ABSTRACT

Context. In this paper we present ultra-deep images of the compact group of galaxies HCG 86 as part of the VEGAS survey.

Aims. Our main goals are to estimate the amount of intra-group light (IGL), to study the light and color distributions in order to address the main formation process of the IGL component in groups of galaxies.

Methods. We derived the azimuthally averaged surface brightness profiles in the $g$, $r$ and $i$ bands with $g - r$ and $r - i$ average colors and color profiles for all group members. By fitting the light distribution, we have extrapolated the contribution of the stellar halos plus the diffuse light from the brightest component of each galaxy. The results are compared with theoretical predictions.

Results. The long integration time and wide area covered make our data deeper than previous literature studies of the IGL in compact groups of galaxies and allow us to produce an extended (∼ 160 kpc) map of the IGL, down to a surface brightness level of ∼ 30 mag/arcsec$^2$ in the $g$ band. The IGL in HCG 86 is mainly in diffuse form and has average colors of $g - r > 0.8$ mag and $r - i > 0.4$ mag. The fraction of IGL in HCG 86 is ∼ 16% of the total luminosity of the group, and this is consistent with estimates available for other compact groups and loose groups of galaxies of similar virial masses. A weak trend is present between the amount of IGL and the early-type to late-type galaxy ratio.

Conclusions. By comparing the IGL fraction and colors with those predicted by simulations, the amount of IGL in HCG 86 would be the result of the disruption of satellites at an epoch of $z < 0.4$. At this redshift, observed colors are consistent with the scenario where the main contribution to the mass of the IGL comes from the intermediate/massive galaxies ($10^{10} \leq M_{*} \leq 10^{11} \text{M}_{\odot}$).

1. Introduction

In the A-Cold Dark Matter scenario, clusters of galaxies are expected to grow over time by accreting smaller groups (e.g. De Lucia et al. 2006). The intra-cluster light (ICL) is the end product of the material stripped from the galaxy outskirts and/or the disruption of dwarf galaxies during the infall of galaxies in the potential well of the brightest cluster galaxy (e.g. Rudick et al. 2010; Cui et al. 2014; Contini et al. 2014; Montes & Trujillo 2014; Jiménez-Teja et al. 2018; Pillepich et al. 2018; DeMaio et al. 2018; Henden et al. 2020; Contini et al. 2019; DeMaio et al. 2020). The ICL is therefore a diffuse and very faint component ($\mu_{g} \geq 27$ mag/arcsec$^2$) that grows over time during the infall process (Mihos 2015).

In this framework, extended and rich structures of clusters of galaxies form by the assembly of smaller elements of groups of galaxies, which have typical virial masses in the range $10^{13} - 10^{14} M_{\odot}$ (e.g. Bower & Balogh 2004). Galaxies spend most of their evolutionary life in groups (Miles et al. 2004; Robotham et al. 2011) and the intra-group light (IGL), which builds during the galaxy interactions and merging in these environments, is the precursor of the ICL in clusters of galaxies (e.g. Cañas et al. 2020). The ICL, as well as the IGL, are therefore key parameters to map the mass assembly history in all dense environments. Given the low-surface brightness levels involved, this is one of the most challenging tasks in the era of deep imaging and spectroscopic surveys. A great improvement has been possible in the last two decades thanks to the effort to study the low-surface brightness (LSB) structures in groups and clusters of galaxies, out to the intra-cluster regions (e.g. Slater et al. 2009; Ferrarese et al. 2012; van Dokkum et al. 2014; Watkins et al. 2014; Duc et al. 2015; Mihos 2015; Fliri & Trujillo 2016; Muñoz et al. 2015; Merritt et al. 2016; Mihos et al. 2017a; Watkins et al. 2016; Trujillo & Fliri 2016; Mihos et al. 2017b; DeMaio et al. 2018; Huang et al. 2018a; Montes & Trujillo 2019; Zhang et al. 2019; DeMaio et al. 2020; Montes & Trujillo 2021; Martinez-Delgado et al. 2021; Cantiello et al. 2021; Cantiello et al. 2021).
et al., 2021]. The VST Early-type Galaxy Survey (VEGAS\footnote{Visit the website \url{http://www.na.astro.it/vegas/VEGAS/Welcome.html}}) has played a pivotal role in this field. By combining the large field of view of OmegaCAM@VST and long integration time, VEGAS data allow us to map the surface brightness of galaxies down to $\mu_{g} \sim 30$ mag/arcsec$^2$ and out to about 10 effective radii ($R_e$), to estimate the ICL/IGL and therefore to relate galaxy structure to the environment (see Rodčík et al., 2017; Spavone et al., 2018; Catapan et al., 2019; Rodčík et al., 2019; Spavone et al., 2020; Raj et al., 2020, and references therein).

In this paper we present new deep images of the Hickson Compact Group HCG 86, as part of the VEGAS sample. Hickson compact groups (HCGs) host from four to ten very close galaxies (Hickson, 1982), with low velocity dispersion ($\sim 200$ km/s) and angular size (i.e. angular diameter of the circle containing the group) in a range of $0.7 - 16.4$ arcmin. The compact configuration makes HCGs among the best sites to study the IGL, since the frequent galactic interactions and intense stripping are very efficient mechanisms in the build-up of the diffuse light component. The most recent studies of IGL in HCGs estimated an IGL fraction ranging from 0% up to 46%, compared to the total light of the group and a maximal extension of 80 kpc from the group center (Da Rocha & Mendes de Oliveira, 2005; Da Rocha et al., 2008). HCG 79 is the most compact group in the Hickson catalogue (Hickson, 1992) and Da Rocha & Mendes de Oliveira (2005) find a very large amount of IGL in this group, about 46% of the total group light. The IGL component presents an irregular shape and there are signs of strong past interactions between group members, which induced bars, tidal tails and dust lanes. They conclude that this group is in a very advanced stage of evolution, close to collapse into a single structure. In contrast no IGL component was detected in HCG 88, formed by four late-type galaxies (Da Rocha & Mendes de Oliveira, 2005). In the group 90% of the neutral HI gas is still associated with the galaxy disks (Verdes-Montenegro et al., 2001), suggesting that it is in an early phase of its evolution. According to the IGL fraction and galaxy morphologies, the other HCGs analyzed in previous works seem to be at intermediate stages of their evolution (Da Rocha & Mendes de Oliveira, 2005). HCG 95 presents a spherical IGL component that corresponds to about 10% of the total light of the group, and to about one third of the total light of HCG 95A, the brightest group galaxy (BGG). Since there are clear signs of interactions between HCG 95A and HCG 95C, the IGL probably formed by the stripping of material from the interacting galaxies (Da Rocha & Mendes de Oliveira, 2005). In HCG 15, HCG 51 and HCG 35 the IGL fraction is very similar, at 19%, 26% and 15% of the total light of the group. These components have irregular morphologies, suggesting that these HCGs are far from being relaxed and virialized structures (Da Rocha et al., 2008). Recently, Polisakov et al. (2021) studied the IGL in a large sample of HCGs. Authors found that the average surface brightness for IGL is in a range of $25.3 < \mu_r < 28.3$ mag/arcsec$^2$ for all groups in the sample, and the fraction in five groups ranges from 7.5% to 25.1%. They concluded that the mean surface brightness of the IGL depends on the total luminosity of the group and becomes brighter in the groups with a larger fraction of early-type galaxies.

