Abstract: The sulfur-iodine (SI) cycle holds great promise as an alternative large-scale process for converting water into hydrogen without CO₂ emissions. A major issue regarding the long-term stability and activity of the catalysts is their poor sulfur deactivation resistance in the HI feeding process. In this work, the effect of Ru addition for enhancing the activity and sulfur resistance of SiO₂-supported Ni catalysts in the HI decomposition reaction has been investigated. The presence of H₂SO₄ molecules in the HI results in severe sulfur deactivation of the Ru-free Ni/SiO₂ catalysts by blocking the active sites. However, Ni–Ru/SiO₂ catalysts show higher catalytic activity without sulfur-poisoning by 25% and exhibit more superior catalytic performance than the Ru-free catalyst. The addition of Ru to the Ni/SiO₂ catalyst promotes the stability and activity of the catalysts. The experimental trends in activity and sulfur tolerance are consistent with the theoretical modeling, with the catalytic activities existing in the order Ni/SiO₂ < Ni–Ru/SiO₂. The effect of Ru on the improvement in sulfur resistance over Ni-based catalysts is attributed to electronic factors, as evidenced by theory modeling analysis and detailed characterizations.

Keywords: hydrogen production; SI cycle; HI decomposition; bimetallic catalysts; sulfur-tolerant

1. Introduction

Hydrogen is considered as an environment-friendly fuel and sustainable energy vector. Due to its good thermal efficiency and operability, various important efforts have been made to promote hydrogen production via the thermochemical sulfur-iodine (SI) cycle [1–9]. The SI cycle consists of the following reactions [10]:

\[ \text{SO}_2(g) + I_2(s) + 2\text{H}_2\text{O}(l) \xrightarrow{293-393 \text{ K}} \text{H}_2\text{SO}_4(aq) + 2\text{HI}(aq) \]  

(1)

\[ 2\text{HI}(g) \xrightarrow{573-773 \text{ K}} \text{H}_2(g) + I_2(g) \]  

(2)

\[ \text{H}_2\text{SO}_4(g) \xrightarrow{873-1173 \text{ K}} \text{SO}_2(g) + \text{H}_2\text{O}(g) + 1/2\text{O}_2(g) \]  

(3)

In Reaction (1) (Bunsen reaction), iodine from reaction (2) reacts with sulfur dioxide and water to generate sulfuric acid and hydrogen iodide. The products of Bunsen reaction are a mixture of H₂SO₄, hydrogen iodide (HI), and H₂O. The mixture is required to be separated, thus processing the thermal decompositions of the two acids. Herein, two non-miscible acidic phases (sulfuric acid and the HI phase) can be produced with an excess of iodine and water [11]. Accordingly, the two acidic phases are purified via a reverse Bunsen reaction at 423 K, and the purified HI is then catalytically dissociated into H₂ and I₂ at 573–773 K. The purified H₂SO₄ decomposes into O₂, H₂O, and SO₂ at about
1073 K. The products from Reaction (2) and Reaction (3) can be entirely recycled in the SI cycle, except the H₂ and O₂.

Consequently, the net reaction of the SI cycle is complete water decomposition at relatively low temperatures. Reaction (2) is the key reaction, and it is hard to proceed without the help of a catalyst, even at 773 K, due to the relatively low homogeneous gas-phase conversion rate (only 2.2% at 773 K). Therefore, numerous HI decomposition catalysts have been studied to increase the conversion rate of HI decomposition.

Up to now, various catalysts have been assessed for use in the catalytic decomposition of HI, including noble metal elements (Pt, Au, Ru, Ag) [12,13], transition metals (Ni, Ce) [14–16], and activated carbon catalysts [17]. Among these, Pt, Ni, and Co loaded on CeO₂ support have shown significant promise. The Pt/CeO₂ has the best, and Co/CeO₂ has the worst catalytic performance [18–20]. The effect of catalysts prepared by loading Ni onto different carbon materials has also been addressed, including Ni/MWCNT, Ni/CMS, Ni/AC, and Ni/GNP [21]. The activity performance and lifespan evaluation of Ni/γ-Al₂O₃ catalysts in HI decomposition have been determined at 773 K [22]. The catalytic kinetics of spheroidal activated carbon have also been studied, and the spherical activated carbon was stable at 140 h [23].

