussed in detail in Ref. [43], each term has an ultra-violet (UV) divergence, which however can be renormalized into the coupling \( g \) and fields \( A_\mu \) [32, 33]. On the other hand, the finite temperature contributions do not have UV divergence and thus we do not need an additional renormalization procedure for the finite temperature part. We regard the coupling and fields as renormalized ones and focus on UV finite pieces in Eqs. (26) and (27).

Our results (26) and (27) are effective actions for chromo-EM fields as well as the Polyakov loop at finite temperature. These are generalization of the previous results in two cases. Indeed, if we consider the pure chromo-electric background with a Polyakov loop (\( B = 0, E \neq 0, A_0 \neq 0 \)), we find \( a \to iE, b \to 0 \) and reproduce Gies’ effective action at finite temperature [41]. Moreover, in case of the pure chromo-magnetic background (\( E = 0, B \neq 0, \bar{A}_4 = 0 \)), we find \( a \to B, b \to 0 \) and reproduce the results obtained in Refs. [40, 50].

B. Quark part of effective action

For the quark part of the effective action, we follow basically the same procedures as in the Yang-Mills part. From the functional integral (11), the quark part of the one-loop effective action reads

\[ iS_{\text{quark}} = \ln \det \left[ i\gamma_\mu \hat{D}^\mu - M_q \right]. \]
Utilizing the proper time integral, we evaluate the effective action as

\[
i S_{\text{quark}} = \text{Tr} \ln \left[ i \gamma_\mu \hat{D}_\mu - M_q \right]
= - \int dx^4 \frac{i e}{2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{e^{-i(m^2_{i,f} - i \delta)s}}{s^{1-\epsilon}} \text{tr} \langle x | e^{-i s \left( - \mathbb{D}_{i,f} - \frac{1}{2} \mathbb{F}_{i,f} \right)} | x \rangle,
\]

where \( \mathbb{D}_{i,f} = \partial^\mu - i \mathbb{A}_{i,f}^\mu \) with the field \( \mathbb{A}_{i,f}^\mu \) being a linear combination of the gluon field \( \mathbb{A}_\mu \) and the photon field \( a^\mu \) as

\[
\mathbb{A}_{i,f}^\mu = g \omega_i \mathbb{A}_\mu + e Q_q a^\mu.
\]

This covariant derivative \( \mathbb{D}_{i,f}^\mu \) can be obtained from \( \hat{D}^\mu \) defined in Eq. [12] with the covariantly constant field employed as the background field. Here \( \omega_i \) (\( i = 1, \cdots, N_c \)) are eigenvalues of an \( N_c \times N_c \) matrix \( n^a T^a \) and satisfy \( \sum_{i=1}^{N_c} \omega_i = 0 \) and \( \sum_{i=1}^{N_c} \omega_i^2 = 1/2 \). The field strength tensor \( \mathbb{F}_{i,f}^{\mu \nu} \) can be expressed in terms of constant chromo-EM fields \( \vec{E}, \vec{B} \) and EM fields \( \vec{\mathcal{E}}, \vec{\mathcal{B}} \) as (with the notation \( \vec{V} = (V_x, V_y, V_z) \))

\[
\mathbb{F}_{i,f}^{\mu \nu} = g \omega_i \mathcal{F}^{\mu \nu} + e Q_q f^{\mu \nu}
= g \omega_i \left( \begin{array}{ccc} 0 & E_x & E_y & E_z \\
- E_x & 0 & B_z & -B_y \\
- E_y & -B_z & 0 & B_x \\
- E_z & B_y & -B_x & 0 \end{array} \right) + e Q_q \left( \begin{array}{ccc} 0 & E_x & E_y & E_z \\
- E_x & 0 & B_z & -B_y \\
- E_y & -B_z & 0 & B_x \\
- E_z & B_y & -B_x & 0 \end{array} \right).
\]

The eigenvalues of the field strength tensor \( \mathbb{F}_{i,f}^{\mu \nu} \) are given by \( \pm i \mathbf{a}_{i,f} \) and \( \pm \mathbf{b}_{i,f} \) with

\[
\mathbf{a}_{i,f} = \frac{1}{2} \sqrt{\mathbb{F}_{i,f}^4 + (\mathbb{F}_{i,f} \cdot \mathbb{F}_{i,f})^2 + \mathbb{F}_{i,f}^2}, \quad \mathbf{b}_{i,f} = \frac{1}{2} \sqrt{\mathbb{F}_{i,f}^4 + (\mathbb{F}_{i,f} \cdot \mathbb{F}_{i,f})^2 - \mathbb{F}_{i,f}^2}.
\]

The dual field strength tensor \( \tilde{\mathbb{F}}_{i,f}^{\mu \nu} \) is defined as \( \tilde{\mathbb{F}}_{i,f}^{\mu \nu} = \frac{1}{2} e^{\mu \nu \alpha \beta} \mathbb{F}_{i,f}^{\alpha \beta} \). By using Eq. [31], \( \mathbb{F}_{i,f}^2 = 2(\mathbf{a}_{i,f}^2 - \mathbf{b}_{i,f}^2) \) and \( \mathbb{F}_{i,f} \cdot \tilde{\mathbb{F}}_{i,f} = 4 \mathbf{a}_{i,f} \mathbf{b}_{i,f} \) can be expressed in terms of chromo-EM fields and EM fields as

\[
\mathbb{F}_{i,f}^2 = 2(\mathbb{B}_{i,f}^2 - \mathbb{E}_{i,f}^2), \quad \mathbb{F}_{i,f} \cdot \tilde{\mathbb{F}}_{i,f} = -4 \mathbb{E}_{i,f} \cdot \mathbb{B}_{i,f}.
\]

\(^4\) Let \( \Omega \) be a diagonal matrix with eigenvalues \( \omega_i \), i.e., \( \Omega = \text{diag}(\omega_1, \cdots, \omega_{N_c}) = U n^a T^a U^\dagger \). Then, \( \sum_{i=1}^{N_c} \omega_i = \text{tr} \Omega = n^a \text{tr} T^a = 0 \) and \( \sum_{i=1}^{N_c} \omega_i^2 = \text{tr} \Omega^2 = \text{tr} (T^a T^b) n^a n^b = 1/2. \)
where we have defined the combined electromagnetic fields as $\vec{E}_{i,f} = g \omega_i \vec{E} + e Q_j \vec{E}$ and $\vec{B}_{i,f} = g \omega_i \vec{B} + e Q_j \vec{B}$. Taking the trace of the matrix $\langle x \mid e^{-is(-D^2_{i,f} - \frac{1}{2} \sigma \cdot F_{i,f})} \mid x \rangle$ at finite temperature, we get

$$\text{tr} \langle x \mid e^{-is(-D^2_{i,f} - \frac{1}{2} \sigma \cdot F_{i,f})} \mid x \rangle = iT \sum_{n=-\infty}^{\infty} \int \frac{d^3p}{(2\pi)^3} e^{-p_0 \chi_{i,f}(i\omega) p_0} e^{-\chi_{i,f}(i\omega) \text{tr} e^{i\frac{1}{2} \sigma \cdot F_{i,f}} \mid_{p_0=ig\omega_i \tilde{A}_4 - i\pi(2n+1)T}}. \quad (34)$$