The Hickson compact group HCG 86 is a quartet of early-type galaxies (ETGs), with a virial mass of $M_{vir} = 8.51 \times 10^{12} M_\odot$ (Coziol et al., 2004), located at a distance of 81.73 Mpc (Hickson, 1992). The mass-to-light ratio of the group in the K-band is 50, and the average velocity dispersion of the group members is 368 km/s (see Tab. I; Díaz-Giménez et al., 2012). According to Proctor et al. (2004), the two brightest members of the group, HCG 86A and HCG 86B, are $12.8$ Gyr and $9$ Gyr old, respectively, based on ages and metallicities of unresolved (integrated light) stellar populations, measured from Lick system analysis. Ribeiro et al. (1998) analyzed the structural and dynamical properties of HCG 86 in a region of $0.5 \times 0.5$ around the group. They found that HCG 86 has the most members and is the most complex group of their catalogue, since it consists of two different kinematic structures, centred on the BGG HCG 86A and on HCG 86B. Based on their analysis, the authors proposed two possible scenarios for group formation: it could be a bimodal structure in a merging process, or it is a single group, not relaxed yet, where HCG 86B is an extension of HCG 86A in the velocity space. In the latter case, considering the numerous dwarf galaxy members ($\sim 18$, Ribeiro et al., 1998), HCG 86 turns to have the most members and be the complex group in the HCGs catalogue. On a larger scale, HCG 86 seems to be part of a loose cluster of galaxies, which is not dynamically relaxed. The particular configuration of HCG 86 can give key insights into the formation of IGL. The new multi-band images presented in this work represent the deepest data available to study the IGL in the HCG environment. This pilot work shows what can be achieved in low surface brightness (LSB) analysis for groups of galaxies.

This work is organized as follows. In Sec. 2 we present the observations and the data reduction. In Sec. 3 we describe in detail the method used for the data analysis (i.e. the surface photometry). In Sec. 4.1 we present the results on the intra-group light in HCG 86 and in Sec. 5 we compare our results with the previous ones presented in the literature, both on the observational and theoretical side. In Sec. 6 we summarise the results obtained in this study and draw conclusions.

We have adopted a distance for HCG 86 of 81.73 Mpc. To estimate all the distances of this work we used the heliocentric radial velocity (see Tab. 2, given by NED (NASA IPAC Extragalactic Database), and $H_0 = 73$ km s$^{-1}$ Mpc$^{-1}$ (Riess et al., 2018). Therefore, 1 arcsec corresponds to $\sim 0.4$ kpc. The magnitudes through out the paper are provided in the AB system, and are corrected for Galactic extinction using the extinction coefficients provided by Schlafly & Finkbeiner (2011).

2. Deep images of HCG 86: observations and data reduction

The data presented in this work are from the VEGAS survey. VEGAS is a multi-band $u, g, r$ and $i$ imaging survey carried out with the European Southern Observatory (ESO) Very Large Telescope Survey Telescope (VST). The VST is a 2.6 m wide field optical telescope (Schipani et al., 2012) equipped with OmegaCAM, a $1^\circ \times 1^\circ$ camera with a resolution of 0.21 arcsec pixel$^{-1}$. The data we present in this work were acquired in visitor mode (run ID: ID:103.A-0181A), during dark time in photometric conditions, with an average seeing of $FWHM \sim 0.99$ arcsec in the $g$ band, $FWHM \sim 0.65$ arcsec in the $r$ band and $FWHM \sim 1.4$ arcsec in the $i$ band. The $g$-band image is the deepest one, with an exposure time of 5 hours. The total integration time in the $r$ and $i$ bands are 3.25 hours and 2.05 hours, respectively. Observations were acquired adopting the standard diagonal dithering strategy. As described in Capaccioli et al. (2015) and Spavone et al. (2017), for the targets observed with this strategy, the background subtraction is performed by fitting a surface, typically a 2D polynomial, to the pixel values of the mosaic that are unaffected by celestial sources or defects.

Notes. Col.1: Group ID. Col.2 and Col.3: right ascension and declination of the HCG 86 centre. Col.4: median velocity of the group. Col.5: number of galaxy members in the HCG 86 within 3 mag of the brightest member. Col.6 and 7: Galactic extinction-corrected K-band apparent magnitude of the brightest galaxy and the Galactic extinction-corrected K-band group surface brightness. Col.8: angular diameter of the smallest circumscribed circle around group members. Col.9: median projected separation among galaxies. Col.10: apparent group elongation. Col.11: radial velocity dispersion of the galaxies in the HCG 86 computed using individual galaxy velocities. Col.12: dimensionless crossing time. Col.13: mass-to-light ratio in the K band. Col.14 and 15: virial mass and virial radius of the group (Coziol et al. 2004).

Fig. 1. Color composite (gri) VST image of the compact group HCG86. The image size is 0.62 x 0.51 degrees. North is up and East is to the left. The brightest group members are labelled on the image. The red crosses mark the stars that were modelled and subtracted from the image before the analysis of the galaxies. See Sec. 3 for details.

All the data were processed using the dedicated AstroWISE pipeline developed to reduce OmegaCam observations (McFarland et al. 2013; Venhola et al. 2018). The various steps of the AstroWISE data reduction were extensively described in Venhola et al. 2017, 2018.

In Fig. 1 we show the resulting sky-subtracted color composite VST image obtained for HCG 86. The surface brightness depths at 5σ over the average seeing area of FWHM=1.26 arcsec, are $\mu_g = 30$ mag/arcsec$^2$, $\mu_r = 29$ mag/arcsec$^2$ and $\mu_i = 28$ mag/arcsec$^2$ in the g, r and i band respectively.
3. Data Analysis: surface photometry

Fig. 2 shows an enlarged region of the deep VST image in the g band centred on the HCG 86 group. The deeper VST data shows a large amount of diffuse light, mainly located in the galaxies’ envelopes. The diffuse light is at least two times more extended than the brightest central regions of the group members. In addition, in the Southern part of the group, we detect a faint stellar bridge ($\mu_r \sim 27.8 - 29.1$ mag/arcsec$^2$) connecting HCG 86C with the group center of about 1.2 arcmin long and 1 arcmin wide, and two faint streams (~ 1.2 arcmin long) protruding from the SE regions of HCG 86A (these are marked with red arrows in Fig. 2). There is also an extended region of diffuse light in the North of the group located about 4 arcmin from the group centre, but this could be due to light emitted from Galactic cirrus, which contaminates the area (see details in Sec. 3.2). Similar features stand out from the unsharp-masked g-band image, shown in Fig. 3. This has been obtained using the FMEDIAN task in IRAF, with smoothing boxes of 50 x 50 pixels, and taking the ratio of the g-band image to its FMEDIAN smoothed version. The image shows the extended envelope of diffuse light associated with the group, which is symmetrically distributed around the galaxies, and the cirrus emission on the West and North-East sides. The bridge connecting the group with HCG 86C and the South-East filamentary structure are also well defined in shape. The small smoothing box allow us to reveal the internal structure of the group members: HCG 86A has a disk in the central part of the group, HCG 86B with the group center of about 1.2 arcmin long and 1 arcmin wide, and two faint streams (~ 1.2 arcmin long) protruding from the SE regions of HCG 86A (these are marked with red arrows in Fig. 2). There is also an extended region of diffuse light in the North of the group located about 4 arcmin from the group centre, but this could be due to light emitted from Galactic cirrus, which contaminates the area (see details in Sec. 3.2). Similar features stand out from the unsharp-masked g-band image, shown in Fig. 3. This has been obtained using the FMEDIAN task in IRAF, with smoothing boxes of 50 x 50 pixels, and taking the ratio of the g-band image to its FMEDIAN smoothed version. The image shows the extended envelope of diffuse light associated with the group, which is symmetrically distributed around the galaxies, and the cirrus emission on the West and North-East sides.