Much research on mechanism analyses has been conducted to develop a suitable and inexpensive catalyst for HI decomposition [24–26]. Nevertheless, sulfur-containing compounds have been previously observed in the iodidric solution [7,9,27–30]. Sulfur poisoning is one of the most critical factors in catalytic deactivation [31,32]. To the best of our knowledge, no current studies are focusing on the improvement of sulfur tolerance for HI decomposition. Consequently, it is essential to evaluate the deactivation mechanism from sulfur poisoning and reduce the presence of sulfur species on the catalyst. Ru is an active noble catalytic component, and the combination of Ni and Ru has been observed to perform multiple roles [33]. As far as we know, Ni–Ru catalysts have not been reported for use in the SI cycle. Therefore, this study synthesized Ni–Ru bimetallic catalysts and examined the catalytic activity and sulfur tolerance performance of Ni and Ni–Ru catalysts supported on SiO₂ in HI decomposition reactions.

2. Experimental Methodology
2.1. Catalyst Preparation

All the chemicals in this study were analytical-grade reagents. The silicon dioxide (Aladdin Reagent Co., Ltd., Shanghai, China) was dried at 393 K for 2 h and then calcined in air at 973 K for 5 h before use. The nickel nitrate hexahydrate (5.60 g), ruthenium nitrosyl nitrate (0.48 g), and polyethylene glycol (5.86 g, average molecular weight = 1000) were dissolved in the solution of solvent containing 300 mL of deionized water and 100 mL of butanol. The mixture was refluxed at 393 K in an oil bath under vigorous stirring for 2 h. Then, 10 g of SiO₂ was introduced with continuous stirring. The formed suspensions were evaporated at 393 K, until the solvent was removed and a paste-like sample formed. The sample was dried in an oven at 393 K for 12 h and subsequently calcined in air at 673 K for 5 h to prepare the supported Ni–Ru/SiO₂ metal oxides. The mass percentage of Ni in the Ni–Ru/SiO₂ was 10 wt%. The samples were first reduced for 2 h in a hydrogen atmosphere at 873 K. Subsequently, the samples were passivated at room temperature in an atmosphere of 1% oxygen. The monometallic Ni/SiO₂ catalyst (10 wt% Ni) was produced via the same preparation method without adding ruthenium nitrosyl nitrate. The Ni and Ni–Ru were supported on SiO₂, and defined as Ni/SiO₂ and Ni–Ru/SiO₂. These catalysts were pressed, crushed, and then sieved into 60–80 mesh particles.

2.2. Characterization

The morphology and elemental compositions of the catalysts were characterized using a transmission electron microscope (TEM) equipped with energy-dispersive X-ray spectroscopy (EDX) on a JEM-2010-HR (JEOL Ltd., Tokyo, Japan). The catalyst powders were ground and then coated on the surface of copper grids with ethanol. The framework
structure of the catalysts was assessed using the X-ray diffraction (XRD) technique with a Rigaku K/max2550/PC (Rigaku Corporation, Tokyo, Japan) diffractometer at 40 kV and 100 mA (step time of 0.02 s and step size of 0.02°). X-ray photoelectron spectroscopy (XPS) analyses were performed on an Escalab 250Xi system (Thermo Scientific Ltd., Bedford, MA, USA) with MgK α radiation under ultra-high vacuum conditions (5 × 10⁻⁸ Pa). Temperature programmed reduction (TPR) was carried out with an AutoChem II 2920 automated catalyst characterization system (Micromeritics Instrument Corporation, Norcross, GA, USA). At the end of HI decomposition tests, the catalysts Ni/SiO₂ and Ni–Ru/SiO₂ were cooled to room temperature, discharged from the fixed-bed reactor, and then transferred to XRD and XPS studies. In this case no precautions were taken to prevent exposure of the catalysts to air prior to the XRD and XPS analysis.

2.3. Catalyst Activity and Stability Test

The catalytic activity and sulfuric acid poisoning process were conducted in a flow fixed-bed reactor, as described in Figure 1. An automated system was installed to produce H₂ from an HI decomposition reaction. A mass-flow controller and syringe pump were used to control the flow of the carrier gases. The fixed-bed reactor consists of an electric heater and a silica tube (18 mm in inner diameter × 458 mm in length). A type K thermocouple was equipped to monitor the reaction temperature in the middle of the catalysts bed. 0.5 g of catalyst, mixed uniformly with coarse quartz particles, was fed into the fixed-bed reactor. The feeding rate of hydroiodic acid (55 wt% at different concentrations of sulfuric acid) into the evaporator (433 K) was 0.5 mL/min and controlled via a syringe pump. 60 mL/min N₂ was used to drive the vaporized HI. A stream of gaseous mixture subsequently entered the fixed-bed reactor. After the HI decomposition reaction, the mixed gases passed through a gyroidal water condenser, several NaOH solution absorbers, and silica gels, accomplishing the purification of residual H₂ and N₂. The outlet gases were collected and analyzed using a hydrogen analyzer.