Here, the functions $X^{\alpha\beta}_{i,f}(\bar{s})$ and $\chi_{i,f}(\bar{s})$ have been defined as

$$X^{\alpha\beta}_{i,f}(\bar{s}) = \left[ F_{i,f}^{-1} \tan(F_{i,f}\bar{s}) \right]^{\alpha\beta}, \quad \chi_{i,f}(\bar{s}) = \frac{1}{2} \text{tr} \ln \cos(F_{i,f}\bar{s}). \quad (35)$$

In the presence of the Polyakov loop $\tilde{A}_4$, the antiperiodic boundary condition for the quark is also modified. Then, the temporal component of the four-momentum vector has been replaced by the Polyakov loop and the Matsubara frequency for a fermion in Eq. (34). The third part $\text{tr} e^{i\frac{1}{2} \sigma \cdot F_{i,f}}$ is common with the case at zero temperature and was computed in Ref. [43]. The result is

$$\text{tr} \exp \left( i \frac{1}{2} \sigma \cdot F_{i,f} \right) = 4\cos(a_{i,f}s)\cosh(b_{i,f}s). \quad (36)$$

Now, performing the three dimensional momentum integral and using the Poisson resummation, we find from Eq. (34),

$$\text{tr} \langle x \mid e^{-is(-D^2_{i,f} - \frac{1}{2} \sigma \cdot F_{i,f})} \mid x \rangle = -\frac{i}{4\pi^2 s^2 \sin(a_{i,f}s)\sinh(b_{i,f}s)} \cos(a_{i,f}s)\cosh(b_{i,f}s)$$

$$\times \left\{ 1 + 2 \sum_{n=1}^{\infty} (-1)^n e^{\frac{i}{\pi^2 h_{i,f}(s)n^2}} \cos \left( \frac{g\omega_i \tilde{A}_4 n}{T} \right) \right\}, \quad (37)$$

where

$$h_{i,f}(s) = \frac{b_{i,f}^2 - e_{i,f}^2}{a_{i,f}^2 + b_{i,f}^2} a_{i,f} \cot(a_{i,f}s) + \frac{a_{i,f}^2 + e_{i,f}^2}{a_{i,f}^2 + b_{i,f}^2} b_{i,f} \coth(b_{i,f}s), \quad (38)$$

with

$$e_{i,f}^2 = (u_{\alpha} F_{i,f}^{\alpha\mu})(u_{\beta} F_{i,f}^{\beta\mu}). \quad (39)$$
In the heat-bath rest frame, we have $u^\mu = (1, 0, 0, 0)$ and then $c^2_{i,f} = \bar{E}^2_{i,f} = (g\omega_i\vec{E} + eQ_{q_f}\vec{E})^2$. Therefore, the quark part of the one-loop effective action reads,

$$iS_{\text{quark}} = \frac{i^{1+\epsilon}}{8\pi^2} \int d^4x \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty \frac{ds}{s^{3-\epsilon}} e^{-i(m^2_{q_f} - i\delta)s} (a_{i,f,s})(b_{i,f,s}) \cot(a_{i,f,s}) \coth(b_{i,f,s})$$

$$\times \left[ 1 + 2 \sum_{n=1}^{\infty} (-1)^n e^{\frac{1}{T} b_{i,f,s}} \cos \left( \frac{g\omega_i\vec{A}_4 n}{T} \right) \right]. \quad (40)$$

As in the YM part, the first (second) term corresponds to the zero (finite) temperature contribution. The zero-temperature contribution agrees with the previous result obtained in Ref. [43].

Again, the first term contains UV divergences. These divergences have two origins: QCD and QED [43]. This is because the resummed quark one-loop diagrams contain contributions from the diagrams with only two EM fields insertions (QED) and only two chromo-EM fields insertions (QCD). The UV divergence coming from purely QCD dynamics is additive to the one which we encounter in the YM part. Then, we can renormalize all the UV divergences into the coupling $g, e$ and fields $A_\mu, a_\mu$. From the renormalization procedure at zero temperature, we have obtained the correct beta functions of both QCD and QED in Ref. [43]. Sum of the three parts (26), (27) and (40) may be called the Euler-Heisenberg-Weiss action in QCD+QED at finite temperature. This result can be applied to several systems where strong EM fields and chromo-EM fields coexist at zero and finite temperatures. In the next section, we will show some applications of our effective actions.

III. APPLICATIONS OF EULER-HEISENBERG-WEISS ACTION IN QCD+QED

In this section we will discuss two applications of our results. The first one is the quark pair production in the presence of both EM and chromo-EM fields. We treat the effective action at zero temperature. The second application is to investigate the effects of EM fields on the effective potential for the Polyakov loop at finite temperature. We will discuss the possible implication for the inverse magnetic catalysis.
A. Quark pair production in QCD+QED fields

Let us first discuss quark-antiquark pair production in constant QCD+QED fields as an application of our effective action. For this problem, only the quark part \[40\] is relevant.