The bridge connecting the group with HCG 86C and the South-East filamentary structure are also well defined in shape. The small smoothing box allow us to reveal the internal structure of the group members: HCG 86A has a disk in the central part of the group, HCG 86B with the group center of about 1.2 arcmin long and 1 arcmin wide, and two faint streams (~ 1.2 arcmin long) protruding from the SE regions of HCG 86A (these are marked with red arrows in Fig. 2). There is also an extended region of diffuse light in the North of the group located about 4 arcmin from the group centre, but this could be due to light emitted from Galactic cirrus, which contaminates the area (see details in Sec. 3.2). Similar features stand out from the unsharp-masked g-band image, shown in Fig. 3. This has been obtained using the FMEDIAN task in IRAF, with smoothing boxes of 50 x 50 pixels, and taking the ratio of the g-band image to its FMEDIAN smoothed version. The image shows the extended envelope of diffuse light associated with the group, which is symmetrically distributed around the galaxies, and the cirrus emission on the West and North-East sides.

The main goal of this work is to estimate the diffuse light in the intra-group region. To this aim, two main steps are needed in the data analysis: i) the contamination from all sources (foreground stars, background galaxies and cirrus emission) that contribute to the light must be carefully taken into account; ii) the light distribution from the bright group members must be modelled and subtracted from the total budget of the emitted light associated with the group (i.e. galaxy light plus IGL). In the following sections we describe the tools and methods adopted in each step. They have all been successfully applied to the previous VST images and optimised to detect and study the LSB features, including the ICL, in several already published papers (see Iodice et al. [2017], Spavone et al. [2018], Cattapan et al. [2019], Iodice et al. [2019, 2020], Spavone et al. [2020], Raj et al. [2020]).

3.1. Galactic Cirrus emission in region of HCG 86

The Galactic cirrus emission is a non-negligible source of contamination in LSB imaging. In the optical, the Galactic cirrus emission is due to the starlight belonging to the Milky Way, diffused by dust in the local interstellar medium, and then re-emitted in the infrared. Therefore, images in the infrared can be used to evaluate the importance of this contamination. In deep optical imaging, such emission creates pseudo-structures that resemble LSB features, like tidal tails or stellar streams (Cortese et al. [2010], Mihos [2019], Duc et al. [2015]). In Fig. 2 many filamentary structures typical of cirrus are clearly visible. The most prominent is in the West, extending North-South for about ~ 20 arcmin. From the NASA/IPAC Infrared Science Archive we derived the 100 $\mu$m map in the region of the HCG 86 group, shown in Fig. 4. The 100 $\mu$m map confirms that light from cirrus dominates in the filamentary structure in the West and also in the South-East of the group. Lower emissions are observed North/North-East and to the South-West of the group.

The lower spatial resolution of the IRAS map does not allow us to resolve all of the features visible in the VST optical images.

The contribution of the cirrus emission to the diffuse light in HCG 86 will be discussed in detail in Sec. 4.2. At this step of the analysis, we derive the intensity contours of the Galactic cirrus emission from the 100 $\mu$m map (see left panel of Fig. 4) to build an accurate mask of all the regions contaminated by the cirrus emission. This is used in the fitting of the light distribution of stars (Sec. 3.2) and galaxies (Sec. 5.3) in order to exclude this contribution from the analysis.

3.2. Removal of the scattered light from the bright stars

In order to remove the contamination of the scattered light from the brightest stars in the field, we performed a 2-dimensional (2D) fit of the light distribution by adopting a circularly symmetric model for each of them. This is based on the isophote fit using the IRAF task ELLIPSE (fixing the centre, position angle and ellipticity), mapping the light almost out to the edge of the frame, i.e. ~ 33 arcmin. This fit was carried out after having carefully masked the core of the group, all background and foreground sources, and all the regions affected by the Galactic cirrus emission (see Sec. 3.1). In order to preserve the light associated with the group, including the faint emission from the IGL, we adopted a circular mask centred on the brightest group member HCG 86A with a radius of 13.5 arcmin. This value corresponds to ~ 0.8 the virial radius of the group (see Tab. 1).

We derived a 2D model of each star using the IRAF task BMODEL, and this was then subtracted from the image. Six stars are modelled in the field two on the East side, two on the West side and one more on the South side of HCG 86C (marked in Fig. 1), all brighter than $m_B = 9.48$ mag. The star next to HCG 86D was also modelled and subtracted to prevent its scattered light from affecting the light profile of the galaxy. Since the 2D model we performed for the brightest stars is symmetric, it cannot account for the bright ghosts that are present around them. They are due to the asymmetry of the point-spread functions, which depends on their position in the camera. However, they do not contribute to the scattered light at larger distance from each stars, which is the contribution that we aim at estimating for the purpose of this work. Therefore, once the symmetric model is subtracted from the parent image, the residuals around each star and the ghosts are masked.

3.3. Estimate of the limiting radius and isophote fitting

To derive the azimuthally averaged surface brightness profiles for the brightest group members, in all bands, we used the method from Pohlen & Trujillo (2006), which has also been used for the analysis of VST data by Iodice et al. (2016) and in all subsequent papers based on VEGAS data. This is based on two steps: 1) estimate of the limiting radius $R_{lim}$, and 2) fit of the isophotes out to $R_{lim}$ for each galaxy of the group.

The limiting radius $R_{lim}$ sets the limit of the data, where the galaxy’s light blends into the background fluctuations and the...
signal-to-noise ratio (S/N) is about one. Since the images are sky-subtracted, the background fluctuations are the deviations with respect to the average sky value. To estimate \( R_{\text{lim}} \) and the background fluctuations (which also provide an estimate of the accuracy of the sky-subtraction and flat-fielding) we have performed the fit of the isophotes, of the brightest group members HCG 86A and of HCG 86C (which maps a different region of the image) out to the edge of the star-removed image, in each band. According to Pohlen & Trujillo (2006), this is done over elliptical annuli (i.e. fixing the ellipticity and position angle), by using the IRAF task ELLIPSE with a median sampling and k-sigma clipping algorithm for cleaning deviant sample points at each annulus. The extensive experience acquired with previous works, shows that this approach (i.e. combining the median sampling and sigma clipping rejection algorithm) improves the isophotal fitting. Since all the other bright group members (HCG 86B and HCG 86D) are close in space to HCG 86A, we can reasonably assume the same value of \( R_{\text{lim}} \) derived for HCG 86A. At this step, we made two new masks. One is needed to exclude from the fit all sources outside the group region (including previous identified background and foreground sources, plus the cirrus emission and residuals around the bright stars, that were subtracted from the image, see Sec. 3.1 and Sec. 3.2) and all the other group members except HCG 86A. For each galaxy, the masking process is very accurate in order to take into account the symmetry of the object and the region overlapping with HCG 86A. The second mask is adapted to exclude also the group center, and allow us to perform the fit centered on HCG 66C.

