Abstract

Near-Earth asteroid (NEA) 1566 Icarus (a = 1.08 au, e = 0.83, i = 22°8) made a close approach to Earth in 2015 June at 22 lunar distances (LD). Its detection during the 1968 approach (16 LD) was the first in the history of asteroid radar astronomy. A subsequent approach in 1996 (40 LD) did not yield radar images. We describe analyses of our 2015 radar observations of Icarus obtained at the Arecibo Observatory and the DSS-14 antenna at Goldstone. These data show that the asteroid is a moderately flattened spheroid with an equivalent diameter of 1.44 km with 18% uncertainties, resolving long-standing questions about the asteroid size. We also solve for Icarus’s spin-axis orientation (λ = 270° ± 10°, β = −81° ± 10°), which is not consistent with the estimates based on the 1968 light-curve observations. Icarus has a strongly specular scattering behavior, among the highest ever measured in asteroid radar observations, and a radar albedo of ~2%, among the lowest ever measured in asteroid radar observations. The low cross section suggests a high-porosity surface, presumably related to Icarus’s cratering, spin, and thermal histories. Finally, we present the first use of our orbit-determination software for the generation of observational ephemerides, and we demonstrate its ability to determine subtle perturbations on NEA orbits by measuring Icarus’s orbit-averaged drift in semimajor axis (∼4.62 ± 0.48) × 10^{-3} au My^{-1}, or ∼60 m per revolution). Our Yarkovsky rate measurement resolves a discrepancy between two published rates that did not include the 2015 radar astrometry.

Key words: methods: data analysis – minor planets, asteroids: individual (1566 Icarus) – planets and satellites: dynamical evolution and stability – planets and satellites: surfaces – techniques: radar astronomy

1. Introduction

Earth-based radar is a powerful tool for determining surface, sub-surface, and dynamical properties of objects within the solar system. Radar imaging has been used to obtain high-resolution images of planets, moons, asteroids, and comets, as well as constrain their orbits and spin pole orientations. In particular, radar is the only remote observing method, other than a physical flyby mission, which can obtain multiple-aspect sub-decimeter shape data for minor planets.

Radar is particularly useful for studying Near-Earth Objects (NEOs). As fragments of leftover planetesimals, NEOs serve as a window into the processes that governed the formation of the solar system. NEO studies probe the accretional, collisional, erosional, radiative, and tidal processes that shape the continued evolution of the minor planets. Determination of NEO orbits and gravity environments opens the door to human exploration of these objects, including potentially valuable sample return missions. Arguably most important of all, the discovery, categorization, and orbit determination of NEOs, as mandated by the United States’ Congress, helps identify those objects that are potentially hazardous to life on Earth.

The first asteroid radar observations occurred at Haystack on 1968 June 13–15 (Pettengill et al. 1969) and Goldstone on 1968 June 14–16 (Goldstein 1969), during a 16 lunar distance (LD) close approach of the object 1566 Icarus. Icarus’s highly elliptical orbit (a = 1.08 au, e = 0.83, i = 22°8) has it passing within radar detection range of the Earth only once every few decades. In modern times, the radar apparitions occurred in 1968, 1996, and 2015. Following the 1996 radar observations, Mahapatra et al. (1999) described Doppler spectra but did not report a detection in delay-Doppler images. Here, we report results from the 2015 Arecibo and Goldstone observations.

Although Icarus has only come within radar range of the Earth on three occasions in modern times, the long temporal separation of these events is invaluable for accurately constraining the orbit of the asteroid, as well as measuring long-term variations in the orbit, such as those caused by the Yarkovsky effect. This is of particular importance because of Icarus’s status as a Potentially Hazardous Asteroid, although the current Earth Minimum Orbit Intersection Distance is 0.0344 astronomical units (au) or 13 LD.

In the following sections, we describe the first radar-derived shape model for this object. We also discuss Icarus’s unusual radar scattering profile, along with potential explanations for its scattering behavior, and compare these radar-derived results to previous thermal and light-curve results. In addition, we present a new orbit-determination program, which is capable of generating observational ephemerides for NEOs and detecting the Yarkovsky effect for both radar and optically observed objects. We use this program to derive the magnitude of long-term non-gravitational forces acting on Icarus.

2. Observations of 1566 Icarus

Observations of Icarus were conducted from 2015 June 13 to 16 at the Goldstone Observatory in California and from 2015 June 17 to 21 at the Arecibo Observatory in Puerto Rico. During the Arecibo observations, the signal-to-noise ratio (S/N) decreased by roughly a factor of two each day (Table 1).