In the early stage of relativistic heavy-ion collisions, extremely strong chromo-EM fields and EM fields could coexist. Notice that the strong electric field in addition to the strong magnetic field could be created on event by event basis \[5\]. The strength of the chromo-EM fields is approximately of the order of the saturation scale: \(|g\vec{B}|, |g\vec{E}| \sim Q_s^2\), whereas strengths of EM fields would reach the QCD nonperturbative scale \(|e\vec{E}|, |e\vec{B}| \sim \Lambda_{QCD}^2\) or even exceed it. Under such strong QCD+QED fields, a number of quark-antiquark pairs must be created through the Schwinger mechanism. The pair production rate per unit space-time volume can be obtained from the imaginary part of the quark effective Lagrangian at zero temperature. Taking the zero temperature contribution in Eq. (40), one finds

\[
\mathcal{L}_{\text{quark}} = \frac{S_{\text{quark}}}{d^4x} = \frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{s^3}{s^3} e^{-is(m^2_{qf} - i\delta)} (a_{i,f,s})(b_{i,f,s}) \cot(a_{i,f,s}) \coth(b_{i,f,s}).
\]

(41)

This is the same as the result obtained in Ref. [43]. The imaginary part of the effective Lagrangian thus reads

\[
\Im \mathcal{L}_{\text{quark}} = -\frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{s^3}{s^3} e^{-s\sin(m^2_{qf}s)} \times (a_{i,f,s})(b_{i,f,s}) \cot(a_{i,f,s}) \coth(b_{i,f,s})
\]

\[
= \frac{1}{2i} \frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \left\{ \int_{-\infty}^0 ds \frac{e^{-is(m^2_{qf} + i\delta)}}{s^3} + \int_0^\infty ds \frac{e^{-is(m^2_{qf} - i\delta)}}{s^3} \right\}
\times (a_{i,f,s})(b_{i,f,s}) \cot(a_{i,f,s}) \coth(b_{i,f,s}).
\]

(42)

The integrand has infinitely many poles along the real axis (from \(\cot(a_{i,f,s})\)) and along the imaginary axis (from \(\coth(b_{i,f,s})\)). With a small positive number \(\delta > 0\), the integral contour along the real axis is inclined. Closing the contour in the lower half of the \(s\) plane as depicted in Fig. 2 and picking up the poles lying on the imaginary axis \(s_{\text{poles}} = -in\pi/b_{i,f}\), we find

\[
\Im \mathcal{L}_{\text{quark}} = \frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} a_{i,f} b_{i,f} \sum_{n=1}^\infty \frac{e^{-m^2_{qf} n^2 \pi}}{n} \cot \left( \frac{a_{i,f} n\pi}{b_{i,f}} \right). \]

(43)

By using this expression, we can investigate quark-antiquark pair productions under arbitrary configurations of constant chromo-EM and EM fields. The production rate per unit
space-time volume is given by \( w_{q\bar{q}} = 2\Re m \mathcal{L}_{\text{quark}} \). When we take \( N_c = N_f = 1, Q = 1, g \to 0, B \to 0 \) and replace \( m_q \to m_e \) in Eq. (43), we reproduce the well-known Schwinger formula for the production rate of \( e^+e^- \) pairs in an electric field [27]:

\[
[w_{e^+e^-} = 2\Re m \mathcal{L}_{\text{EH}} = \frac{(eE)^2}{4\pi^3} \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-\frac{m_e^2}{eE} n\pi} ], \tag{44}
\]

as we expected. On the other hand, in the pure chromoelectric field case, we obtain the same formula for quark productions derived by G.C. Nayak [51].

1. Quark pair production in purely electric background

First, we shall consider quark pair productions in purely electric background with vanishing magnetic fields: \( \vec{B}, \vec{B} \to 0 \). In this case, the production rate for \( q\bar{q} \) pairs of flavor \( f \) becomes

\[
w_{q\bar{q}f} = \frac{1}{4\pi^3} \sum_{i=1}^{N_c} \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-\frac{m_{qf}^2}{E} n\pi}, \tag{45}
\]

where \( b_{i,f} = \sqrt{E_i^2} = \sqrt{(g\omega_i)^2 + (eQ_q)^2 E^2 + 2g\omega_i eQ_q E \cos \theta_{\xi E}} \) with \( E = \sqrt{E^2}, \xi = \sqrt{\xi^2} \) and \( \theta_{\xi E} \) being the angle between \( \vec{E} \) and \( \vec{\xi} \). For \( N_c = 3 \), the eigenvalues \( \omega_i \) are given by \( \omega_1 = 1/2, \omega_2 = -1/2 \) and \( \omega_3 = 0 \). Recall that a factor \( g\omega_i \) plays the role of an effective
coupling between the chromo-EM field and quarks (see Eq. (30)). Thus, a quark (or an antiquark) with \( \omega_3 = 0 \) does not interact with the chromo-EM field in this representation. Still, since there is always a coupling with the EM fields, \( q\bar{q} \) production with \( \omega_3 = 0 \) is possible due to electric fields, i.e., \( b_{i=3,f} = |eQ_qE| \neq 0 \).

Let us see the dependences of production rates on the quark mass \( m_q \) and the angle \( \theta_{EE} \). We first consider the case with light quark masses \( m^2_q \ll b_{i,f} \). The left panel of Fig. 3 shows the light (up) quark production rate with \( m_q = 5 \) MeV and \( Q_q = +2/3 \). The chromo-electric field is fixed to \( gE = 1 \) GeV\(^2\) which is a typical value realized in heavy-ion collisions at RHIC and LHC, while we take several values of strength for the \( E^-\) field. The production rate increases with increasing \( E^-\) field, which is an expected behavior of the usual Schwinger mechanism, but it does not show dependence on the angle \( \theta_{EE} \) while \( b_{i,f} \) certainly depends on \( \theta_{EE} \). This unexpected behavior can be understood as follows. When the quark mass is small enough \( m^2_q \ll b_{i,f} \), we can approximate the production rate as

\[
  w_{q\bar{q}} \sim \frac{1}{4\pi^3} \sum_{i=1}^{N_c} b_i^2 \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{1}{4\pi^3} \left\{ \frac{(gE)^2}{2} + N_c(eQ_qE)^2 \right\} \zeta(2),
\]

where \( \zeta(2) = \pi^2/6 \) and \( b_i = \sqrt{(g\omega_i)^2 E^2 + (eQ_q)^2 E^2 + 2g\omega_i eQ_qE \cos \theta_{EE}} \). Notice that the angle dependence in \( b_i \) drops out thanks to the relations \( \sum_{i=1}^{N_c} \omega_i^2 = 1/2 \) and \( \sum_{i=1}^{N_c} \omega_i = 0 \). Therefore, the production rate is independent of the angle \( \theta_{EE} \).