In Fig. 5 we show the fitted isophote intensity as a function of the semi-major axis (sma) centered on HCG 86A (HCG 86B and HCG 86D share the same envelope as HCG 86A) and HCG 86C. Both fits provide consistent values for \( R_{\text{lim}} \), with \( R_{\text{lim}} = 6.67 \) arcmin in the \( g \) band and \( R_{\text{lim}} = 8.33 \) arcmin in the \( r \) band. Since the \( r \)-band images are shallower, the limiting radius is smaller, \( R_{\text{lim}} = 2 \) arcmin, for both regions. The S/N is shown in the lower panels of Fig. 5. At \( R \geq R_{\text{lim}} \) from the galaxy center S/N \sim 1 - 3 in both \( g \) and \( r \) bands, and the residual background fluctuations are \( I_g = -0.29 \pm 0.05 \) ADU, \( I_r = -0.39 \pm 0.09 \) ADU and \( I_i = 0.10 \pm 0.1 \) ADU in the \( g \), \( r \) and \( i \) bands, respectively. These values have been taken into account to compute the corresponding surface brightness magnitude limits and error estimate. The total uncertainty on the surface brightness magnitudes takes into account the uncertainties on the photometric calibration (~ 0.003 - 0.006 mag) and the RMS in the background fluctuations. They have been calculated with the following formula: 
\[
\text{err} = \sqrt{(2.5/\text{adu} \times \ln(10))^2 \times ((\text{err}_{\text{adu}} + \text{err}_{\text{sky}})^2 + \text{err}_{\text{zp}}^2)}
\]
where \( \text{err}_{\text{adu}} \) is the rms on the sky background and \( \text{err}_{\text{zp}} \) is the error on the photometric calibration (Capaccioli et al. 2015; Seigar et al. 2007).
3.4. Fit of the galaxy light distribution

In order to estimate the total amount of the IGL, the contribution to the light of the brightest inner regions of the galaxies in the group must be modelled and subtracted. As mentioned in the previous section, this is an iterative process made of the following steps. For each of the four brightest group members, starting with HCG 86A, and in each band, we have:

1. Performed the isophote fit (see Sec. 3.3) to derive the azimuthally-averaged surface brightness profile, out to $R_{\text{lim}}$
2. Fitted the 1-dimensional (1D) profiles adopting multi-component empirical laws to estimate the transition radius $R_{\text{tr}}$ between the brightest central region of the galaxy and the faintest outskirts.
3. Derived the 2D model of the inner component at $R \leq R_{\text{tr}}$, using the IRAF task BMODEL, and subtracted it from the entire image. On this residual image we perform the isophote fit of each group member in turn. A new mask is made at each step of the fitting analysis, where all contributions from background/foreground objects, cirrus emissions, residuals from subtracted stars are included. In addition, at each step, the residuals of the subtracted 2D model of the brightest regions of each galaxy is also masked and excluded from the fit.

The first fit was performed on the brightest group member, HCG 86A, since it dominates the light distribution. The resulting azimuthally average surface brightness and color profiles for HCG 86A are shown in Fig. 6, where R corresponds to the semi-major axis (sma) in arcmin. We map the surface brightness profiles down to $\mu_g \sim 30 \text{ mag/arcsec}^2$, $\mu_r \sim 28 \text{ mag/arcsec}^2$ and $\mu_i \sim 26 \text{ mag/arcsec}^2$ in the g, r and i band, respectively.

To proceed with the isophote fit for all the other group members, it is necessary to model and subtract the light distribution of each galaxy in the group. To this aim, we need to derive the transition radius $R_{\text{tr}}$ between the brightest parts and the faint outskirts. This is derived by performing the 1D decomposition of the galaxies’ azimuthally-averaged surface brightness profiles. We adopted the fitting procedure introduced by Spavone et al. (2017), also used in other VEGAS papers (see e.g. Spavone et al. 2018, 2020; Cattapan et al. 2019; Iodice et al. 2016, 2020).
Rossella Ragusa et al.: VEGAS: A VST Early-type GAlaxy Survey.

Fig. 4. **Left panel** - Cirrus map derived from the 100µm image available at the NASA/IPAC Infrared Science Archive, with superimposed contours (blue) in the flux interval from 9.25 – 9.78 MJy/sr. **Right panel** - Residual image in the g band, where the brightest regions of the group members were subtracted from the original image. The image is 35 × 30 arcmin. The blue lines are the cirrus intensity levels shown in the left panel. The dashed black circle indicates the circular region of $R = 600$ arcsec. The green cross indicates the centre of the HCG 86 group in both panels. The residual image shows an extended envelope of diffuse light symmetrically distributed around the group, as already pointed out from unsharp-masked image of HCG 86 (see Fig. 3).
Fig. 5. Top panels: Intensity profiles for HCG 86A (left panel) and HCG 86C (right panel) in the $g$ and $r$ bands. The two vertical dashed lines show the estimated value for $R_{lim}$ for each band and the horizontal lines indicate the average value of the residual background fluctuations in each band. Bottom panels: Signal to noise ratio profiles for HCG 86A (left panel) and HCG 86C (right panel) in the $g$ (blue points) and $r$ (green points) bands. The vertical dashed lines indicate the $R_{lim}$ for each band and the horizontal lines indicate the zero value for signal to noise ratio. The bump observed at $\sim$ 1000-2000 pixels, in both $g$ and $r$ profiles centred on the HCG 86C, reasonably corresponds to the IGL contribution around the core of the group.

This is motivated by several observational and theoretical works, which suggested that the stellar envelope in the galaxies’ outskirts can be reproduced by adding an additional component to the Sérsic law, which fits well the inner and brightest regions of the galaxy (Seigar et al. 2007; Donzelli et al. 2011; Arnaboldi et al. 2012; Iodice et al. 2016; Spavone et al. 2017, 2020). As addressed in these studies, based on the photometry alone, the contribution of the diffuse light cannot be separated from the stellar envelope (e.g. González et al. 2007; Seigar et al. 2007). However an estimate of the total contribution from the faint out-
skirts (i.e. stellar envelope plus diffuse light) can be disentangled from the bounded and bright emission in galaxies by fitting the total integrated light with analytic models. This is particularly enhanced in compact groups (as HCG 86) where galaxies are so close in projection that their stellar envelopes merge with each other, fully engulfing the intra-group diffuse light.

In all HCG 86 group members, we used a Sérsic law to model the main body of the galaxies and an exponential law to reproduce the diffuse component (stellar halo plus the IGL). The results of the fit are provided in Appendix A. The best-fitting parameters are reported in Tab. A, including $R_{\text{tr}}$.

