Abstract. The Kohn variational principle and the hyperspherical harmonic technique are applied to study $p-^3$He elastic scattering at low energies. Preliminary results obtained using several interaction models are reported. The calculations are compared to a recent phase shift analysis performed at the Triangle University Nuclear Laboratory and to the available experimental data. Using a three-nucleon interaction derived from chiral perturbation theory at $N^3$LO, we have found a noticeable reduction of the discrepancy observed for the $A_p$ observable.

1 Introduction

The four nucleon system has been object of intense studies in recent years. In first place, this system is particularly interesting as a “theoretical laboratory” to test the accuracy of our present knowledge of the nucleon-nucleon (NN) and three nucleon (3N) interactions. In particular, the effect of (i) the NN P-wave and of (ii) the 3N force are believed to be larger than in the $A = 2$ or 3 systems. Moreover, it is the simplest system where the 3N interaction in channels of total isospin $T = 3/2$ can be studied. In second place, there is a number of reactions involving four nucleons which are of extreme importance for astrophysics, energy production, and studies of fundamental symmetries. As an example, reactions like $d + d \rightarrow ^4\text{He} + \gamma$ or $p + ^3\text{He} \rightarrow ^4\text{He} + \nu_e + e^-$ (the hep process) play important roles in solar models and in the theory of big-bang nucleosynthesis.

Nowadays, the four-nucleon bound state problem can be numerically solved with good accuracy. For example, in Ref. [1] the binding energies and other properties of the $a$-particle were studied using the AV8$^*$ [2] NN interaction; several different techniques produced results in very close agreement with each other (at the level of less than 1%). More recently, the same agreement has also been obtained considering different realistic NN+3N force models [3-5,6].

In recent years, there has also been a rapid advance in solving the four nucleon scattering problem with realistic Hamiltonians. Accurate calculations of four-body scattering observables have been achieved in the framework of the Faddeev-Yakubovsky (FY) equations [7,8,9], solved in momentum space, where the long-range Coulomb interaction is treated using the screening-renormalization method [10,11]. Also solutions of the FY equations in configuration space [12,13,14] and several calculations using the resonating group model [15,16,17,18] were reported. Calculations of scattering observables using the Green Function Monte Carlo method are also underway [19].

In this contribution, the four-body scattering problem is solved using the Kohn variational method and expanding the internal part of the wave function in terms of the hyperspherical harmonic (HH) functions (for a review, see Ref. [20]). Previous applications of this method [21-23] were limited to consider only local potentials, as the Argonne $v_{18}$ (AV18) [23] NN potential. Recently, the HH method has been extended to treat also non-local potentials, given either in coordinate- or momentum-space [24,25]. A first application of the HH method to compute $n-^3\text{H}$ elastic observables with non-local potentials was reported in Ref. [26]. Here, we report the first results obtained for $p-^3\text{He}$. The potentials used in this paper are the I-N3LO model by Entem and Machleidt [27], with cutoff $\Lambda = 500$ MeV, and the AV18. The I-N3LO potential has been derived using an effective field theory approach and the chiral perturbation theory up to next-to-next-to-next-to-leading order. We have also performed calculations by adding to the I-N3LO potential a 3N interaction, derived at next-to-next-to-leading order in Refs. [28,29] (I-N3LO/N-N2LO interaction model). The two free parameters in this N-N2LO 3N potential have been chosen from the combination that reproduces the $A = 3, 4$ binding energies [29]. The development of a 3N interaction including N3LO contribution is still under progress [30]. Finally, we have also considered the Urbana IX (UIX) 3N potential [31], which has been used together with the AV18 potential (AV18/UIX interaction model).