We next discuss the production of heavy quark-antiquark pairs. Since the heavy quark limit just implies that the pair creation does not occur, we consider the case where quark masses are comparable to the background field \( m^2_q \sim b_{i,f} \). This is realized for charm quarks if we again take the typical value of chromo-electric field \( gE = 1 \) GeV\(^2\). For \( m_c = 1.25 \) GeV and \( Q_q = Q_{charm} = +2/3 \), the production rate of a charm quark pair is shown in the right panel of Fig. 3. This time, while the production rate becomes small, one can see a clear dependence on the angle \( \theta_{EE} \). Both effects (small production rate and angle dependence) come from the exponential factor in Eq. (45). In particular when the electric field is parallel (or anti-parallel) to the chromoelectric field, the production rate has a maximum. Since the exponential factor is very sensitive to the change of \( b_{i,f} \), the rate is largely enhanced at \( \theta_{EE} = 0, \pi \). Symmetric shape of the angle dependence with respect to \( \theta_{EE} = \pi/2 \) is not so trivial. Notice that the effective field strengths of the combined field at \( \theta_{EE} = 0 \) and \( \pi \) are not equivalent for a fixed value of \( i \), namely, it is the strongest for the parallel configuration (for \( \omega_i > 0 \))

\[
  b_{i, charm}(\theta_{EE} = 0) = \sqrt{(g\omega_i)^2 E^2 + (eQ_{charm})^2 E^2 + 2g\omega_i eQ_{charm}E}
\]

and the weakest for the
anti-parallel configuration $b_{i,\text{charm}}(\theta_{\mathcal{E}E} = \pi) = \sqrt{(g\omega_i)^2\mathcal{E}^2 + (eQ_{\text{charm}})^2E^2 - 2g\omega_ieQ_{\text{charm}}E}\mathcal{E}$ implying that pair production is most enhanced for the parallel configuration. This is true for any index of $i$ giving a positive eigenvalue $\omega_i > 0$. However, this eigenvalue appears with a partner $\omega_j$ having an opposite sign $\omega_j = -\omega_i$ (for SU(3) we have $\omega_1 = -\omega_2 = 1/2$), and the anti-parallel configuration gives the strongest effective field for the index $j$, $b_{j,\text{charm}}(\theta_{\mathcal{E}E} = \pi) = b_{i,\text{charm}}(\theta_{\mathcal{E}E} = 0)$. Therefore, after summing over all the pairwise modes $i$, we obtain the angle dependence symmetric with respect to $\theta_{\mathcal{E}E} = \pi/2$.

2. Quark pair production in purely chromo-EM background

Next, we investigate quark pair production under chromo-EM fields in the absence of EM fields. Lorentz-invariant quantities $\mathbb{F}_{i,f}^2$ and $\mathbb{F}_{i,f} \cdot \tilde{\mathbb{F}}_{i,f}$ are now explicitly given as (see Eq. (33))

$$\mathbb{F}_{i,f}^2 = 2(g\omega_i)^2(B^2 - \mathcal{E}^2), \quad \mathbb{F}_{i,f} \cdot \tilde{\mathbb{F}}_{i,f} = -4(g\omega_i)^2\mathcal{E}B\cos\theta_{\mathcal{E}B}, \quad (47)$$

where $B = \sqrt{\vec{B}^2}$ and $\theta_{\mathcal{E}B}$ stands for the angle between $\vec{\mathcal{E}}$ and $\vec{B}$. When $\theta_{\mathcal{E}B} = \pm\pi/2$ and $\mathcal{E} > B$, we can move into a system with pure chromoelectric fields with $a_{i,f} = a_i = 0$ and $b_{i,f} = b_i = |g\omega_i|\sqrt{\mathcal{E}^2 - B^2}$ by the Lorentz transformation. Then, the production rate for a
FIG. 4: Light (up) quark production rate as a function of $\theta_{E_{\text{cho}}B_{\text{cho}}}$ which stands for $\theta_{EB}$ with vanishing electromagnetic fields. We take the strength of the chromoelectric field as $gE = 1 \text{ GeV}^2$.

certain flavor of quark becomes

$$2\Im m L_{\text{quark}} = \frac{1}{4\pi^2} \sum_{i=1}^{N_c} b_i^2 \sum_{n=1}^{\infty} \frac{1}{n^2} e^{-\frac{m^2_{q_i} b_i}{n^2 e}},$$

(48)

which decreases as $B$ increases. Furthermore, for $B \geq E$ the production rate vanishes since in this case the system is equivalent to the pure chromo-magnetic field system. When $\theta_{EB} = 0, \pi$ which would be relevant configurations for relativistic heavy-ion collisions, $a_i$ and $b_i$ become $a_i = |g_{\omega_i} B|$, $b_i = |g_{\omega_i} E|$. Then, the production rate reads

$$2\Im m L_{\text{quark}} = \frac{1}{4\pi^2} \sum_{i=1}^{N_c} |g_{\omega_i} B||g_{\omega_i} E| \sum_{n=1}^{\infty} \frac{1}{n} e^{-\frac{m^2_{q_i}}{n^2 e \theta_{EB}} n \pi} \coth \left( \frac{B}{\theta_{EB} n \pi} \right).$$

(49)

This production rate is the same result as obtained in Ref. [52, 53]. It increases as either chromo-electric fields or chromo-magnetic fields increases. Figure 4 shows $\theta_{EB}$-dependence of light quark production rate with a fixed value of the chromo-electric field, $gE = 1 \text{ GeV}^2$. The maxima appear when the chromomagnetic field is parallel (or anti-parallel) to the chromoelectric field.
3. Quark pair production in a glasma with EM fields

Now we shall consider a specific configuration of chromo-EM fields that are relevant for relativistic heavy-ion collisions accompanied by EM fields. Suppose that the chromo-electric field and the chromo-magnetic field are parallel to each other $\vec{B} \parallel \vec{E}$ and that these strengths are approximately equal to the saturation scale: $|g\vec{B}| = |g\vec{E}| = 1 \text{ GeV}^2 \sim Q_s^2$. This configuration of chromo-EM fields is indeed realized at the very early stage of the glasma evolution. Under this condition, we investigate light (up) quark productions. Let us turn on the EM fields. In the heavy-ion collisions, the dominant EM field is the magnetic field perpendicular to the beam direction (equivalent to the direction of the glasma fields). But here we consider the case $|e\vec{B}| \neq 0$ and $|e\vec{E}| = 0$, with arbitrary orientation. Then, the quantities $F_{i,f}^2$, and $\vec{F}_{i,f} \cdot \tilde{\vec{F}}_{i,f}$ read (see Eq. (33))

$$F_{i,f}^2 = 2 \left[ (eQ_q)^2 B^2 + 2 g\omega_i eQ_q B B \cos\theta_{BB} \right],$$

$$\vec{F}_{i,f} \cdot \tilde{\vec{F}}_{i,f} = -4 \left[ (g\omega_i)^2 \mathcal{E} B + g\omega_i eQ_q \mathcal{E} B \cos\theta_{BB} \right],$$

with $B = \sqrt{\bar{B}^2}$. Here we have used the fact that $\cos\theta_{\mathcal{E}B} = \cos\theta_{BB}$. Note that in the case of anti-parallel configuration of $\vec{B}$ and $\vec{E}$, results are the same as those of the parallel case since this changes $\vec{F}_{i,f} \cdot \tilde{\vec{F}}_{i,f} \rightarrow -\vec{F}_{i,f} \cdot \tilde{\vec{F}}_{i,f}$ but it is squared in $a_{i,f}$ and $b_{i,f}$.