The 1D fit of HCG 86A shows an extended exponential component in the outskirts, at $R \geq 51$ arcsec ($\sim 20.4$ kpc), with a...
central surface brightness of \( \mu_0 = 26.30 \text{mag/arcsec}^2 \) and a scale length \( r_s = 132 \text{ arcsec} (~53 \text{ kpc}) \) in the g band. Based on the 1D-fitting results, the 2D model for HCG 86A has been made for the brightest regions of the galaxy, i.e. for \( R \leq R_e = 51 \text{ arcsec} \), and then subtracted from the image in each band. Using the residual image, the other two galaxies in the core of the group, HCG 86B and HCG 86D, have been modelled in turn, i.e. the azimuthally-averaged surface brightness profiles are obtained from the isophotal analysis and then fitted. As expected, since they are all physically close in projection and completely embedded in a diffuse stellar halo, the surface brightness profiles all show the extended outer exponential component (see Fig. 6).

Based on the 1D fit, we have modelled and subtracted only the brightest regions of each galaxy (i.e. out to their \( R_e \)) and, consistently, the remaining outer component has a scale length of the same order of magnitude and comparable \( \mu_0 \) (see Tab. 3). As a final step, on the resulting image where all the three galaxies in the core of the group have been modelled and subtracted, we have performed the analysis of HCG 86C, the S0 galaxy located to the SE of the group centre (see Fig. 1). The surface brightness profiles for this object also show an extended envelope in g and r bands, as detected for the three galaxies in the core of the group (see Fig. 3).

The resulting final residual image where all the 2D models of the brightest regions of group members have been subtracted, is shown in the right panel of Fig. 4. This image is then used to estimate the total amount of IGL in the group, assumed to be the contribution of the stellar envelope plus the diffuse light in the intra-group medium.

4. Results

For all the galaxies in the group, the isophote fits give the azimuthally-averaged surface brightness and color profiles as output, shown in Fig. 6. Because the g and r images are deeper than the i-band, the \( g - r \) color profiles are more extended in radius (out to ~6 arcmin) than the \( r - i \) (out to ~0.5 – 2 arcmin). For the galaxies in HCG 86 a gradient toward redder colors (~1.2 – 2 mag) is observed in all the \( g - r \) profiles at \( R \geq 2 - 4 \text{ arcmin} \). As discussed in detail later in Sec. 4.2, the region where HCG 86 group resides is contaminated by the Galactic cirrus emission. Therefore, we suspect that the observed reddening is due to this contamination, which is stronger in the r band with respect to the g band (Román et al. 2020). This change in slope in the color profile was observed by Watkins et al. (2016) for the spiral galaxy M64, where the \( g - r \) color profiles of the galaxies get redder with radius, and is addressed by cirrus contamination.

This effect does not occur in the \( r - i \) color since the cirrus in these bands has a comparable emission (for details see also Fig. 2 of Román et al. 2020), even though the \( r - i \) color profile of the BGG (see top panel in Fig. 5) becomes shallower at \( R > 0.9 \text{ arcmin} \). As described in detail in the following section, this corresponds to the transition radius of the HCG 86A, beyond which the IGL component begins to be present. A similar trend in the \( r - i \) color profile was also found in several works (e.g. Zibetti et al. 2005; Coccato et al. 2008; Greene et al. 2015). In particular, for the Abell Cluster 85, Montes et al. (2021) suggested that the reddening in \( r - i \) color profile, at larger radii, could be an observational evidence of ICL as accreted stars on the BCG.

Finally, from the azimuthally-averaged surface brightness profile we have derived the total magnitude for each group member and, therefore, the integrated \( g - r \) and \( r - i \) colors. These are reported in Tab. 2. The total luminosity of the four brightest group members, which includes the brightest central parts, the stellar envelope and IGL, is \( L_{TOT}^\ast = 1.76 \times 10^{11} L_\odot \) and \( L_{TOT}^i = 2.8 \times 10^{11} L_\odot \), in the g and r bands respectively.

4.1. The intra-group light in HCG 86

The residual image, obtained by subtracting the models of the brightest stars and galaxies of the group (see Sec. 3.2 and Sec. 3.3), derived in the g band, is shown in Fig. 6. This image reveals the distribution of the diffuse intra-group light in HCG 86. The HCG 86 group is fully embedded in an extended envelope of diffuse light, indistinguishable from the stellar halos of the brightest galaxies, elongated in the West-East direction, like the distribution of the members of the group. Several faint filamentary structures, also noted in the original image in Fig. 3, are present in the Southern regions of HCG 86A, where the contamination from the cirrus’s light is at a minimum (see Sec. 4.2).

From this image we have derived the azimuthally-averaged surface brightness profiles of the IGL, in both g and r bands, by fitting the light distribution in circular isophotes, fixing the centre in HCG 86A. These are shown in Fig. 7. We adopted the same mask used for the surface photometry of the galaxies, where all bright sources (foreground stars and background galaxies) and the regions contaminated by cirrus emission (right North of the group and the filament to the West, see Fig. 4) are excluded from the fit. The g and r IGL surface brightness profiles extend out to the limiting radius estimated from the isophote fit for each band (see Sec. 3), i.e. out to 6.67 arcmin (~160 kpc) and down to ~30 mag/arcsec² in g band from the centre of HCG 86A, and out to 8.33 arcmin (~200 kpc) and down to ~29 mag/arcsec².

| Galaxy | Morph. | R.A. | Decl. | He-rad. | \( m_g \) | \( m_g[R \leq R_e] \) | \( R_e,g \) | \( R_e,r \) | g-r | r-i |

Notes. Column 1 report the name of the HCG 86 group members. In Col 2 is given the morphological type. In Cols 3 and 4 are listed the celestial coordinates of each group member. In Col 5 is listed the heliocentric radial velocity. Velocities for HCG 86 A, HCG 86 B and HCG 86 D are from de Carvalho et al. (1997), while that for HCG 86 C is from Jorgensen et al. (1995). In Cols 6 and 7 are reported the total magnitude and the total magnitude at the transition radius in g band, while in Cols 8 and 9 list the effective radius in the g band, in arcsec and kpc respectively. The average \( g - r \) and \( r - i \) colors, derived up to transition radius, are listed in Cols 10 and 11. Magnitudes and colors were corrected for Galactic extinction using the extinction coefficients provided by Schlafly & Finkbeiner (2011).

Notes. Columns 2, 3, 4, 5 report the effective surface brightness, effective radius (in arcsec and kpc scale) and Sérsic index for the inner component of each fit, in the g band, whereas columns 6, 7 and 8 list the central surface brightness and scale length for the outer exponential component, in arcsec and kpc scale. Columns 9 and 10 give a transition radii, in arcsec and kpc scale respectively, derived by the intersection between the first and the second component of the fit.[4]

in r band from the centre of HCG 86A. We map the g − r color profile of the IGL out to 160 kpc. This is the most extended estimate of the IGL derived in a group of galaxies. Previous observations find that the IGL in HCGs spans a range in radii from 30 to 80 kpc from the center of the group (Da Rocha & Mendes de Oliveira 2005; Da Rocha et al. 2008). Recent measurements by Poliakov et al. (2021) map the IGL out to R_r ∼ 100 kpc.