At the Arecibo Observatory, continuous wave (CW) and delay-Doppler data were taken at the S-band transmitter’s
nominal frequency of 2380 MHz. CW data were taken on each day of observations. Delay-Doppler data were taken on the first three days of observations. The baud length of the delay-Doppler data, which controls the range resolution, was adjusted each day as the Icarus–Earth distance increased, with 0.1 μs and 0.2 μs bauds (corresponding to 15 m and 30 m range resolution, respectively) used on June 17, 0.5 μs (75 m) on June 18, and 1.0 μs (150 m) on June 19. The CW data were reduced with frequency resolutions ranging from 0.25 to 1.5 Hz, depending on that day’s S/N. The delay-Doppler data were reduced with frequency resolutions ranging from 0.30 to 1 Hz.

During data-taking, transmission power was limited to ∼25% of nominal (278 kW) on the first day and ∼60% (600 kW) on the remaining days, due to problems with the transmitter klystrons (Table 2). This power limitation reduced the overall data quality taken at Arecibo.

At Goldstone, CW and delay-Doppler data were taken at the X-band transmitter’s nominal frequency of 8560 MHz. Each day began with CW observations, followed by coarse (10 or 11 μs baud) ranging and 1 μs or 0.5 μs imaging. The primary purpose of coarse ranging observations is to improve the quality of an object’s ephemeris. The ranging measurements taken at Goldstone were the first ever ranging observations of Icarus. The CW data were reduced with frequency resolutions ranging from 0.5 to 2 Hz, depending on that day’s S/N. The delay-Doppler data were reduced with frequency resolutions ranging from 0.50 Hz to 3.8 Hz.

### Table 1

Pre-observational Information Generated for 1566 Icarus

| Date (UTC) | R.A. (deg) | Decl. (deg) | Distance (au) | S/N/run | Observatory | Band |
|------------|------------|-------------|---------------|---------|-------------|------|
| 2015 Jun 13 13:14:06:01 | 106 | +63 | 0.072 | 8 | Goldstone | X |
| 2015 Jun 14 14:34:07:58 | 137 | +64 | 0.061 | 13 | Goldstone | X |
| 2015 Jun 16 20:00:09:06 | 190 | +42 | 0.054 | 22 | Goldstone | X |
| 2015 Jun 17 22:52:01:18 | 200 | +29 | 0.059 | 475 | Arecibo | S |
| 2015 Jun 18 23:04:01:50 | 207 | +17 | 0.068 | 290 | Arecibo | S |
| 2015 Jun 19 23:31:01:50 | 211 | +8 | 0.080 | 165 | Arecibo | S |
| 2015 Jun 21 00:08:01:30 | 215 | +1 | 0.093 | 98 | Arecibo | S |

Note. Signal-to-noise ratio (S/N) calculations assume nominal transmitter power, but equipment problems reduced the available transmitter power at the Arecibo Observatory (see the text).

| A   | 2015 Jun 21      | 57194 | u01 | 93  | 642     | cw   | ... | 1.5 | none | 004449–010517            | 7    |

Note. The first column indicates the telescope: Arecibo (A) or Goldstone (G). UT date is the universal-time date on which the observation began. MJD is the corresponding Modified Julian Date. Eph is the ephemeris solution number used. RTT is the round-trip light time to the target. $p_t$ is the transmitter power. Baud is the length of each code element of the pseudo-random code used for imaging; it dictates the range resolution. Spb is the number of complex samples per baud giving a pixel height of baud/Spb. CW data are typically sampled at a rate of 12.5 kHz. Res is the frequency resolution of the processed data. Code is the length (in bauds) of the pseudo-random code used. The timespan of the received data is listed by the UT start and stop times. Runs is the number of completed transmit-receive cycles.
3. Methods

3.1. Shape Analysis

3.1.1. Radar Scattering Properties

In order to determine a shape from radar images, one must simultaneously fit for the shape, spin, and radar scattering properties of the surface and sub-surface of the object. Radio waves incident on the surface of an object will scatter over a variety of angles with a range of associated powers, and the relationship between scattering angle and back-scattered power determines the object’s specularity. This scattering behavior can be described by \( \frac{\partial A}{\partial \theta} \), or the differential radar cross section per surface element area, as a function of the incidence angle \( \theta \) (Evans & Hagfors 1968).