Figure 5 shows quark production rate as a function of the angle $\theta_{BB}$ with several strengths of the magnetic field. At the angle relevant for relativistic heavy-ion collisions, $\theta_{BB} = \pi/2$, the production rate slightly decreases with increasing $B$-field. This can be understood from Eq. (43) as follows. In this case, the quantity $a_{i,f} = \frac{1}{2} \sqrt{\sqrt{4(eQ_q)^4 B^4 + 16(g\omega_i)^4 \mathcal{E} B^2 + 2(eQ_q)^2 B^2}}$ (or, $b_{i,f} = \frac{1}{2} \sqrt{\sqrt{4(eQ_q)^4 B^4 + 16(g\omega_i)^4 \mathcal{E} B^2 - 2(eQ_q)^2 B^2}}$) increases (decreases) with increasing $B$, while the product $a_{i,f} b_{i,f} = |\vec{E}_{i,f} \cdot \vec{B}_{i,f}| = (g\omega_i)^2 \mathcal{E} B$ is independent of $B$. Therefore, at $\theta_{BB} = \pi/2$, the quark production rate monotonically decreases due to the exponential factor $\exp\{-m_q^2/b_{i,f}/n\pi\}$. This result is independent of the sign of $\omega_i$.

On the other hand, Fig. 5 shows that the quark production rate increases with increasing $B$ at $\theta_{BB} = 0$, and $\pi$. This can be understood as follows. At $\theta_{BB} = 0, \pi$, the quark production rate reads from Eq. (43),

$$2\Im \mathcal{L}_{\text{quark}} = \frac{1}{4\pi^2} \sum_{i=1}^{N_c} \left| g\omega_i \right| \mathcal{E} B_{i,f} \sum_{n=1}^{\infty} \frac{1}{n} e^{-\frac{m_q^2}{|g\omega_i|\mathcal{E} n\pi}} \coth \left( \frac{B_{i,f}}{|g\omega_i|\mathcal{E} n\pi} \right),$$

(51)
FIG. 5: Light (up) quark production rate in $B$-field as a function of $\theta_{B_{\text{chro}B}}$ which stands for $\theta_{BB}$ with a parallel configuration of $\vec{E}$ and $\vec{B}$. We take strengths of chromoelectromagnetic fields as $gB = gE = 1 \text{ GeV}^2$.

where the strength of the combined magnetic field has been defined as $B_{i,f} = |g_\omega B + eQ_q B|$ for $\theta_{BB} = 0$ whereas $B_{i,f} = |g_\omega B - eQ_q B|$ for $\theta_{BB} = \pi$. This production rate has a similar form with Eq. (49). When the chromo-magnetic field and the magnetic field are (anti-)parallel to each other $\theta_{BB} = 0$ ($\theta_{BB} = \pi$) with $\omega_i > 0$, the production rate increases (decreases) with increasing $B$-field. The opposite behavior happens when $\omega_i < 0$. After summing over all the modes $i$, the production rate at $\theta_{BB} = 0, \pi$ monotonically increases with increasing $B$-field, which can be seen in Fig. 5. Furthermore, we again obtain the angle dependence symmetric with respect to $\theta_{BB} = \pi/2$ in the production rate.

Next we consider the case with $|e\vec{E}| \neq 0$ and $|e\vec{B}| = 0$. In this case, $F_{i,f}^2$ and $F_{i,f} \cdot \bar{F}_{i,f}$ become (see Eq. (33))

$$F_{i,f}^2 = 2 \left[ -(eQ_q)^2 E^2 - 2g_\omega eQ_q E \mathcal{E} E \cos \theta_{EE} \right] ,$$

$$F_{i,f} \cdot \bar{F}_{i,f} = -4 \left[ (g_\omega)^2 \mathcal{E} B + g_\omega eQ_q B \mathcal{E} E \cos \theta_{EE} \right] ,$$

(52)

where $E = \sqrt{\mathcal{E}^2}$. In this expression, we have used $\cos \theta_{BE} = \cos \theta_{EE}$. Again, the results are the same as those of the case where $\vec{B}$ is anti-parallel to $\vec{E}$. Figure 6 shows quark production rate as a function of the angle $\theta_{EE}$ with several values of strength of the electric field. As the electric field increases, the production rate increases for whole angle regions.
FIG. 6: Light (up) quark production rate in $E$-field as a function of $\theta_{E\text{chro}E}$ which stands for $\theta_{E\bar{E}}$ with a parallel configuration of $\vec{E}$ and $\vec{B}$. We take strengths of chromoelectromagnetic fields as $gB = gE = 1 \text{ GeV}^2$.

This can be understood in a similar way as the previous case as follows. At $\theta_{E\bar{E}} = \pi/2$, the factor $a_{i,f} b_{i,f} = |\vec{E}_{i,f} \cdot \vec{B}_{i,f}| = (g\omega_i)^2 \mathcal{E} \mathcal{B}$ is independent of the electric field. As for each factor, $a_{i,f} = \frac{1}{2} \sqrt{4(eQ_q)^4 E_4^4 + 16(g\omega_i)^4 \mathcal{E} \mathcal{B} - 2(eQ_q)^2 E^2}$ decreases as increasing electric field, while $b_{i,f} = \frac{1}{2} \sqrt{4(eQ_q)^4 E_4^4 + 16(g\omega_i)^4 \mathcal{E} \mathcal{B} + 2(eQ_q)^2 E^2}$ increase. These behaviors are opposite to the previous case with $|e\vec{E}| = 0$ and $|e\vec{B}| \neq 0$, and thus the production rate at $\theta = \pi/2$ monotonically increases. At $\theta_{E\bar{E}} = 0, \pi$, the quark production rate (43) can be rewritten as

$$2 \Im m \mathcal{L}_{\text{quark}} = \frac{1}{4\pi^2} \sum_{i=1}^{N_c} \mathcal{E}_{i,f} |g\omega_i| \mathcal{B} \sum_{n=1}^{\infty} \frac{1}{n} e^{-\frac{m^2}{g\omega_i \mathcal{E}_{i,f} n \pi}} \coth \left( \frac{|g\omega_i| \mathcal{B} n \pi}{\mathcal{E}_{i,f} n \pi} \right),$$

where the strength of the combined electric field has been defined as $\mathcal{E}_{i,f} = |g\omega_i E + eQ_q E|$ for $\theta_{E\bar{E}} = 0$ and $\mathcal{E}_{i,f} = |g\omega_i E - eQ_q E|$ for $\theta_{E\bar{E}} = \pi$. This production rate is the same form as Eq. (51) and thus enhanced as the strength of electric field $E$ increases.