Figure 1. Schematic of the test facility for assessing catalytic activity and poisoning.

The HI conversion can be expressed by the following equation:

\[
\alpha = \frac{2ND}{Rn(1-D)}
\]  

(4)
where $\alpha$ is the value of HI conversion. $D$ denotes hydrogen concentration. $R$ is the molar volume constant of gas. $N$ is the volume flow rate of driving gas ($N_2$), and $n$ is the molar flow rate of HI solution.

The deactivation ratio can be expressed by following equation:

$$\beta = \frac{1 - \alpha}{\alpha_0} \times 100\%$$

(5)

where $\beta$ is the value of deactivation ratio. $\alpha_0$ denotes HI conversion in a standard HI decomposition step with an HI solution (55 wt%) in the absence of $H_2SO_4$. $\alpha_i$ is the HI conversion in poisoning step with a solution at different $H_2SO_4$ concentrations, and $i$ denotes poisoning steps at different $H_2SO_4$ concentrations.

2.4. Theoretical Modeling

The different adsorption energies of HI and S on various Ni–Ru clusters were assessed by the Vienna Ab-initio Simulation Package (VASP) [34,35], using the density functional theory (DFT) and the Projected Augmented Wave (PAW) methods [36]. The Perdew-Burke-Ernzerhof (PBE) function was used to express the exchange and correlation effect [37]. For all geometry optimizations, the cutoff energy was set to be 450 eV. Spin-polarization was included in the calculations of Ni-containing groups. The simulation models were constructed in a $19 \times 19 \times 19 \text{ Å}$ box, which is sufficient to eliminate the influence of neighboring clusters. The Monkhorst-Pack grids were set to be $1 \times 1 \times 1$ for all calculations [38].

The adsorption energy of HI and S on the Ni–Ru clusters was defined as:

$$\Delta E_{ads} = E_{ads} - E_{slab} - E_{HI(S)}$$

(6)

where $E_{ads}$ is the electronic energy of the cluster with an adsorbed HI or S, $E_{slab}$ is the electronic energy of the clean cluster, and $E_{HI(S)}$ is the electronic energy of one HI or S. The electronic energy of one S atom was referenced as the energy of one $S_8$ cluster. Under this definition, a more negative value indicated a stronger binding.

3. Results and Discussion

3.1. Properties of the Catalysts

As shown in Figure 2, the diffraction patterns of fresh Ni/SiO$_2$ and Ni–Ru/SiO$_2$ catalysts exhibit similar typical peaks. The pattern for the supports is that of crystallized materials with wide diffraction peaks in the $2\theta$ range between 15 and 30, which are features of amorphous silica. Additionally, three diffraction peaks around 44.5, 51.85 and 76.37 are ascribed to the (111), (200) and (220) planes of the cubic structure of Ni [JCPDS No. 04-0850]. The presence of only metallic nickel in the XRD analyses indicates that most NiO phases are reduced to form metallic Ni during the pre-reduction of the catalyst, which may have been active for HI decomposition. No significant diffraction peak of Ru is detected in the Ni–Ru/SiO$_2$ catalysts. These results suggest that the Ru is well dispersed on the SiO$_2$. The particle size of Ru is very small, and the dispersion of the granules is homogeneous.