In the inner regions (R ≤ 100 kpc) the IGL profiles have an exponential decrease which resembles the contribution of the stellar envelopes. At larger radii, it is shallower and this might be the "pure" contribution of the diffuse and not-bound light in the group. These components cannot be separated using photometry alone, and deep spectroscopic observations are needed. Therefore, as has been the custom for previous photometric studies of IGL and ICL using multi-component fits, (Seigar et al. 2007; Gonzalez et al. 2007; Zibetti et al. 2005), we refer to the IGL as the contribution from the stellar envelope (see Sec. 3.4) plus the diffuse light in the outskirts. The IGL surface brightness profile for the HCG 86 group is compared with the average ICL profile derived by Zibetti et al. (2005) for galaxy clusters (at z ∼ 0.25; see Fig. 7). In the region where the intra-cluster light dominates (at R ≳ 100 kpc), both distributions have a comparable surface brightness (μ_{e,g} ∼ 29−31 mag/arcsec^2) in the g band. At smaller radii, the IGL surface brightness profile is mainly dominated by the light distribution of the stellar envelopes around the group members (≈ 26.5−28.5 mag/arcsec^2 in the g band). In the bottom panel of Fig. 7 we show the azimuthally averaged g − r color profile for the IGL in HCG 86. It is constant at g − r ∼ 0.75 mag for R ≤ 120 kpc. At larger radii, the colors tend to be redder, as also observed in the color profiles derived for each galaxy of the group (see Fig. 5). As discussed in Sec. 4.2, this could be due to contamination from cirrus. An average g − r ∼ 0.75 mag for the IGL in HCG 86A is comparable with the average value derived by Zibetti et al. (2005) for ∼ 600 stacked galaxy clusters (scaled at the redshift of HCG 86, see Fig. 7). Moreover, such a value is consistent with the g − r colors derived in other groups and galaxy clusters, where g − r ∼ 0.68 mag in the Abell Cluster 2744 at z=0.3 (Montes & Trujillo 2014), g − r ∼ 0.7 mag in the Fornax Cluster (Codise et al. 2017; Raj et al. 2020) and also consistent with g − i ∼ 1.3 mag found in the Abell Cluster 85 (Montes et al. 2021).

Since we consider that the IGL profile could be contaminated by cirrus emission at R ≤ 120 kpc, we have derived two different estimates of the total integrated flux for the IGL in HCG 86, in the g and r bands. In a circular area centred on the BGG (HCG 86A), a conservative value is derived within R ≤ 120 kpc, where the surface brightness and colors are comparable with previous studies, and a second value has been obtained by including the whole IGL profile out to 160 kpc. The extinction-corrected magnitude of the IGL within 120 kpc is m_g = 13.9 ± 0.1 mag in the g band, with an average color of g − r = 0.83 ± 0.3 mag. Within this radius, i) the total luminosity of the IGL is L_{IGL}^g = 2.80 × 10^{10} L_⊙ and L_{IGL}^r = 3.02 × 10^{10} L_⊙ in g and r bands respectively, and ii) the fractions of IGL with respect to total luminosity of the group (given in Sec. 5) are ≳ 16 ± 3% and ≳ 11 ± 2% in the g and r bands, respectively. Since the total luminosity of the BGG HCG 86A is L_{vir}^g = 9.55 × 10^{11} L_⊙ in the g band and L_{vir}^r = 1.29 × 10^{11} L_⊙ in the r band, the IGL fraction with respect to the BGG is ∼ 28 ± 5% and ∼ 23 ± 7% in the g and r band, respectively.

At R < 160 kpc, the extinction-corrected magnitude of the IGL is m_g = 13.7 ± 0.2 mag in the g band, with an average color of g − r = 0.85 ± 0.3 mag. The total luminosity of the IGL is L_{IGL}^g = 3.35 × 10^{10} L_⊙ and L_{IGL}^r = 3.79 × 10^{10} L_⊙ in g and r bands respectively. The fractions of IGL with respect to the total luminosity of the group (given in Sec. 5) are ≳ 19 ± 3% and ≳ 14±2% in the g and r bands, respectively. The two estimates of the IGL fraction provided above are consistent within the uncertainties and are within the estimated contamination of the cirrus (see Sec. 4.2). The fractions of IGL at R < 160 kpc, with respect to the luminosity of the BGG are ∼ 35 ± 5% and ∼ 29±6% in the g and r bands, respectively. By photometric decomposition with double Sérsic decomposition, Kluge et al. (2021) found a ICL/BCG fraction in a range of 31% ≤ ICL/BCG < 73%, which is consistent with our results. The BGG (BBG+IGL) fraction in HCG 86 is equal to 60%, in agreement with the simulations performed by Contini & Gu (2021) for a halo with M_{vir} ∼ 10^{13} M_⊙.

The average colors derived for the IGL in HCG 86 are also comparable with values published by Da Rocha & Mendes de Oliveira (2005) and Da Rocha et al. (2008), for their detailed analysis of the IGL in compact groups. They found that the B-R colors for the IGL range from 0.85 − 1.75 mag, which corresponds to g−r ∼ 0.3−0.8 mag, adopting the color transformation from Kostov & Bonev (2018).

4.2. Cirrus contamination

As reported in the Sec. 5.1, the field around HCG 86 is affected by the contamination of Galactic cirrus. In order to provide an accurate estimate of the IGL, we need to quantify the amount of contamination from cirrus. From the 100μm map we have estimated the minimum and maximum values of the flux along the

[5] The IGL magnitudes and color were corrected for Galactic extinction using the extinction coefficients provided by Schlafly & Finkbeiner (2011).
filament to the West, which is assumed to be pure cirrus emission. These values range from 9.25 to 9.78 MJy/sr. According to the location of HGC 86 in the 100 µm map, the group resides in a region where the cirrus emission is about 9.30 MJy/sr, so very close to the minimum (see Fig. 4). Therefore, we expect that the contribution of the cirrus’ light to the IGL is low.

Unfortunately, when dealing with Galactic cirrus, a direct decontamination of optical images is not possible (Mihos 2019). As suggested by Román et al. (2020), a multi-wavelength approach can help to discriminate between Galactic cirrus emission and real LSB features. To achieve this, we have used the cirrus contour levels from the IR map to define the regions on the optical images where cirrus contributes. In these regions, we have derived the $g-r$ and $r-i$ integrated colors of the cirrus. Since the $R_{lim}$ estimated in the $g$ and $r$ bands are 6.67 arcmin and 8.33 arcmin, respectively (see Sec. 3.3), it is reasonable to assume that the emission from the western filament, which is further from the center of the group (~ 8–10 arcmin), comes from cirrus. In this region, from the optical VST $g$, $r$ and $i$ images, we have derived the $g-r$ and $r-i$ colors in several circular areas along the filament and they are shown in Fig. 8 by masking the contribution of all foreground stars and background objects. In this color-color
that some of them come from diﬀerent approaches and tracers, other estimates for the IGL amount available in the literature are provided by Aguerri et al. (2006), who find a fraction of IGL equal to 4.7% for HCG 44, using Intra Group planetary nebulae (IGPNes), Fig. 9 also shows that groups and clusters of galaxies with similar virial mass (10^{13.5} M_⊙) show diﬀerent total amounts of diffuse light, ranging from low fractions of 10%–20% (as observed in the triplet NGC 1533, HCG 86, HCG 35 and in the Virgo cluster) to high fractions ~ 40% (in NGC 5018 loose group of galaxies, HCG 90, HCG 79, HCG 94 and the Coma cluster). In the literature data, HCG 79 is the compact group with the highest IGL fraction of 46%. Other literature estimates for the fractions of ICL range from 10% to 40% going from groups to clusters (e.g. Feldmeier et al. 2004, Zibetti et al. 2005, McGee & Balogh 2010, Toledo et al. 2011).