From these results, we expect that strong EM fields created in the early state of relativistic heavy ion collisions would largely affect quark productions from a glasma (chromo-EM fields) depending on the field configurations and thus possibly influence the formation of QGP.
B. Weiss potential with electromagnetic fields

In this subsection, we will investigate the effects of EM fields on the confinement-deconfinement phase transition by using the effective potential of the Polyakov loop in the presence of EM fields.

Prior to going into the details, let us briefly explain the effective potential without external fields being imposed. The one-loop calculation at finite temperature in SU(2) gauge theory and in massless fermion limit yields the effective potential for the temporal component of the gauge field \( C = \frac{g A_4}{2\pi T} \) as \([44, 45]\)

\[
V^{\text{Weiss}}[C] = V^{\text{Weiss}}_{\text{YM}}[C] + V^{\text{Weiss}}_{\text{quark}}[C], \tag{54}
\]

where the YM and quark parts are respectively given by

\[
V^{\text{Weiss}}_{\text{YM}}[C] = -\frac{3}{45} \pi^2 T^4 + \frac{3}{4} \pi^2 T^4 C^2 (1 - C)^2, \tag{55}
\]

\[
V^{\text{Weiss}}_{\text{quark}}[C] = -\frac{7}{90} \pi^2 T^4 + \frac{1}{6} \pi^2 T^4 C^2 (2 - C^2). \tag{56}
\]

This result is called the Weiss potential. In Fig. 7, we show the Weiss potential \( V^{\text{Weiss}}[C] \) and its breakdown. We see that in the YM part the minima appear at \( C = 0 \) and \( C = 1 \) reflecting the center symmetry \( C \to C + 1 \) in SU(2). Thus, selecting one of the two minima spontaneously breaks the center symmetry. Since the system should be in the deconfined phase in high temperature region where a perturbative approach becomes valid, this result seems to be natural. The quark part of the effective potential explicitly breaks the center symmetry, and \( C = 0 \) and \( C = 1 \) are no longer degenerate. In the presence of the quark part, \( C = 0 \) is favored, which corresponds to the deconfined phase. We are now going to investigate how this picture is modified by the presence of external EM fields.

Now we come back to our most general results \((26), (27)\) and \((40)\). Taking vanishing limit of the chromo-EM fields, \( \vec{E}, \vec{B} \to 0 \), but keeping the Polyakov loop \( \bar{A}_4 \) and EM fields...
FIG. 7: Weiss potential as a function of $C$. Constant terms which are independent of $C$ are subtracted.

nonzero in the results, we obtain the effective potential

$$V_{\text{eff}}[\bar{A}_4, E, B] = -\frac{S_{\text{eff}}}{\int dx^4}$$

$$= \frac{1}{32\pi^2} \sum_{n=1}^{N_f^2-1} \int_0^\infty ds \frac{1}{s^3} \{4 - 2\} \sum_{n=1}^\infty e^{\frac{n^2}{4T^2}} \cos \left( \frac{g\nu_{\bar{A}_4}}{T} n \right)$$

$$- \frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{s}{s^3} e^{-im_{ij}^f s} (a_{ij}^f)(b_{ij}^f) \cot(a_{ij}^f) \coth(b_{ij}^f)$$

$$\times 2 \sum_{n=1}^\infty (-1)^n e^{\frac{i}{4T^2} h_f(s)n^2} \cos \left( \frac{g\omega_i\bar{A}_4}{T} n \right).$$

(57)

where $a_f$ and $b_f$ are just given by the EM fields as

$$a_f = \frac{1}{2} \sqrt{\sqrt{F_f^4 + (F_f \cdot \bar{F}_f)^2 + F_{ij}^2}}, \quad b_f = \frac{1}{2} \sqrt{\sqrt{F_f^4 + (F_f \cdot \bar{F}_f)^2 - F_{ij}^2}},$$

(58)

with $F_f^2 = 2(eQ_{q_f})^2(\vec{B}^2 - \vec{E}^2)$ and $F_f \cdot \bar{F}_f = -4(eQ_{q_f})^2 \vec{E} \cdot \vec{B}$. The factor $h_f(s)$ is given by

$$h_f(s) = \frac{b_f^2 - c_f^2}{a_f^2 + b_f^2} a_f \cot(a_{ij}^f) + \frac{a_f^2 + c_f^2}{a_f^2 + b_f^2} b_f \coth(b_{ij}^f),$$

(59)

where $c_f^2 = (u_\alpha F_f^{\alpha\mu})(u_\beta F_{ij}^{\beta\mu}) = (eQ_{q_f})^2 E^2$ with $u_\mu = (1, 0, 0, 0)$. Here we have subtracted divergences appearing in the zero temperature contribution, which are independent of $\bar{A}_4$.
1. Weiss potential in magnetic fields

Consider a pure magnetic field case, \( \vec{E} \to 0, \vec{B} \neq 0 \). Then, the effective potential reads,

\[
V_{\text{eff}}[\bar{A}_4, B] = \frac{1}{32\pi^2} \sum_{h=1}^{N_c^2 - 1} \int_0^\infty ds \frac{4s}{s^3} \{4 - 2\} 2 \sum_{n=1}^\infty e^{i\frac{n^2}{4T^2}s} \cos \left( \frac{g v_h \bar{A}_4}{T} n \right)
\]

\[
- \frac{1}{8\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{e^{-im^2_f \sigma}}{s^3} (e|Q_{q_f}|B_s) \cot(e|Q_{q_f}|B_s)
\times 2 \sum_{n=1}^\infty (-1)^n e^{i\frac{n^2}{4T^2}s} \cos \left( \frac{g \omega_i \bar{A}_4}{T} n \right).
\]

(60)