The TEM micrographs are used to observe the sizes and morphologies of the species on the catalysts. As shown in Figure 3, the fresh Ni–Ru/SiO$_2$ catalysts are investigated by TEM-EDX. It is noted that the nickel and ruthenium particles are small and homogeneously dispersed on the SiO$_2$ surface. Further EDX analysis of the Ni–Ru/SiO$_2$ catalysts are used to characterize the particles on the catalysts, as shown in Figure 3b. The Ni, Ru, O, and Si elements are clearly deposited. These observations suggested that the bimetallic Ni–Ru species are spread on the Ni–Ru/SiO$_2$ catalysts.
The TPR profiles of the Ni/SiO<sub>2</sub> and Ni–Ru/SiO<sub>2</sub> samples are shown in Figure 4. For the Ni/SiO<sub>2</sub> catalyst, a large hydrogen-consuming peak at 562 K accompanied by an obvious shoulder between 650 and 850 K is observed. The former reduction peak can be ascribed to the reduction of NiO species contacting weakly with the SiO<sub>2</sub> supports, and the high-temperature shoulder peak around 700 K indicates the formation of hard-reducible NiO species bearing a strong interaction with the SiO<sub>2</sub> support [39]. The hydrogen consumption peak of the Ni–Ru/SiO<sub>2</sub> sample around 453 K can be attributed to the reduction of RuO<sub>2</sub> (RuO<sub>2</sub> + H<sub>2</sub> → Ru + H<sub>2</sub>O), which can be easily reduced at a comparatively low temperature. Additionally, this peak markedly overlaps with the subsequently large H<sub>2</sub> consuming peaks, and the NiO reduction temperature obviously changes from 562 K to 549 K, implying that active hydrogen species produced at the pre-generated Ru<sup>0</sup> particles could easily spill into adjacent NiO sites to promote their reduction [33]. Therefore, the reducibility of the Ni–Ru/SiO<sub>2</sub> catalysts is significantly increased, in contrast to the Ru-free Ni/SiO<sub>2</sub> samples. In accordance with the literature [40], the appearance of the overlapping
hydrogen-consuming peaks indicates that the RuO₂ species can closely interact with the NiO species, resulting in their high dispersion on the Ni–Ru/SiO₂ sample. This effect may accelerate the reduction of NiO with a lower interaction. Moreover, it can be conjectured that the presence of Ru on the catalyst decreases the interactions between the small NiO particles and the supports; hence, improving the reducibility and facilitating the formation of bimetallic Ni–Ru species.

3.2. Catalytic Activity and Sulfur-Tolerant Performance

The experimental data of the measured HI conversion rate versus the reaction time over the Ni/SiO₂ and Ni–Ru/SiO₂ catalyst with different H₂SO₄ concentrations is presented in Figure 5a. The activity and poisoning experiments were investigated via a series of different conduct steps. Initially, a standard HI decomposition step with an HI solution (55 wt%) is used in the absence of H₂SO₄ at 773 K. Subsequently, various poisoning steps were executed, in which a solution at different H₂SO₄ concentrations (500, 1000, 2000, and 3000 ppm), HI (55 wt%), and H₂O were pumped in the test facility. Finally, at the end of the 800-min experiment, the standard HI decomposition step was repeated, closely following the poisoning steps, without changing the catalysts. These steps were continuously processed and monitored. Under the same experimental conditions of the standard HI decomposition, the HI conversion over Ni–Ru/SiO₂ is strongly promoted from 16% to 20% compared to Ni/SiO₂. As is evident, the addition of Ru to the Ni catalysts significantly promotes the HI decomposition reaction. However, as can be seen in Figure 5a, significant changes in the HI conversion rate are observed over both catalysts in the poisoning steps, even at 500 ppm. It is to be noted that the activity of the Ni/SiO₂ is obviously weakened in the poisoning step (3000 ppm H₂SO₄), which was about a quarter of the activity prior to H₂SO₄ poisoning. Importantly, the deactivation effect was markedly reversible, indicating that the regeneration of some sulfur-poisoned sites may be achieved. In the repeated standard HI decomposition step without H₂SO₄ contamination, the activity of the Ni/SiO₂ becomes partly irreversible. Moreover, upon removal of H₂SO₄, the activity of the Ni–Ru/SiO₂ catalysts returns to nearly the same level as prior to the H₂SO₄ exposure. The reversible deactivation is primarily based on competitive adsorption due to the sulfur species deposition on the catalyst surface [32]. It is concluded that Ni–Ru/SiO₂ exhibits better activity in all the above steps.
Figure 5. (a) Experimental HI conversion rate over Ni/SiO$_2$ and Ni–Ru/SiO$_2$ measured in serial runs and (b) deactivation ratios at different H$_2$SO$_4$ concentrations.

Figure 5b shows the deactivation ratios at the different H$_2$SO$_4$ concentrations. Notably, the deactivation rates are gradually varied, and this can be due to the H$_2$SO$_4$ concentration gradients and the possible loss of the catalyst activities. Meanwhile, Ni/SiO$_2$ has more severe deactivation compared to Ni–Ru/SiO$_2$. This indicates that Ni–Ru/SiO$_2$ could resist the sulfur poisoning. These results show that the addition of Ru to the Ni/SiO$_2$ catalyst promotes the stability and activity of the catalysts.