5.2. Diﬀuse light versus virial mass

As already noted by Iodice et al. (2020), the large scatter observed in Fig. 9 might indicate that there is no signiﬁcant relationship between the diffuse light content and the virial mass of the environment, since large ICL fractions (30–45%) are observed in groups with M_{vir} ~ 10^{13} M_⊙ and in massive clusters of galaxies like Fornax (with M_{vir} ~ 10^{14} M_⊙) and Coma (with M_{vir} ~ 10^{15} M_⊙). To date, there is no general agreement in the literature regarding the relationship between M_{vir} and ICL fraction (see review by Montes 2019). On the observational side, Sampao-Santos et al. (2021) found that the surface brightness of the diffuse light, in a sample of 528 clusters at 0.2 < z < 0.35, shows an increasing dependence on cluster total mass at larger radii. On the other hands, Zibetti et al. (2005) ﬁnd a constant fraction of ICL as a function of the halo mass, consistent with our results from Fig. 9. On the theoretical side, several works have also found that the relationship between ICL and virial mass is ﬂat and the fraction of diffuse intra-cluster light ranges between 20% and 40% (Sommer-Larsen 2006, Monaco et al. 2006, Henriques & Thomas 2010, Rudick et al. 2011, Contin et al. 2014). These results would suggest that the driving factor for the IGL formation would not be related to the virial mass of the group or cluster environment (Canas et al. 2020).

In contrast, Purcell et al. (2007) found a slight increase in the ICL fraction with the mass of the halo, from 20% to 30% from halos with M_{vir} ~ 10^{13} M_⊙ to those of M_{vir} ~ 10^{15} M_⊙. Also Lin & Mohr (2004) and Murante et al. (2007) ﬁnd that the ICL fraction increases weakly with cluster mass in their simulations. Given such a large scatter in the observations, any deﬁnitive conclusion cannot be addressed at this point.

5.3. Diﬀuse light versus ETGs-to-LTGs ratio

Da Rocha et al. (2008) suggested that a high fraction of IGL is expected for groups dominated by early-type galaxies (ETGs), like compact groups. In the left panel of the Fig. 9, we have color-coded the IGL fraction in groups and clusters based on their ETG to late-type galaxy (LTG) ratio. In right panel we show the fraction of the diffuse light with respect to the total luminosity of the cluster or group as a function of the ETGs-to-LTGs ratio. In this ﬁgure we have included recent values published by Poliakov et al. (2021) for ﬁve HGCs. Compared to HCGs of similar IGL fraction (HCG 35, HCG 95, HCG 15 and HCG 37), the ETG-to-LTG ratio in HCG 86 is quite large (see right panel of Fig. 9). This is four, since it is made up of only elliptical and
Fig. 8. $g - r$ versus $r - i$ color-color diagram. Colors of the cirrus derived in the West filament are in black. The integrated colors of the group members in HCG 86 are in blue. The average value of the IGL in the group is shown as magenta triangle (see Sec. 4). The small red points are the colors derived for Cirrus from (Román et al. 2020). The two vertical dashed lines indicate the range of $g - r$ colors of the IGL in the HCGs studied by (Da Rocha & Mendes de Oliveira 2005; Da Rocha et al. 2008). In this color-color plot the region in which the IGL lies is different both from those typical of cirrus (Román et al. 2020) and from cirrus in the HCG 86 space. This confirms that IGL in HCG 86 are not largely contaminated by cirrus.

5.4. What could be the origin of IGL in HCG 86?

As suggested by simulations (e.g. (Contini et al. 2014; 2019)), the gravitational interactions between galaxies play an important role in the formation mechanism of the diffuse light in groups and clusters of galaxies. As stated in Sec. 1 these are predicted to be more efficient in groups of galaxies where the velocity dispersion of group members is low ($\sim 350$ km s$^{-1}$). In these simulations, from 5 to 25% of the diffuse light builds from the infalling galaxies in the potential well of the BCG/BGG during the mass assembly history. Most simulations predict that the bulk of the ICL is produced by the most massive satellite galaxies, $M_s \sim 10^{10-11} M_{\odot}$ at lower redshifts, whereas the contribution to the build-up of the diffuse light from the stripping of lower-mass...
galaxies ($M_* \leq 10^9 M_\odot$) is more efficient at higher ($z \sim 1$) redshifts (Purcell et al. 2007; Contini et al. 2014; Martel et al. 2012; Contini et al. 2019).

By comparing the IGL fraction and colors with simulations from Contini et al. (2014, 2019), we address a possible origin for the IGL in HCG 86. It is worth noting that HCG 86 has $M_{200} \sim 13$, which is close to the lower limit of their simulations. Since Contini et al. (2014, 2019) predict the fractions of mass in the ICL, we have derived the mass-to-light ratios ($M/L$) corresponding to the $g-r$ and $r-i$ integrated colors derived for the IGL component and for the BGG (see Tab. 2). In order to reproduce the ratio $M_{IGL}/M_{TOT}$ we gave for the light component, the integrated $g-r$ and $r-i$ colors for the BGG are obtained by considering the bright regions plus the faint outskirts. Taking into account the error estimates on the colors, using the stellar population synthesis models based on the EMILES library (Vazdekis et al. 2010), we have derived the $M/L$ in the following ranges: $1.06 \leq g-r_{BGG} \leq 1.10$ mag, $0.7 \leq g-\text{IGL} \leq 0.9$ mag, $0.77 \leq r-i_{BGG} \leq 0.81$ mag and $0.3 \leq r-\text{IGL} \leq 0.5$ mag. Therefore, we have obtained that $M/L_{\text{IGL}} \sim 2-8$ and $M/L_{\text{BGG}} \sim 5-7$, with average values of $M/L_{\text{IGL}} \sim 5$ and $M/L_{\text{BGG}} \sim 6$. Since the integrated colors of the other group members are comparable with that for the BGG (see Tab. 2 and Fig. 3), it is reasonable to assume the same $M/L$ ratio for all of them. As such, the $M_{\text{IGL}}/M_{\text{TOT}} \sim 14\%$, which is consistent with the estimates we based on the luminosity ratio of $(16\%/\pm 3\%)$.

According to Contini et al. (2014), a fraction of IGL of about 20%, comparable to that estimated in HCG 86, is consistent with a formation redshift within $z \sim 0.4-0.6$, which corresponds to a look back time of $\sim 7-8$ Gyr for formation of the group halo. These models predict that, at this epoch and with this IGL fraction, disruption of satellite galaxies is the main channel to form the diffuse light. Tidal forces would give a higher fraction of IGL. This scenario is consistent with the absence of any prominent bright tidal features or disturbed morphology in the core of HCG 86 and observing the IGL mainly in a diffuse form (see Fig. 2). The faint and diffuse bridge connecting HCG 86 to the rest of the group is the only evident tidal feature in the group, which would reconcile with the ‘late assembly’ scenario proposed by Díaz-Giménez et al. (2021), where HCG 86C might be the last member joining the group.

However, accretion events might have also contributed to the IGL in HCG 86, but remnants (as tidal tails) of this process could have already dissolved, since their lifetime is about 1 Gyr (Rudick et al. 2009; Mancillas et al. 2019). As a comparison, the HCG 90 and NGC 5018 groups, which are highly interacting systems showing disturbed morphologies in the galaxies’ outskirts and the presence of tidal stellar tails, have larger fractions of IGL ($\sim 40\%$).