We rewrite the proper time integrals in two steps. Recall that the integral should be defined with an infinitesimally small number \( \delta \) which makes the contour slightly inclined to avoid the poles along the real axis (in the second term). Then we can easily change the contour from \([0, \infty]\) along the real axis to \([-i\infty, 0]\) along the imaginary axis (the Wick rotation) since there is no pole along the imaginary axis. Finally, by renaming the variable \( s \) by \(-i\sigma\), we obtain the following representation with integrals defined by real functions:

\[
V_{\text{eff}}[\bar{A}_4, B] = -\frac{1}{8\pi^2} \sum_{h=1}^{N_c^2 - 1} \int_0^\infty d\sigma \frac{d\sigma}{\sigma^3} \sum_{n=1}^\infty e^{-\frac{n^2}{T^2}\sigma} \cos \left( \frac{g v_h \bar{A}_4}{T} n \right)
\]

\[
+ \frac{1}{4\pi^2} \sum_{i=1}^{N_c} \sum_{f=1}^{N_f} \int_0^\infty d\sigma \frac{e^{-m^2_f \sigma}}{\sigma^2} (e|Q_{q_f}|B) \cot(e|Q_{q_f}|B\sigma)
\times \sum_{n=1}^\infty (-1)^n e^{-\frac{n^2}{T^2}\sigma} \cos \left( \frac{g \omega_i \bar{A}_4}{T} n \right)
\]

(61)

For simplicity, we shall restrict ourselves to \( N_c = 2 \), which provides us with all the essential features of the perturbative effective potential in the presence of EM fields. In this case, the eigenvalues \( \omega_i \) and \( v_h \) are simply given by \( \omega_i = \pm 1/2 \) and \( v_h = 0, \pm 1 \). The effective potential reads,

\[
V_{\text{eff}}[C, B] = -\frac{3}{45} \pi^2 T^4 + \frac{3}{4} \pi^2 T^4 C^2 (1 - C)^2
\]

\[
+ \frac{1}{2\pi^2} \sum_{f=1}^{N_f} \int_0^\infty d\sigma \frac{e^{-m^2_f \sigma}}{\sigma^2} (e|Q_{q_f}|B) \cot(e|Q_{q_f}|B\sigma) \sum_{n=1}^\infty (-1)^n e^{-\frac{n^2}{T^2}\sigma} \cos (C\pi n).
\]

(62)

The first line does not depend on the magnetic field and corresponds to the YM part \( V_{\text{YM}} \). This is nothing but the Weiss potential \([55][44]\). The second line corresponds to the quark part \( V_{\text{quark}} \), and the integral and summation over \( n \) can be easily performed numerically.
From now on, we further restrict ourselves to the one flavor $f = 1$ with the electric charge $Q_{q_f} = 1$ for simplicity. Now, analytic expressions are available in two limiting cases: One is the $B \to 0$ and $m_q \to 0$ limit, where the quark part of the effective potential is reduced to that of the Weiss potential [55]:

$$V_{\text{quark}}[C] = -\frac{7}{90} \pi^2 T^4 + \frac{1}{6} \pi^2 T^4 C^2 (2 - C^2) = V_{\text{Weiss}}^{\text{quark}}[C].$$  \hspace{1cm} (63)

The other is the strong magnetic field limit: $eB \gg m_q^2$, where the quark part can be written as

$$V_{\text{quark}}[C, B] = -2 \frac{(eB)^2 T^2}{\pi^2} \left\{ \frac{\pi^2}{12} - \frac{(C\pi)^2}{4} \right\}. \hspace{1cm} (64)$$

Figure 8 shows magnetic field dependence of the quark part of the effective potential which is given by the second line of Eq. (63). Here, we show only one flavor contribution with $x = m_q^2 / T^2 = 0.5$. An important observation is that as the magnetic field increases, the explicit breaking of the center symmetry is enhanced, and $C = 0$ (deconfined phase) becomes more stable. This is qualitatively consistent with the analytic representation at strong magnetic fields (see Eq. (64)) in that the potential value at $C = 0$ becomes more negative and the rising behavior becomes steeper with increasing magnetic field. The enhancement of the center symmetry breaking effects due to increasing magnetic field indicates that the quark loop interacting with magnetic fields can be one of the important sources for reducing the (pseudo-)critical temperature $T_c$ of confinement-deconfinement phase transition, as observed in recent lattice QCD simulations [19]. In the last part of this subsection, we will see within a phenomenological model that this is indeed the case.

2. Weiss potential in electric fields

In the case of a pure electric field, $\vec{B} \to 0$ and $\vec{E} \neq 0$, the situation is a bit subtle. The effective potential of the quark part can be written as

$$V_{\text{quark}}[\vec{A}_4, E] = -\frac{1}{2\pi^2} \sum_{f=1}^{N_f} \int_0^\infty ds \frac{d^3 e^{-im_{q_f}s}}{s^3} \left( e|Q_{q_f}|Es \right) \coth \left( e|Q_{q_f}|Es \right) \cos \left( \frac{g\vec{A}_4}{2T} n \right). \hspace{1cm} (65)$$

Note that we can not reach this result from Eq. (60) by replacing $B$ by $iE$, unlike the zero temperature contribution. This is due to the form of the factor $h_f(s) = \cdots$
FIG. 8: Quark part of the effective potential as a function of $C$ for several values of magnetic fields. $x$ and $y$ are given as $x = m^2_q/T^2$ and $y = eB/T^2$ respectively.

$(e|Q_q|Es)\coth(e|Q_q|Es)$ in the exponential. Because of this factor, the full calculation (even numerical evaluation) is rather difficult. Furthermore, since there are singularities (poles) on the imaginary axis, we cannot perform the Wick rotation of the proper time $s$, unlike the Weiss potential in magnetic fields. To avoid these difficulties, we expand the effective potential with respect to the electric field. Using $x \coth x \sim 1 + x^2/3 \cdots$, we get

\[
V_{\text{quark}}[\bar{A}_4, E] = -\frac{1}{2\pi^2} \sum_{f=1}^{N_f} \int_0^\infty \frac{ds}{s^3} e^{-im^2_q s} \sum_{n=1}^\infty (-1)^n e^{i\frac{n^2}{4T^2}s} \cos \left( \frac{g\bar{A}_4}{2T}n \right) \\
- \frac{1}{6\pi^2} \sum_{f=1}^{N_f} (e|Q_q|E)^2 \int_0^\infty \frac{ds}{s} e^{-im^2_q s} \sum_{n=1}^\infty (-1)^n e^{i\frac{n^2}{4T^2}s} \left( 1 + \frac{n^2}{4T^2s} \right) \cos \left( \frac{g\bar{A}_4}{2T}n \right) \\
+ O(E^4). \tag{66}
\]

At this stage, we can perform the Wick rotation for the proper time $s$. Then, the effective potential reads,

\[
V_{\text{quark}}[C, E] = \frac{1}{2\pi^2} \sum_{f=1}^{N_f} \int_0^\infty \frac{d\sigma}{\sigma^3} e^{-m^2_q \sigma} \sum_{n=1}^\infty (-1)^n e^{-\frac{n^2}{4T^2\sigma}} \cos (C\pi n) \\
- \frac{1}{6\pi^2} \sum_{f=1}^{N_f} (e|Q_q|E)^2 \int_0^\infty \frac{d\sigma}{\sigma} e^{-m^2_q \sigma} \sum_{n=1}^\infty (-1)^n e^{-\frac{n^2}{4T^2\sigma}} \left( 1 - \frac{n^2}{4T^2\sigma} \right) \cos (C\pi n) \\
+ O(E^4). \tag{67}
\]
FIG. 9: Quark part of the effective potential as a function of \( C \) for several values of electric fields. \( x \) and \( y \) are given as \( x = m_q^2/T^2 \) and \( y = eE/T^2 \) respectively.