The four-body studies performed so far have evidenced several discrepancies between the theoretical predictions and experimental data. Let us consider first $n-^3\text{H}$ elastic scattering. Calculations based on NN interaction models only disagree [21,22,32,33] rather sizably with the measured total cross section [33], both at zero energy and in the “peak” region ($E_n \approx 3.5$ MeV). Such an
The HH Technique for Scattering States

In the following, we consider a $p-^{3}\text{He}$ scattering state with total angular momentum quantum number $JJ_z$, and parity $\pi$ (the dependence on the wave function and other quantites on $JJ_z, \pi$ will be understood in the following). The wave function $\Psi_{i+3}^{LS}$ describing the two particles with incoming relative orbital angular momentum $L$ and channel spin $S$ ($S=0, 1$) can be written as

$$\Psi_{i+3}^{LS} = \Psi_{C}^{LS} + \Psi_{A}^{LS},$$

where the part $\Psi_{C}^{LS}$ vanishes in the limit of large intercluster separations, and hence describes the system in the region where the particles are close to each other and their mutual interactions are strong. On the other hand, $\Psi_{A}^{LS}$ describes the relative motion of the two clusters in the asymptotic regions, where the $p-^{3}\text{He}$ interaction is negligible (except for the long-range Coulomb interaction). In the asymptotic region the wave functions $\Psi_{A}^{LS}$ reduces to $\Psi_{A}^{LS}$, which must therefore be the appropriate asymptotic solution of the Schrödinger equation. $\Psi_{A}^{LS}$ can be decomposed as a linear combination of the following functions

$$\Omega_{LS}^{i} = D_{3+1} \sum_{l=1}^{4} \left[ Y_l(y_i) \right] \left[ \phi_s(ijk) \otimes s13 \right]_{J_f} \times \left( f_l(y_i) G_l(q_y, q_y) \pm F_l(q_y, q_y) \right),$$

where $y_i$ is the distance between the proton (particle $i$) and $^{3}\text{He}$ (particles $ijk$), $q$ is the magnitude of the relative momentum between the two clusters, $s$ the spin state of particle $i$, and $\phi_s$ is the $^{3}\text{He}$ wave function. The total kinetic energy $T_{c.m.}$ in the center of mass (c.m.) system and the proton kinetic energy $E_p$ in the laboratory system are

$$T_{c.m.} = \frac{q^2}{2\mu}, \quad E_p = \frac{4}{3} T_{c.m.},$$

where $\mu = (3/4)M_N$ is the reduced mass of the system ($M_N$ is the nucleon mass). Moreover, $F_l$ and $G_l$ are the regular and irregular Coulomb function, respectively, with $\eta = 2\mu c^2/q$, and $D_{3+1}$ is a normalizing factor defined to be

$$D_{3+1} = \frac{\sqrt{\frac{3}{2}}}{} \kappa_{3+1} = \sqrt{\frac{3}{2}}.$$
\[ x_{2p} = \sqrt{\frac{4}{3}} \left( r_i + \frac{r_j + r_l}{2} \right), \]
\[ x_{3p} = r_j - r_i, \]
where \( p \) specifies a given permutation corresponding to the order \( i, j, k \) and \( l \) of the particles. By definition, the permutation \( p = 1 \) is chosen to correspond to the order 1, 2, 3 and 4.

