Abstract

In many areas, such as social science, politics or market research, people need to deal with dataset shifting over time. Distribution drift phenomenon usually appears in the field of sentiment analysis, when proportions of instances are changing over time. In this case, the task is to correctly estimate proportions of each sentiment expressed in the set of documents (quantification task). Basically, our study was aimed to analyze the effectiveness of a mixture of quantification technique with one of deep learning architecture. All the techniques are evaluated using the SemEval-2017 Task4 dataset and source code, mentioned in this paper and available online in the Python programming language. The results of an application of the quantification techniques are discussed.

1 Introduction

A traditional classification task is often based on the assumption that data for training a classifier represent test data. But in many areas, such as customer-relationship management or opinion mining, people need to deal with dataset shift or population drift phenomenon. The simplest type of dataset shift is when training set and test set vary only in the distribution of the classes of the instances aka distribution drift. If we would like to measure this variation, the task of accurate classification of each item is replaced by the task of providing accurate proportions of instances from each class (quantification). George Forman suggested defining the ‘quantification task’ as finding the best estimate for the amount of cases in each class in a test set, using a training set with a substantially different class distribution (Forman, 2008).

Application of the quantification approach in opinion mining (Esuli et al., 2010), network-behavior analysis (Tang et al., 2010), word-sense disambiguation (Chan and Ng, 2006), remote sensing (Guerrero-Curieses et al., 2009), quality control (Sánchez et al., 2008), monitoring support-call logs (Forman et al., 2006) and credit scoring (Hand and others, 2006) showed high performance even with a relatively small training set.

Although quantification techniques are able to provide accurate sentiment analysis of proportions in situations of distribution drift, the question of an optimal technique for analysis of tweets still raises a lot of questions. It is worth mentioning that sentiment analysis of tweets presents additional challenges to natural language processing, because of the small amount of text (less than 140 characters in each document), usage of creative spelling (e.g. “happpyyy”, “somet y bner2 tulus”), abbreviations (such as “wth” or “lol”), informal constructions (“hahahaha yava quiet so !ma I m bored av even home nw”) and hashtags (BREAKING: US GDP growth is back! #kidding), which are a type of tagging for Twitter messages.

We participated in D and E subtasks of the tweet sentiment quantification competition SemEval-2017 Task 4. To solve them we used a quantification method, which showed good accuracy last year (Karpov et al., 2016) and deep learning architecture mentioned in literature for text classification task.

The paper is organized as follows. In Section 2, we first look at the notation, then we briefly overview a method to solve the quantification problem. Section 3 describes a deep learning architec-
ture and approach to train our network. In Section 4 we show an experiment methodology. Section 5 describes the results of our experiments, while Section 6 concludes the work defining open research issues for further investigation.

2 Quantification Method

In this section, we describe methods used to handle changes in class distribution.

First, let us give some definition of notation. X: vector representation of observation x; C = {c1, ..., cn}: classes of observations, where n is the number of classes; 
Pc (c): a true a priori probability (aka “prevalence”) of class c in the set S; 
PcM (c): estimated prevalence of c using the set S; 
Pc (c): a posteriori probability to classify an observation x to the class c; 
TRAIN, TEST: training and test sets of observations, respectively; 
TEST_CD: a subset of TEST set where each observation falls within class c; 
TRAIN_CD = \{p_{TRAIN}(c_i)\}; i=1, n: class probability distribution of the training set; 
TEST_CD = \{p_{TEST}(c_i)\}; i=1, n: class probability distribution of the test set;

The problem we study has some training set, which provides us with a set of labeled examples – TRAIN, with class distribution TRAIN_CD. At some point, the distribution of data changes to a new, but unknown class distribution – TEST_CD, and this distribution provides a set of unlabeled examples – TEST. Given this terminology, we can state our quantification problem more precisely.

2.1 Expectation Maximization

A simple procedure to adjust the outputs of a classifier to a new a priori probability is described in the study by (Saerens et al., 2002).

\[ p(c_j/x_k) = \frac{p_{TEST}(c_j)p(c_j/x_k)}{\sum_{j=1}^{n} p_{TEST}(c_j)p(c_j/x_k)} \quad (1) \]

It is important that authors suggest using not only a well-known formula (1) to compute the corrected a posteriori probabilities, but also an iterative procedure to adjust the outputs of the trained classifier with respect to these new a priori probabilities, without having to refit the model, even when these probabilities are not known in advance.

To make the Expectation Maximization (EM) method clear, we specify its algorithm in Figure 1 using a pseudo-code. The algorithm begins with counting start values for class probability distribution, using labels on the training set TRAIN (line 1), then builds an initial classifier C_i from the TRAIN set (line 2) and classifies each item in the unlabeled TEST set (line 3), where the classify functions return the a posteriori probabilities (TEST_prob) for the specified datasets. The algorithm then iterates in lines 4-9 until the maximum number of iterations (maxIterations) is reached. In this loop, the algorithm first uses the previous a posteriori probabilities TEST_prob to estimate a new a priori probability (line 6). Then, in line 7, a posteriori probabilities are computed using Equation (1). Finally, once the loop terminates, the last a posteriori probabilities return (line 9).