3.3. Characterization of the Deactivated Catalysts

The crystal structures of the deactivated catalysts after exposure to the H$_2$SO$_4$-containing HI solution are observed by XRD, and the results are presented in Figure 6. Different from the Ni/SiO$_2$, the Ni–Ru/SiO$_2$ catalyst has a small peak around 28.09, 35.11 and 54.38°, which is the diffraction peak of RuO$_2$ [JCPDS No. 70-2662]. It also has an NiO crystal peak around 39.26, 43.29 and 62.89° [JCPDS No. 89-5881], and exhibits the characteristic diffraction peak of Ni$_2$O$_3$ (2θ ≈ 39.13 and 51.59°) [JCPDS No. 14-0481]. It is possible to conclude that the appearance of the small amounts of RuO$_2$ and nickel oxide reflections in XRD patterns can be explained by contact of discharged samples with air, since such oxides could not be stable in the presence of hydrogen in the HI decomposition tests. In addition, the peak of the Ni$_2$SiO$_4$ phase is observed for the Ni/SiO$_2$ catalyst [JCPDS No. 74-0563], which shows that some nickel silicate has formed on the Ni/SiO$_2$ sample. This indicates that the Ni species strongly interacts with the SiO$_2$ supports, as the silica and nickel oxide gradually transform to nickel silicate during the H$_2$SO$_4$ poisoning process.

On the other hand, after long reaction times, the reflections of cristobalite [JCPDS No. 75-0923] appear in diffraction patterns of the poisoned Ni/SiO$_2$ and Ni–Ru/SiO$_2$ catalysts while being absent in the patterns of fresh initial samples. This indicates that the presence of sulfuric acid along with steam in reaction conditions facilitates silica crystallization. Such crystallization weakens the interaction of support with Ni and Ru, resulting in the aggregation of catalysts. The calculated crystal diameters of the poisoned samples are larger than the fresh catalysts. These observations reveal that trace H$_2$SO$_4$ contamination in the HI contributed to the sintering of Ni$^{0}$ particles and their aggregation, while no NiSx crystals appear on the catalysts.

XPS is used to detect the surface composition of the catalysts and provide further evidence of their electronic structures. Nevertheless, there is no S element existing based on the XPS analysis for each poisoned catalyst. Therefore, the oxidation state on the Ni surface is the only concern. At the Ni 2p$^{3/2}$ level of the fresh Ni–Ru/SiO$_2$ and Ni/SiO$_2$
catalysts (as shown in Figure 7), the prominent asymmetric peaks of NiO species appear at 855 eV, accompanied by the obvious shoulder peaks. These results are consistent with the TPR results (Figure 2).

![Figure 6. XRD patterns of the poisoned Ni/SiO$_2$ and Ni–Ru/SiO$_2$ catalysts after exposure to 3000 ppm H$_2$SO$_4$.](image)

![Figure 7. XPS measurements for 3000 ppm H$_2$SO$_4$ poisoned and fresh Ni/SiO$_2$ and Ni–Ru/SiO$_2$ catalysts in the Ni 2p region.](image)
Additionally, the shoulder peak at 852 eV is attributed to the Ni$^{0}$ species [41]. It is noted that the poisoned Ni/SiO$_2$ and Ni–Ru/SiO$_2$ catalysts consists of the nickel in higher oxidation states (e.g., Ni$^{2+}$), possibly in oxidic or hydrated form, with small amounts of the Ni$^{0}$. It confirms that nickel was relatively easy to be oxidized in the presence of oxygen if no precautions are taken to prevent exposure of the discharged catalysts to air.

3.4. Adsorption Modeling

Although the activity loss in the presence of H$_2$SO$_4$ for the HI decomposition reaction is primarily due to competitive sulfur species adsorption at the active sites, the mechanism of the reactions between the sulfur-containing contaminants remains unclear, and the bimetallic effect may be complex. It is desirable to gain a further mechanism understanding of the chemical composition and particle structure in regard to competitive sulfur species adsorption, as this may contribute to the further exploration and the development of highly sulfur-tolerant Ni-based catalysts. Accordingly, computational modeling is used to assess the adsorption energies of HI and S on the bimetallic and Ni-based surfaces. In particular, dissociative sulfur-species adsorption has been shown to constantly happen on the surfaces or clusters of transition metals [42]. Therefore, the various structures of tetrahedral clusters are focused on modeling the Ni and bimetallic surfaces. Furthermore, the adsorption of HI on the Ru, Ni–Ru, and Ni clusters are explored. Figure 8a illustrates that the adsorption of HI on the Ni clusters appears to be much less significant than that on the Ni–Ru and Ru clusters. The HI absorption in the presence of Ru is much stronger, and this may be the major reason that Ni–Ru/SiO$_2$ demonstrates a better activity than that of Ni/SiO$_2$.