For a given choice of the Jacobi vectors, the hyperangular coordinates are given by the so-called hyperradius \( \rho \), defined by
\[ \rho = \left( x_{2p}^2 + x_{3p}^2 + x_{3p}^2 \right)^{1/2}, \quad \text{(independent of } p), \] and by a set of angular variables which in the Zernike and Brinkman [43,44] representation are (i) the polar angles \( \hat{x}_{ip} \equiv (\theta_{ip}, \phi_{ip}) \) of each Jacobi vector, and (ii) the two additional “hyperspherical” angles \( \varphi_{2p} \) and \( \varphi_{3p} \) defined as
\[ \cos \phi_{2p} = \frac{x_{2p}}{\sqrt{x_{2p}^2 + x_{3p}^2}}, \quad \cos \phi_{3p} = \frac{x_{3p}}{\sqrt{x_{2p}^2 + x_{3p}^2}}, \]
where \( x_{jp} \) is the modulus of the Jacobi vector \( x_j \). The set of angular variables \( \chi_{1p}, \hat{x}_{2p}, \hat{x}_{3p}, \phi_{2p}, \) and \( \phi_{3p} \) is denoted hereafter as \( \Omega_p \). The expression of a generic HH function is
\[ H_{\ell_1, \ell_2, \ell_3, \ell_4, n_1}^{\Lambda, \Sigma, \mu}(\Omega_p) = \left[ N_{\ell_1, \ell_2, \ell_3, \ell_4}^{\Lambda, \Sigma, \mu} \left( \frac{2}{\sqrt{2}} Y_{\ell_1, \ell_2}(\hat{x}_{1p}) Y_{\ell_3, \ell_4}(\hat{x}_{2p}) \right)_{L_2} \right] \]
\[ \times \sin \ell_1 \ell_3 \cos \ell_1 \ell_3 \sin \ell_2 \ell_4 \cos \ell_2 \ell_4 \sin \ell_1 \ell_3 \ell_4 \cos \ell_1 \ell_3 \ell_4 \]
\[ \times F_n^{\ell_1 \ell_3 \ell_4 \ell_1 \ell_3 \ell_4} \cos \phi_{2p} \phi_{3p} \cos \phi_{2p} \phi_{3p} \]
\[ \left( \cos \phi_{2p} \phi_{3p} \right), \]
where \( F_n^{\ell_1 \ell_3 \ell_4 \ell_1 \ell_3 \ell_4} \) are Jacobi polynomials and the coefficients \( N_{\ell_1, \ell_2, \ell_3, \ell_4}^{\Lambda, \Sigma, \mu} \) are the first-order normalized functions. The quantity \( K = \ell_1 + \ell_2 + \ell_3 + 2(n_2 + n_3) \) is the so-called grand angular quantum number. The HH functions are the eigenfunctions of the hyperangular part of the kinetic energy operator. Another important property of the HH functions is that \( \rho^{(K)} H_{\ell_1, \ell_2, \ell_3, \ell_4, n_1}^{\Lambda, \Sigma, \mu}(\Omega_p) \) are homogeneous polynomials of the particle coordinates of degree \( \Lambda \).

A set of antisymmetrical hyperangular–spin–isospin states of grand angular quantum number \( K \), total orbital angular momentum \( \Lambda \), total spin \( \Sigma \), and total isospin \( T \) for the given values of total angular momentum \( J \) and parity \( \pi \) can be constructed as follows:
\[ \psi_{\mu}^{\Lambda, \Sigma, T}(i, j, k, l) = \sum_{p=1}^{12} \phi_{\mu}^{(K)}(i, j, k, l), \]
where the sum is over the 12 even permutations \( p = 1, 2, 3, \ldots, 12 \) and \( \phi_{\mu}^{(K)}(i, j, k, l) \) is a "hyperradial" function of the HH state \( \psi_{\mu}^{\Lambda, \Sigma, T}(i, j, k, l) \) defined in Eq. (10), and \( s_1 \) \((s_2)\) denotes the spin (isospin) function of particle \( i \). The total orbital angular momentum \( \Lambda \) of the HH function is coupled to the total spin \( \Sigma \) to give the total angular momentum \( J J_{\pi}, \) whereas \( \pi = (1 - 1)^{\ell_1 + \ell_2 + \ell_3} \). The quantum number \( T \) specifies the total isospin of the state. The integer index \( \mu \) labels the possible choices of hyperangular, spin and isospin quantum numbers, namely
\[ \mu = \{ \ell_1, \ell_2, \ell_3, L_2, n_2, n_3, S_a, S_b, T_a, T_b \}, \]
which is fulfilled when the condition
\[ \ell_3 + S_a + T_a = \text{odd}, \]
is satisfied.

The number \( M_{\Lambda, \Sigma, T} \) of antisymmetrical functions \( \psi_{\mu}^{\Lambda, \Sigma, T} \) having given values of \( K, \Lambda, \Sigma, \) and \( T \) but different combinations of quantum numbers \( \mu \) (see Eq. (13)) is in general very large. In addition to the degeneracy of the HH basis, the four spins (isospins) can be coupled in different ways to \( \Sigma (T) \). However, many of the states \( \psi_{\mu}^{\Lambda, \Sigma, T} \), \( \mu = 1, \ldots, M_{\Lambda, \Sigma, T} \) are linearly dependent between themselves. In the expansion of \( \psi_{\mu}^{\Lambda, \Sigma, T} \) \( S_\Lambda S_T \) is necessary to include only the subset of linearly independent states, whose number is fortunately noticeably smaller than the corresponding value of \( M_{\Lambda, \Sigma, T} \).