The systematic expansion with respect to \( E \)-field is possible, and the integral and sum can be performed numerically at each order.

In Fig. 9 we show the electric field dependence of the quark part of the effective potential. From this figure, we see that the electric field decreases the explicit breaking of the center symmetry. This is completely opposite to the \( B \)-dependence of the effective potential. Thus, we expect that \( T_c \) increases with increasing \( E \)-field and approaches the pure YM’s one.

3. Phenomenological analysis on \( T_c(B) \)

We have seen that imposing magnetic fields enhances the explicit breaking of the center symmetry. What we have evaluated is a perturbative contribution (in the sense that we assume that the coupling is small enough) and thus we discussed how the Weiss potential (that is also evaluated in a perturbative framework) is modified in the presence of the EM fields. Within this perturbative calculation, we are not able to approach the region where phase transition will take place. Indeed, even if the quark part of the effective potential depends on the magnetic fields \( V_{\text{quark}}[C, B] \), the total effective potential \( V_{\text{eff}}[C, B] = V_{\text{YM}}[C] + V_{\text{quark}}[C, B] \) selects the center broken state \( C = 0 \) and thus confinement-deconfinement transition never occurs within this perturbative framework. However, recall that the magnetic field can affect
on the effective potential of the Polyakov loop only through the quark loop at leading order. Therefore, we expect that even the perturbative evaluation of the quark part $V_{\text{quark}}[C, B]$ can make sense if combined with some nonperturbative effective potential $V_{\text{nonpert}}[C]$ for study of the effects of magnetic fields on the phase transition. Here we discuss this is indeed the case.

Let us introduce a simple model of a gluonic potential reproducing confinement-deconfinement phase transition,

$$U[C] = -\frac{1}{2}a(T)\Phi^2 + b(T) \ln \left[1 - 6\Phi^2 + 8\Phi^3 - 3\Phi^4\right]$$

with

$$a(T) = a_0 + a_1(T_0/T) + a_2(T_0/T)^2, \quad b(T) = b_3(T_0/T)^3.$$  (69)

Now, we consider $N_c = 3$ case. Here the parameters are $a_0 = 3.51$, $a_1 = -2.47$, $a_2 = 15.2$, $b_3 = -1.75$ and $T_0 = 270$ MeV, which are fixed to reproduce the quenched lattice QCD results [54]. Combining this gluonic potential with $V_{\text{quark}}[C, B]$, we can study how the temperature dependence of the Polyakov loop changes with magnetic fields. Notice that the quark part of the perturbative effective potential $V_{\text{quark}}[C, B]$ with $N_c = 3$ is the same as the one with $N_c = 2$ since the quark with $\omega_3 = 0$ does not contribute to the potential. Therefore, we can use the same potential evaluated in the second line of Eq. (63). The result is shown in Fig. 10. In this analysis, we have used $\omega_i = \pm 1/2, 0$ and a constituent quark mass $m_q = 350$ MeV. Thanks to the explicit center symmetry breaking, the Polyakov loop increases with increasing $B$-field, in particular below the phase transition temperature, which eventually brings about decreasing pseudo-critical temperature $T_c(B) < T_c(B = 0)$. This result is very encouraging, but obviously we need to couple quark dynamics to the gluon dynamics for understanding the effects of magnetic fields on the actual phase transition.

Very recently, the inverse magnetic catalysis of the chiral sector, namely decrease of the critical temperature of chiral phase transition has been reproduced from functional approaches including the Dyson-Schwinger equations and the functional renormalization group [24, 25]. Once the inverse magnetic catalysis of the chiral sector occurs, dynamical quark masses decrease with increasing magnetic field around $T_c$. Then, the quark loop contribution is enhanced, and thus the effect of the explicit center symmetry breaking becomes larger. Therefore, the inverse magnetic catalysis of chiral sector would support the decreasing of $T_c$ of confinement-deconfinement phase transition through the quark loop.
FIG. 10: Temperature dependence of the Polyakov loop for different values of magnetic fields.

IV. SUMMARY AND CONCLUSION

In the present paper, we analytically derived the Euler-Heisenberg action for QCD+QED in the presence of the Polyakov loop, called the Euler-Heisenberg-Weiss action, by using the Schwinger’s proper time method. The effective action contains EM-fields and chromo-EM fields as well as the Polyakov loop in a nonlinear form and reproduces the known one-loop effective actions for QED, QCD, QCD+QED and also the Weiss potential for the Polyakov loop in appropriate limits.

As an application of our effective action, we investigated quark pair productions under strong EM fields and chromo-EM fields. Using the effective action of the quark part at zero temperature, we derived the formula describing the quark pair production rate in arbitrary configurations of the QCD fields and QED fields. In particular configurations, EM-fields enhance the quark pair productions induced by choromo-EM fields. This indicates that strong EM-fields created in relativistic heavy-ion collisions would largely affect quark-antiquark pair productions from a glasma and thus could give sizable contributions to the formation of QGP.

We also studied the perturbative effective action of the Polyakov loop in the presence of strong EM-fields. We found that the magnetic (electric) field enhances (reduces) the explicit center symmetry breaking through the quark loop. This indicates that the Polyakov
loop increases as the magnetic field increases and thus the (pseudo-)critical temperature of confinement-deconfinement phase transition decreases. In contrast, the electric field would raise the critical temperature. In order to demonstrate this, we combined the quark part of our perturbative effective potential with a simple model which can reproduce the confinement-deconfinement phase transition. The resultant Polyakov loop indeed increases with increasing $B$-field, and then (pseudo-)critical temperature decreases. This result is consistent with recent lattice data. As a future work, we will extend our work to further non-perturbative analyses in terms of functional approaches. The inclusion of chiral sector (quark-quark interaction mediated by gluons) will be also an important ingredient in the future work.