The shape software package (Hudson & Ostro 1994; Magri et al. 2007b) can estimate \( \frac{\partial A}{\partial \theta} \) by fitting the parameters of this function along with an object’s surface shape. We found that the Icarus data were well fit by either a two-component cosine scattering law (Appendix C) or a “hagfors” scattering law. For the analysis performed in this paper, we chose to use a “hagfors” scattering law, which is defined as

\[
\frac{\partial A}{\partial \theta} = H(\theta_0 - |\theta|) \times \frac{RC}{2}(\cos^4 \theta + C \sin^2 \theta)^{\frac{3}{2}},
\]

where \( R \) and \( C \) are tunable parameters of the scattering law, \( H(\cdot) \) is the Heaviside step function, and \( \theta_0 \) is a fixed angular cutoff value. This scattering law is the standard Hagfors Law (Hagfors 1964) with an angular cutoff.

3.1.2. Shape and Spin Pole Determination

Shape analysis was performed using the shape software package with the fitting algorithm described in Greenberg & Margot (2015). The shape was modeled with a triaxial ellipsoid during all stages of the fitting process. Attempts to utilize a more complex model (e.g., a spherical harmonic model) resulted in no changes being applied during the minimization process when starting from a best-fit ellipsoid, which suggests that the data quality is not high enough to support a more complex model. The spin period was fixed at 2.273 hours (Harris 1998; Gehrels et al. 1970).

Our analysis used both CW and imaging data. Initial tests showed that including imaging data taken after the first night of Arecibo observations (June 17) had no effect on the fit. This result is to be expected because the lower S/N (Table 1 and Figure 2) for the later nights necessitated relatively low-resolution images to be taken. Therefore, all subsequent fits were performed only with imaging data taken at 0.1 and 0.2 \( \mu \)s resolution on the first night of Arecibo observations. Similarly, the Goldstone delay-Doppler images were not included in the fits due to low resolution and S/N. All CW data from both Arecibo and Goldstone were used.

The initial shape model was chosen as the ellipsoid representation of a sphere with a radius of 0.63 km (Harris 1998). We explored a variety of initial conditions for the spin pole using a grid of evenly spaced positions, with neighboring points \( \sim \)15° apart. During this grid search, the spin pole positions were allowed to float along with the axial ratios of the ellipsoid and scattering parameters. Simultaneous fitting of both size and spin pole parameters was made possible due to previous modifications made to the shape software (Greenberg & Margot 2015).

We performed a \( \chi^2 \) analysis to place constraints on the possible spin pole orientations. \( \chi^2 \) is the element-wise sum of squared differences between a model’s predicted CW power or delay-Doppler image pixel value and the corresponding measurement. Specifically, after running the grid search described above, we calculated the quantity \( \Delta \chi_i \) for each of the initial grid positions, where

\[
\Delta \chi_i \equiv \frac{\chi_i^2 - \chi_{\min}^2}{\sqrt{2k}},
\]

where \( \chi_i \) is the \( \chi^2 \) associated with the \( i \)th grid position after convergence, \( \chi_{\min}^2 \) is the lowest \( \chi^2 \) achieved across all grid positions, and \( k \) is the number of degrees of freedom for the fit. \( \Delta \chi_i \) can be thought of as the distance in \( \chi^2 \) space between the \( i \)th grid position and that of the best fit, in units of standard deviations of the \( \chi^2 \) distribution. Grid positions with \( \Delta \chi_i < 1 \) yield results that are statistically indistinguishable from those of the best fit, and thus represent positions with potentially valid shape, spin pole, and scattering behavior solutions.

3.2. Orbit Determination

Smearing of radar images in the range dimension occurs when the object’s range drift is not properly taken into account. Provided that the direction and magnitude of the target’s motion is known prior to taking data, this range drift can be compensated for entirely at the data-taking stage by delaying the sampling clock appropriately. If there are residual errors due to imperfect knowledge of the object’s orbit, additional image corrections at the pixel level are necessary before summing individual images, which is suboptimal (Ostro 1993). For this reason, radar observers place a high priority on securing an accurate knowledge of the object’s trajectory before the observations or during the first few minutes of the observations.