The internal part of the wave function can be finally written as
\[ \psi_{\alpha}^{S} = \sum_{\alpha_{\Lambda, \Sigma, T}} u_{\alpha_{\Lambda, \Sigma, T}}^{S}() \psi_{\mu}^{\Lambda, \Sigma, T} \]
where the sum is restricted only to the linearly independent functions. We have found convenient to expand the "hyperradial" functions \( u_{\alpha_{\Lambda, \Sigma, T}}^{S}() \) in a complete set of functions, namely
\[ u_{\alpha_{\Lambda, \Sigma, T}}^{S}() = \sum_{m=0}^{M-1} c_{\alpha_{\Lambda, \Sigma, T},m} g_m(), \]
and we have chosen
\[ g_m() = \sqrt{\frac{m!}{(m + 8)!}} L_{\gamma}^{(8)}() e^{-\gamma^2}, \]
where \( L_{\gamma}^{(8)}() \) are Laguerre polynomials [45] and \( \gamma \) is a parameter to be variationally optimized.
The main problem is the computation of the matrix elements of the Hamiltonian. This task is considerably simplified in two steps. First, by using the following transformation

$$\phi_{\mu}^{K\alpha T}(i,j;k,l) = \sum_{p} a_{\mu p}^{K\alpha T}(p) \phi_{\mu p}^{K\alpha T}(1,2;3;4), \quad (19)$$

where the coefficients $a_{\mu p}^{K\alpha T}(p)$ have been obtained using the techniques described in Ref. [46]. Second, by “projecting” the asymptotic states over a complete set of angular-spin-isospin states, constructed in terms of the Jacobi vectors $x_\ell$ corresponding to the particle order 1, 2, 3, 4, as follows:

$$\Omega_{LS}^\alpha = \sum_{\alpha} F_{\alpha}^{LS}(x_1, x_2, x_3) Y_\alpha(\hat{x}_1, \hat{x}_2, \hat{x}_3), \quad (20)$$

where

$$Y_\alpha(\hat{x}_1, \hat{x}_2, \hat{x}_3) = \left\{ \begin{array}{l}
\left\{ Y_{\ell_1}(\hat{x}_1) | x_1, x_2 \right\}_J J_1 \left\{ Y_{\ell_2}(\hat{x}_2) | x_3 \right\}_J J_2 \\
Y_{\ell_3}(\hat{x}_3) | x_4 \right\}_J J_3 \end{array} \right\}_{J_J}\left( T_{12}^{34} \right) \left( T_{23}^{14} \right) \left( T_{13}^{24} \right) \left( T_{12}^{34} \right) \left( T_{23}^{14} \right) \left( T_{13}^{24} \right) \left( T_{12}^{34} \right), \quad (21)$$

and $\alpha = (\ell_1, \ell_2, \ell_3, j_1, j_2, j_3, S_2, T_2, T_3, T)$. Note that due to the antisymmetry of the wave function, we must have $\ell_1 + S_2 + T_2 = \text{odd}$. This “partial wave expansion” is performed to include all states $\alpha$ such that $\ell_\ell \leq \ell_{\text{max}}$. The functions $F_{\alpha}^{LS}$ can be obtained very accurately by direct integration

$$F_{\alpha}^{LS}(x_1, x_2, x_3) = \int d\hat{x}_1 d\hat{x}_2 d\hat{x}_3 \left[ Y_{\alpha}(\hat{x}_1, \hat{x}_2, \hat{x}_3) \right]^* \Omega_{LS}^\alpha, \quad (22)$$

using Gauss quadrature techniques.