EM (TRAIN, TEST)

1.TEST_CD = prevalence(TRAIN)
2.C_i = build_clf(TRAIN)
3.TEST_prob = classify(C_i, TEST)
4.for (i=1; i<maxIterations; i++)
5.{
6.TEST_CD = prevalence(TEST_prob)
7.TEST_prob = bayes(TEST_CD, TEST_prob)
8.}
9.return TEST_CD

Figure 1: Pseudo-code for the EM algorithm.

To build a classifier in the function build_clf, we use support vector machines (SVM) with a linear kernel.

2.2 Iterative Class Distribution Estimation

Another interesting method is iterative cost-sensitive class distribution estimation (CDE-Iterate) described in the study by (Xue and Weiss, 2009).

The main idea of this method is to retrain a classifier at each iteration, where the iterations progressively improve the quantification accuracy of performing the «classify and count» method via generated cost-sensitive classifiers.

For the CDE-based method, the final prevalence is induced from the TRAIN labeled set with the cost of classes COST. The COST value is computed with Equation (2), utilizing the class distribution calculated during the previous step TEST_CD. For each iteration, we recalculate:
The CDE-Iterate algorithm is specified in Figure 2, using the pseudo-code. The algorithm begins with counting the class distribution TRAIN_CD for training labels TRAIN (line 1). Then it builds an initial classifier $C_i$ from the TRAIN set (line 2). In a loop, this algorithm uses the previous classifier $C_i$ to classify the unlabeled TEST set by estimating a posterior probability $\text{TEST\_prob}$ for each item in a test set (line 5). Then in line 6, the a priori probability distribution is computed and the cost ratio information is updated (line 7). In line 8, a new cost-sensitive classifier $C_i$ is generated using the TRAIN set with the updated cost ratio COST. The algorithm then iterates in lines 4-9 until the maximum number of iterations (maxIterations) is reached. Finally, once the loop terminates, the last a priori probability distribution of classes is returned $\text{TEST\_CD}$ (line 10).

CDE-Iterate(TRAIN, TEST, COST_start)
1. $\text{TRAIN\_CD} = \text{prevalence}(\text{TRAIN})$
2. $C_i = \text{build}\_\text{clf}(\text{TRAIN}, \text{COST\_start})$
3. for (i=1; i<maxIterations; i++)
4. {
5. $\text{TEST\_prob} = \text{classify}(C_i, \text{TEST})$
6. $\text{TEST\_CD} = \text{prevalence}(\text{TEST\_prob})$
7. $\text{COST} = \text{TEST\_CD}/\text{TRAIN\_CD}$
8. $C_i = \text{build}\_\text{clf}(\text{TRAIN}, \text{COST})$
9. }
10. return $\text{TEST\_CD}$

Figure 2: Pseudo-code for the CDE-Iterate algorithm.

Last year we did not find any open library where baseline quantification methods were implemented. We, therefore, shared all the algorithms, which we had programmed using the Python language, on the Github repository\textsuperscript{1}. We believe that this library can help to pool information on quantification.

3 Deep Learning Architecture

As the classifier for quantification algorithm, we used a neural network with traditional architecture for text classification task. In this section, we briefly describe our choice of architecture, a regularization method and a training algorithm.

### 3.1 Pre-trained Embedding Layer

The organizers provided a dataset of messages of SemEval Task4 since 2013 till 2016. But it still contained not so many samples to effectively train deep architecture. Therefore, we additionally used weekly labeled Sentiment140 corpus of tweets, (Go et al., 2009), to pre-train our network so as to learn semantic and sentiment specific representation of words and phrases.

A sequence of words of the input tweet maps to the corresponding real-valued vectors by the embedding layer. The length of its vector is called the dimension of the embeddings. To find out good embeddings we utilize GenSim\textsuperscript{2} to pre-trained CBOW model for vectors with a dimensionality of 300. We choose these over the CBOW embeddings trained on Twitter data because of the higher dimensionality, considerably larger training corpus and vocabulary of unique words.

Word vectors from GenSim used as a starting point and they have updated during network training by back-propagating the classification errors.

### 3.2 Recurrent layers

Recurrent layers are proved to be useful in handling variable length sequences (Tang et al., 2015). We use two series-connected long short-term memory (LSTM) cells to compute continuous representations of tweets with semantic composition.