From EMILES library, the IGL colors $g-r \sim 0.7 - 0.9$ mag and $r-i \sim 0.3-0.5$ mag are consistent with an age ranging from 7.8 to 11 Gyr (assuming a value for the metallicity $(\log(Z/Z_\odot))$ in a range of $[-0.4, 0]$ , as predicted by Contini et al. (2019) for the IGL at $z=0$). This interval would be even smaller towards lower ages considering that the $r-i$ IGL color is an upper limit (see Fig. 8 and Sec. 3). Such an estimate is consistent with those based on the theoretical predictions discussed above.

Recent works have proved that ICL colors are a useful parameter to constrain the main formation process that contributed to the build up of this component (Contini et al. 2019; Morishita et al. 2017; Montes & Trujillo 2018; Montes et al. 2021). The range of values for the ICL colors of $0.7 \leq g-r \leq 0.9$ mag in HCG 86 is also consistent with the range of $g-r$ colors predicted for the ICL by Contini et al. (2019), where $0.7 \leq g-r \leq 0.8$ mag at $z=0$. According to Contini et al. (2019), in this redshift range, the colors of the intra-cluster diffuse light are comparable with those of intermediate/massive galaxies ($10^{10} \leq M_* \leq 10^{11} M_\odot$), which therefore are the main contribution to the mass of the ICL and IGL. Since HCG 86 is dominated by ETGs, this would suggest that this group is quite evolved in the mass assembly framework. Therefore, the existence of massive satellites that are merging into the gravitational potential of the group members would be consistent with the evolutionary phase of the whole system.

6. Conclusions

In this paper we presented deep images for the compact group of galaxies HCG 86 as part of the VEGAS survey. The long integration time and wide area make our data deeper than previous literature studies of the IGL in compact groups of galaxies and allow us to detect IGL out to $(\sim 160$ kpc) and down to a surface brightness level of $\sim 30$ mag/arcsec$^2$ in the $g$ band.

The main results are:

- The IGL in HCG 86 is mainly in diffuse form, since we do not detect any bright or extended tidal tails or stellar streams in the intra-group space. The average IGL colors are in the range $0.7 \leq (g-r)_{\text{IGL}} \leq 0.9$ mag and $0.3 \leq (r-i)_{\text{IGL}} \leq 0.5$ mag. The $r-i$ color must be considered as an upper limit since the $i$-band image is shallower ($\sim 26$ mag/arcsec$^2$) than the other bands, therefore we are not able to map the entire region of the IGL as in the $g$ and $r$ bands.

- The fraction of IGL in HCG 86 is about $16\%$ of the total luminosity of the group in the $g$ band, and this is consistent with the same estimates available for other compact groups and loose groups of galaxies of similar virial masses (see left panel in Fig. 5).

- By comparing the amount of ICL with the cluster/group $M_{\text{vir}}$ (see left panel in Fig. 9) no strong correlation seems to be present. On the other hand, according with previous studies, the ICL fraction seems to be weakly related to ETGs-to-LTGs ratio, where larger amount of intra-cluster light is found in more evolved structures, dominated by ETGs (see right panel in Fig. 9).

- We have estimated that the IGL fractions suffers from 10% of cirrus contamination. As shown in Fig. 8, the IGL is well separated from the cirrus area of the color-color diagram, suggesting that the estimate of the IGL colors is robust.

- According to the theoretical models of Contini et al. (2014), the amount of IGL in HCG 86 would be the result of the accretion from intermediate/massive satellites at an epoch of $z \sim 0.4-0.6$ ($\sim 7-8$ Gyr). Such an age estimate is consistent with that derived to account for the average IGL $g-r \sim 0.7$ mag and $r-i \sim 0.4$ mag colors, using stellar population synthesis models.

- The $g-r$ IGL color is consistent with the range of $g-r$ colors predicted for the ICL by Contini et al. (2019), where $0.7 \leq g-r \leq 0.8$ mag at $z=0$. In this redshift range, the colors are consistent with the scenario where the main contribution to the mass of the ICL comes from the intermediate/massive galaxies ($10^{10} \leq M_* \leq 10^{11} M_\odot$).

This work is a pilot project within the VEGAS survey aimed at studying the low-density and less massive environments of galaxy groups, which are still relatively unexplored in the low-surface brightness regime. In particular, with the upcoming VEGAS data, we plan to fill the gap at low virial masses in the IGL-$M_{\text{vir}}$ plane (see Fig. 2), where, to date, we still lack both deep
Fig. 9. Left panel: Luminosity of the ICL/IGL component normalised to the total cluster/group luminosity as a function of the virial mass. The value derived for HCG 86 is compared with those for several Hickson Compact Groups, taken from Pildis et al. (1995), Poliakov et al. (2021). The estimate for HCG 94 and HCG 37 are provided by Pildis et al. (1995) and Poliakov et al. (2021) without an error range, respectively. In addition, values for the IGL estimated for other groups of galaxies derived using VEGAS data are also shown. These are: NGC 5018 group (Spavone et al. 2018), NGC 1533 triplet, IC 1459 group (Iodice et al. 2020), and Fornax A subgroup (Raj et al. 2020). The ICL fraction for the Fornax cluster is derived by Spavone et al. (2020) using FDS data. We also report the values for Virgo (Mihos et al. 2017b), Coma (Melnick et al. 1977), Thuan & Kormendy (1977), Bernstein et al. (1995), Adami et al. (2005), Jiménez-Teja et al. (2019) and Abell 85 clusters (Brough et al. 2017; Montes et al. 2021). Although these estimates are all obtained with the same approach, it must be taken into account that some of them come from different photometric bands.

The color of each point is coded according to its ETGs-to-LTGs ratio. The black line corresponds to the best fit for the linear correlation and it seems that any evident trend exists between the amount of ICL and Mvir. Right panel: Luminosity of the ICL component normalised to the total cluster or group luminosity as a function of the ETGs-to-LTGs ratio. The IGL for all HCGs available in literature are marked as blue points. Other estimates for groups and clusters of galaxies are indicated with the black points. The value found in this work for HCG 86 is marked with magenta star-like point. The coral solid line corresponds to the best fit for the linear correlation and the dashed coral lines mark the 2σ significance range of the correlation. The values for HCG 74, HCG 8, HCG 37, and HCG 17 (the latter overlaps to HCG 86) are from Poliakov et al. (2021).

observations and theoretical predictions. New observations and analysis will provide a comprehensive database of observables that can be directly compared with simulations on hierarchical mass assembly.

Appendix A: Results of multi-component fits

In this section we show the 1D multi-component fit performed on the azimuthally averaged surface brightness profiles in the \( g \) band, for all the four group members. See in Fig. A.1.
Fig. A.1. Two components models of the azimuthally averaged surface brightness profiles of galaxies in HCG 86 group. The blue line indicates a fit to the outer diffuse component (halo+IGL). The red line indicates a fit to the inner regions with a Sérsic profile, and the black line indicates the sum of the components in each fit. The vertical dashed lines show the estimated value for $R_e$ for each galaxy. Bottom panel: $\Delta$ rms scatter of the data minus the model (see text for details).