Finally, the wave function using the transformation [19] and the partial wave expansion given above can be rewritten as

$$\psi_{LS}^{13} = \sum_{\alpha} F_{\alpha}^{LS}(x_1, x_2, x_3) Y_\alpha(\hat{x}_1, \hat{x}_2, \hat{x}_3), \quad (23)$$

where $F$ is a combination of Jacobi polynomials of the hyperspherical functions $g_\mu(p)$, and functions $F_\alpha$ coming from the asymptotic parts. Then, the matrix elements of a two-body potential can be evaluated as follows:

$$\langle \psi_{LS}^{13} | V(i,j) | \psi_{LS}^{13} \rangle = 6 \langle \psi_{LS}^{13} | V(1,2) | \psi_{LS}^{13} \rangle, \quad (24)$$

due to the asymmetry of the wave function. The matrix element of $V(1,2)$ (note that $x_3 = x_2 - r_1$) is easily obtained using the decomposition given in Eq. (23). For example, for a non-local potential

$$\langle \psi_{LS}^{13} | V(1,2) | \psi_{LS}^{13} \rangle = \int d^3x_1 d^3x_2 d^3x_3 d^3x'_3 \left( \psi_{LS}^{13}(x_1, x_2, x_3) \right)^* \times V(x_3, x'_3) \psi_{LS}^{13}(x_1, x_2, x'_3). \quad (25)$$

Table 1. Phase-shift and mixing angle parameters for $n - ^3\text{H}$ elastic scattering at incident neutron energy $E_n = 3.5$ MeV calculated using the I-N3LO potential. The values reported in the columns labeled FF have been obtained using the HH expansion and the Kohn variational principle, whereas those reported in the columns labeled FY by solving the FY equations [3].

| Phase-shift | HH | FY | Phase-shift | HH | FY |
|-------------|----|----|-------------|----|----|
| $S_0$       | $-65.66$ | $-65.54$ | $P_0$       | $20.21$ | $20.31$ |
| $S_1$       | $-58.20$ | $-57.99$ | $P_1$       | $20.90$ | $20.74$ |
| $D_1$       | $-0.92$  | $-0.91$  | $P_1$       | $40.98$ | $40.94$ |
| $\epsilon$ | $-0.67$  | $-0.72$  | $\epsilon$  | $9.57$  | $9.45$  |
| $D_2$       | $-1.45$  | $-1.50$  | $P_2$       | $43.58$ | $43.98$ |
| $\epsilon$ | $-0.82$  | $-0.84$  | $\epsilon$  | $0.05$  | $0.07$  |
| $\epsilon$ | $2.63$   | $2.69$   | $\epsilon$  | $1.14$  | $1.17$  |

The calculation of the above integral is performed in two steps. First, the spin-isospin-angular matrix elements

$$\int d\hat{x}_1 d\hat{x}_2 d\hat{x}_3 d\hat{x}_4 \psi_{\alpha}(\hat{x}_1, \hat{x}_2, \hat{x}_3, \hat{x}_4)^* \times V(x_3, x'_3) \psi_{\alpha}(\hat{x}_1, \hat{x}_2, \hat{x}_3, \hat{x}_4) \quad (26)$$

are computed analytically, and, second, the integration over the moduli of the Jacobi vectors,

$$\int_0^{\infty} dx_1 dx_2 dx_3 dx_4 \chi_{1}^1 \chi_{2}^2 \chi_{3}^3 \chi_{4}^4 (F_{\alpha}^{LS}(x_1, x_2, x_3))^* \times (F_{\alpha}^{LS}(x_1, x_2, x_3)) \quad (27)$$

can easily obtained by using Gauss quadrature methods, being a 4-dimensional integral. The accuracy of the matrix elements so calculated depends mainly on $\ell_{\text{max}}$, the maximum value of the orbital angular momentum used to truncate the expansion (20). Values $\ell_{\text{max}} = 5$ or 6 have been found appropriate to obtain a sufficient numerical accuracy.