3.3 Regularization

We use dropout as the regularizer to prevent our network from overfitting (Srivastava, 2013). Our

\textsuperscript{2}http://radimrehurek.com/gensim/
dropout layer selects a half of the hidden units at random and sets their output to zero and thus prevents co-adaptation of the features.

3.4 Training algorithm

The Sentiment140 dataset and all messages from SemEval Task4 competition since 2013 till 2016 were used (except sarcasm dataset) to pre-train neural network layers. Then we fine tuned them on the train subsets for extract subtask. We used Adam method for stochastic optimization of an objective function.

4 Experiment Methodology

This section describes our experimental setup for participation in the SemEval-2017 Task 4 called “Sentiment Analysis in Twitter”. Task 4 consists of five subtasks, but we only participated in topic-based message polarity quantification – subtasks D, E according to a two-point scale and five-point scale, respectively. Its dataset consists of Twitter messages (aka observations) divided into several topics. These subtasks are evaluated independently for different topics, and the final result is counted as an average of evaluation measure out of all the topics (Rosenthal et al., 2017).

For the quantification algorithm described in Section 2, we need to build a cost-sensitive classifier in the function build_clf.

4.1 Approach 2016

Last year we tried few cost-sensitive classifiers and finally chose a fast logistic regression classifier.

Since observation x in this dataset is a message written in a natural language, we first need to transform it to a vector representation X. Based on a study by (Gao and Sebastiani, 2015), we choose the following components of the feature vector:

- TF-IDF for word n-grams with n varies from 1 to 4
- TF-IDF character n-grams where n varies from 3 to 5.

A feature vector is extracted with a Scikit-Learn tool. We also perform data preprocessing. Several text patterns (e.g. links, emoticons, and numbers) were replaced with their substitutes. For word n-grams we apply lemmatization using WordNetLemmatizer.

It is interesting to characterize messages using the SentiWordNet library. For each token x_i in document X we obtain its polarity value from the SentiWordNet. First, we recognize the part of speech using a speech tagger from the NLTK library (Bird et al., 2009). Second, we get the SentiWordNet first polarity value for this token using the part of speech information.

The organizers provide a default split of the SemEval2016 data into training, development, development-time testing and testing datasets. The algorithms evaluation is performed using these subsets. The training, development and development-time testing subsets are used as a TRAIN set. The testing subset is used as a TEST set.

4.2 Approach 2017

This year we try to apply neural network as a cost-sensitive classifier.

We remove punctuations from input text message. Then we split tweets into words and transform them into a sequence of word index with fixed length. All preprocessing is performed using Keras library with Tensor Flow backend. We do not apply character sequences and lemmatization or stemming of words. As a TRAIN set, we use all datasets provided by organizers of topic-based message polarity challenge.

The chosen parameters of our network are as follows: the maximum input sequence length is set to 30, vocabulary size is 300000, the dimensionality of word embedding is 300, LSTM units hidden state vector size is 64, two LSTM layers and dropout of 50% while training. We use the dense layer with output dimension equals to one for subtask D and five for subtask E with sigmoid activation.

The metrics that we use to evaluate the classifier performance are described in (Rosenthal et al., 2017) and are not described here.

5 Experiment Results

The results of five point scale subtask are shown in Table 1. During the development period, we compare our system with last year one on the last year dataset. New system produced an EMD
measure of 0.347 while last year system was slightly better - 0.334. We explain this by the fact that dataset for network fine-tuning was relatively small last year. This year training dataset is three times bigger, that is why we decide to submit results from the new version of the algorithm.

EMD of our new system on the new dataset is 0.317 while the best system scored 0.245.

| Settings                  | EMD  |
|---------------------------|------|
| Approach and dataset 2017 | 0.317 (5) |
| Approach 2017, dataset 2016 | 0.347 |
| Approach and dataset 2016 | 0.334 (4) |

Table 1: Results of Task 4E.

The results of two-point scale subtask are shown in Table 2. Our algorithm shows KLD equals to 0.078 while the best system is 0.036.

| Settings                  | KLD  | RAE  |
|---------------------------|------|------|
| Approach and dataset 2017 | 0.078 (8) | 1.528 (8) |
| Approach and dataset 2016 | 0.084 (7) | 0.767 (4) |

Table 2: Results of Task 4D.

6 Conclusion and future work

The aim of this research was to try to solve sentiment quantification task with deep learning architecture. We compared our deep learning approach used this year with an approach without deep learning used last year.

For tweet quantification on a five-point scale (Subtask E) and a two-point scale (Subtask D), we used the same iterative method proposed by (Xue and Weiss, 2009). As a classifier we used deep learning network which was retrained on the big corpus and fine tune on the small. These approaches showed the 5-th and the 8-th best places in the competition subtasks E and D respectively.

In our future work, we are planning to move in two directions. First, we plan to apply new deep architecture and pre-train it using more data. Second, we want to explore the bias property of the CDE-Iterate quantification method.