![Figure 8](image-url)  
**Figure 8.** The most probable adsorption model and energies of (a) HI adsorbed on Ru$_4$, Ni$_1$Ru$_3$, Ni$_2$Ru$_2$, Ni$_3$Ru$_1$, and Ni$_4$ clusters, and (b) S adsorbed on Ru$_4$, Ni$_1$Ru$_3$, Ni$_2$Ru$_2$, Ni$_3$Ru$_1$, and Ni$_4$ clusters.

Figure 8b presents the adsorption energies and the most stable geometries of S adsorption on the clusters. The differences in sulfur adsorption energies among the five kinds of clusters provides insights into the S resistance of the bimetallic catalysts. The adsorption energy of S on the pure Ni$_4$ surface is much more significant than on the Ru-containing clusters, suggesting that S deposition is lower on Ru compared to the Ni catalysts. Such adsorption S coverage will block the active sites and accelerate catalyst sintering. The
Ru₄ clusters show the lowest adsorption energy, demonstrating that S adsorption is less competitive on the Ru clusters than on the Ni–Ru or Ni clusters. Compared with the pure Ni₄ clusters, the higher sulfur tolerance of the Ni–Ru binary metal may be explained by the weaker S blocking. Thus, calculation results of the S adsorption are consistent with the above experimental investigations, as no NiSₓ crystals are observed experimentally on the Ni or Ni–Ru catalysts. The addition of Ru promotes activity and sulfur resistance of the catalyst for HI decomposition by reducing the S adsorption, as evidenced by the theoretical modeling analyses. Consequently, the Ni–Ru/SiO₂ catalyst can maintain a more significant activity and demonstrate increased sulfur-tolerance for HI decomposition.

Based on the previous analysis, it can be found that the addition of Ru can form a specific interaction with NiO and promote the reduction of NiO particles. The specific catalytic mechanism is shown in Figure 9. During the formation process of the Ni–Ru/SiO₂ catalyst, RuO₂ is firstly reduced to Ru metal particles at a relatively low temperature, and gradually correlates with NiO particles to form a NiO–Ru bimetallic structure. In the meantime, Ru can also activate H₂ and easily produces a hydrogen overflow phenomenon, which promotes the formation of a Ni–Ru bimetallic structure. Additionally, the active hydrogen species generated at Ru particles can easily spill into the adjacent NiO particles, thus promoting their reduction reaction. According to the theoretical simulation results, the presence of Ru can enhance the HI adsorption over Ni–Ru/SiO₂ catalyst. This makes the catalytic activity of Ni–Ru/SiO₂ catalyst better than that of Ni/SiO₂ catalyst. The Ni/SiO₂ catalyst does not show enhanced sulfur resistance since single metal Ni or NiO particles do not reduce the adsorption of sulfur while Ni–Ru/SiO₂ catalyst offers good sulfur resistance.

### 4. Conclusions

The effects of Ru addition on HI conversion and sulfur adsorption of Ni and Ni–Ru catalysts supported on SiO₂ have been investigated in this study. TPR, TEM-EDX, XRD, and XPS techniques were used to observe their physicochemical properties. The experimental trends in activity and sulfur tolerance are consistent with the theoretical modeling, with the catalytic activities existing in the order Ni/SiO₂ < Ni–Ru/SiO₂, as the addition of Ru to a Ni catalyst can promote HI adsorption. Modeling calculations were applied to identify bimetallic Ni–Ru surfaces with lower sulfur adsorption and to enhance HI adsorption energies. In the presence of trace S species, the specific S coverage on the catalysts blocked the active sites and enhanced sintering. The adsorption modeling results are consistent with the experiments for the supported bimetallic Ni–Ru catalysts, demonstrating that sulfur resistance for the HI decomposition reaction is promoted by the bimetallic Ni–Ru catalysts, which can reduce the competitive adsorption of sulfur and minimize the effect of sulfur poisoning. The activity and sulfur tolerance of the catalysts are highly dependent on HI and S adsorption. The presence of Ru can increase the HI–Ni₀ interaction and reduce S adsorption. Thus, a remarkable improvement in catalytic activity and sulfur tolerance of bimetallic Ni–Ru in HI decomposition was obtained, providing new insights for maintaining more significant activity during HI decomposition in the presence of sulfur.