The $S$-matrix elements $S_{LS.L'S'}(q)$ and coefficients $c_{K\alpha T\mu \ell}$ occurring in the expansion of $\psi_{LS}^{13}$ are determined by making the functional

$$\left[ \Delta S_{LS.L'S'}(q) \right] = S_{LS.L'S'}(q) - \frac{1}{2i} \langle \psi_{LS}^{13} | [H-E] | \psi_{LS}^{13} \rangle \quad (28)$$

stationary with respect to variations in the $S_{LS.L'S'}$ and $c_{K\alpha T\mu \ell}$ (Kohn variational principle). By applying this principle, a linear set of equations for $S_{LS.L'S'}$ and $c_{K\alpha T\mu \ell}$ is obtained. The linear system is solved using the Lanczos algorithm.

The main difficulty of the application of the HH technique is the slow convergence of the basis with respect to the grand angular quantum number $K$. This problem has been overcome by dividing the HH basis in classes. More details of this method can be found in Ref. [26].

3 Comparison between HH and FY results

The calculated phase-shift and mixing angle parameters for $n - ^3\text{H}$ elastic scattering at $E_n = 3.5$ MeV using the
I-N3LO potential are reported in Table 1 The values reported in the columns labeled HH have been obtained using the HH expansion and the Kohn variational principle, whereas those reported in the columns labeled FY by solving the FY equations [8]. As can be seen, there is a good overall agreement between the results of the two calculations. Similar comparisons for $p - {^3}\text{He}$ are currently underway.

4 Results

In this Section, we present preliminary calculations of elastic $p - {^3}\text{He}$ observables. Final results with complete tests of convergence with respect to $K$ and $\ell_{\text{max}}$ will be reported in a forthcoming paper.

In the energy range considered here ($E_p \leq 6$ MeV), the various $p - {^3}\text{He}$ observables are dominated by S-wave and P-wave phase-shifts (D-wave phase shifts give only a marginal contribution, and more peripheral phase shifts are negligible). Let us first concentrate on the comparison of calculated S-wave and P-wave phase shifts with those obtained by the recent PSA [42], shown in Figs. 1–4. The results obtained including NN interactions only slightly overpredict (in absolute value) the PSA values. Including the 3N force, the calculated phase shifts agree very well with the PSA (in absolute value) the PSA values. Including the 3N force slightly diminishes the phase shift, especially the $\ell_{\text{max}}$ phase shifts. On the contrary, the results obtained with I-N3LO and I-N3LO/N-N2LO are very close to the data. The inclusion of such a 3N force slightly increases the $^3P_1$ phase shift.

A similar behavior can be observed for the $^3P_2$ and $^3P_0$ phase shifts, reported in Fig. 5. The $^3P_2$ phase shift is well reproduced by I-N3LO and I-N3LO/N-N2LO models.
Fig. 5. $p - ^{3}$He differential cross sections calculated with the I-N3LO (blue dashed line), the I-N3LO/N-N2LO (blue solid line), and the AV18/UIX (thin green solid line) interaction models for three different incident proton energies. The experimental data are from Refs. [34,35,36].

Fig. 6. $p - ^{3}$He $A_{y}$ observable calculated with the I-N3LO (blue dashed line), the I-N3LO/N-N2LO (blue solid line), and the AV18/UIX (thin green solid line) interaction models for three different incident proton energies. The experimental data are from Refs. [37,22,36].
while with AV18 and AV18/UIX we observe an underprediction. For the $^3P_0$ phase shift we observe that the models including NN interaction only overpredict the PSA values. With the inclusion of the 3N forces, the results come close to the PSA values. This behavior is not unexpected, as it was already known that this phase shift “scales” with the $^3$He binding energy [7].

Finally, in Fig. 4 the comparison is performed for the $1^-$ and $1^+$ mixing parameters. For $\alpha(1^-)$, the PSA results have quite large errors, however it is significant that only the I-N3LO/N-N2LO values are in the error bar. For $\alpha(1^+$), the results obtained with all the four models are more less consistent with the (largely scattered) PSA values.

In conclusion, with AV18, the S-wave and most of the P-wave phase shifts are at variance with the results of the PSA. Including the UIX 3N force, only the S-wave shifts are adjusted. With I-N3LO, the S-wave phase shifts are overpredicted (in absolute value), but the P-wave phase shifts are much better reproduced. Including the N-N2LO 3N interaction, the S-wave shifts become well reproduced, while the agreement with the P-wave shifts is not spoiled. In this case also the mixing parameters are well reproduced. We observe therefore an overall good agreement between the results obtained with the I-N3LO/N-N2LO model and the PSA values.

Let us now compare the results of the calculations directly with the available experimental data. The potential models considered hereafter are the I-N3LO, I-N3LO/N-N2LO, and AV18/UIX. The calculated $p - ^3$He differential cross sections at energies $E_p = 2.25$, 4, and 5.54 MeV are reported in Fig. 5 and compared with the experimental data of Refs. [37,41]. As can be seen, there is a good agreement between the theoretical calculations and experimental data. In fact, this observable is sensitive to small changes of the phase shifts only in the “interference” region around $\theta = 30$ deg. We note only a slight deviation of the AV18/UIX results from the data in such a region.

More interesting is the situation for the proton vector analyzing power $A_y$. Here, we observe a larger sensitivity to the employed interaction model. The calculations performed using AV18/UIX largely underpredict the experimental points, a fact already observed before [22,36]. Using I-N3LO, no significative changes are observed. A sizable improvement is found by adopting the I-N3LO/N-N2LO model, as it was expected from the discussion regarding the comparison with the PSA phase shifts. To be more quantitative, let us consider the ratio $A_y^{\text{theo}}/A_y^{\text{exp}}$ at the peak, reported in Table 2. For the AV18, AV18/UIX, and I-N3LO models, there is approximately a 30% underprediction of the peak height. The underprediction is reduced approximately by a factor 2 for the I-N3LO/N-N2LO model.

Finally, in Figs. 7 and 8 we show two further polarization observables, the $^3$He analyzing power $A_y$ and the spin correlation coefficient $A_y$. These observables (and other spin correlation coefficients) are not very sensitive to the interaction model. We observe however, that the I-N3LO/N-N2LO model produces slightly better agreement with data.

### 5 Conclusions

In this paper preliminary results for $p - ^3$He elastic scattering obtained using the HH function expansion have been reported. We have considered four interaction models. The first two are based on phenomenological NN interactions (AV18 and AV18/UIX). The other two are derived from a chiral effective theory (I-N3LO and I-N3LO/N-N2LO). Both NN interactions (AV18 and I-N3LO) reproduce the NN scattering data with a $\chi^2$ per datum very close to 1. The UIX 3N interaction has been fixed in order to reproduce the trinucleon binding energies, whereas the N-N2LO by fitting simultaneously both $A = 3, 4$ binding energies.

| Pot.     | 2.25 MeV | 4 MeV  | 5.54 MeV |

[36]: Refs. [37,41].
We have compared the results obtained with the four interaction models with the available experimental data and a very recent PSA performed at TUNL [42]. We have found that the phase shifts obtained with I-N3LO are consistent with those derived from the PSA. The direct comparison of the I-N3LO/N-N2LO results with the experimental data has shown that there are still some discrepancies, but the $A_p$ problem is noticeably reduced. In fact, we observe that now the discrepancy is of the order of 15% at the peak, much less than what observed with other interaction models.

In this regard, it is interesting to note that in the $N - d$ case, the use of the I-N3LO/N-N2LO model does not give such a reduction of the $N - d$ “$A_p$ Puzzle”, as can be seen for example in Fig. 9. We observe in fact only a small increase of the $A_p$ computed with the I-N3LO/N-N2LO model with respect to that calculated, for example, using the AV18/UIX model. Note that also for $p - d$, the calculated $A_p$ with I-N3LO and AV18/UIX are very similar. In this case the ratio $\frac{A_p^{\text{theor}}}{A_p^{\text{exp}}}$ at the peak is approximately $0.81$ ($0.74$) for I-N3LO/N-N2LO (AV18/UIX). Investigations to understand this behavior are in progress.

**Acknowledgments.** We would like to thank T.V. Daniels and T.B. Clegg for providing us with their experimental data prior to publication, and A. Deltuva and A. Fonseca for useful discussions.