Therefore, radar observations require the generation of ephemerides that encode the knowledge of the object’s position and velocity. Traditionally we have used the On-site Orbit-determination software (Giorgini et al. 2002) to generate ephemerides for radar observations. For observations of Icarus, A.H.G., J.L.M., and A.K.V. wrote a new ephemeris-generating program called the Integration and Determination of Orbits System (IDOS). Central to IDOS’ operation is the Mission analysis, Operations, and Navigation Toolkit Environment (MONTE), a powerful tool developed by the Jet Propulsion Laboratory (JPL) for a variety of space-related science and aeronautical goals (Evans et al. 2016). MONTE has been used as an integral tool for trajectory design and spacecraft tracking of most modern NASA missions, and has therefore been thoroughly tested in this context. More recently, MONTE has also been tested as a scientific tool for mapping the internal structure of Mercury through gravitational field determination (Verma & Margot 2016).

IDOS utilizes MONTE’s built-in orbital integrator, DIVA. DIVA uses Adams’ method with variable timesteps to integrate the differential equations of motion. DIVA can account for gravitational perturbations from any set of masses, as well as arbitrary accelerations, including non-gravitational forces. For the analyses performed in this paper, we considered the major planets and 24 of the most massive minor planets (Folkner et al. 2014) as gravitational perturbers. During close
approaches, DIVA can take into account a detailed description of a perturber’s gravitational field. DIVA also considers general relativistic effects during orbital integration.

IDOS also uses MONTE’s built-in residual minimization capabilities. The underlying algorithm is based on a Kalman filter (Kalman 1960) and the work of Bierman (1977).

IDOS can process both optical and radar astrometric measurements. Optical measurements are automatically downloaded from the Minor Planet Center (MPC) database (Minor Planet Center 2015). Measurements are corrected for star catalog bias based on the reference catalog and sky location and weighted based on the reference catalog, observatory, observation type, and date. Both debiasing and weighting are calculated using the methods described in Farnocchia et al. (2015).

3.3. Yarkovsky Force Model

The Yarkovsky effect (e.g., Peterson 1976; Vokrouhlický & Farinella 1998; Rubincam 2000; Vokrouhlický et al. 2000) is a secular thermal effect that causes an affected object’s semimajor axis to change over time, on the order of 10^{-19} au My^{-1} for a kilometer-size object. By equating this thermal acceleration \( \dot{a} \) with the change in momentum per unit mass due to incident radiation (Appendix A), one finds that

\[
\dot{a} = \frac{\xi}{\rho} \frac{L_\odot}{c} X_P(\phi) r(t) \left( |r(t)|^3 \right),
\]

where \( r(t) \) is the heliocentric radial vector for the object at time \( t \), \( \hat{p} \) is the unit spin-axis vector, \( \phi \) is the phase lag, \( L_\odot \) is the luminosity of the Sun, \( c \) is the speed of light, and \( X_P(\phi) \) is the rotation matrix about \( \hat{p} \). \( \xi \) is an efficiency factor.

IDOS models the Yarkovsky effect by applying this acceleration at every integration time step. The diameter \( D \) and density \( \rho \) are assumed to be 1 km and 1 g cm^{-3} unless more specific values can be determined for the object. We note that these assumptions do not ultimately have any effect on the final reported value of \( \langle \dot{a}/d \rangle \) (Section 3.4.1)—any inaccuracies in assumptions concerning \( \rho \) and \( D \) are absorbed by the efficiency factor \( \xi \).

Icarus’s semimajor axis exhibits substantial variations as a function of time due to close planetary encounters, including the 1968 and 2015 Earth encounters. Our modeling of the Yarkovsky effect considers all the gravitational dynamics but adds a non-gravitational acceleration to the dynamical model.

3.4. Yarkovsky Determination

3.4.1. Measuring Yarkovsky Drift

As discussed in Section 3.2, we used our orbit-determination software to detect and determine the magnitude of the Yarkovsky effect on Icarus. Both positive and negative values for \( \xi \) were considered, allowing for the possibility that the object is either a retrograde or prograde rotator, respectively.

We recorded a goodness-of-fit metric, \( \chi^2 \), where

\[
\chi^2 = \sum_{i=1}^{N} \frac{(E_i - O_i)^2}{\sigma_i^2},
\]

where \( E_i, O_i \) is the expected and observed value, respectively, for the \( i \)th astrometric measurement, \( \sigma_i \) is the measurement uncertainty for that observation, and \( N \) is the number of observations. These measurements included both radar and optical astrometry.

We then identified the best-fit \( \xi \) value and assigned one-standard-deviation error bars corresponding to \( \xi = \xi (\chi_{\text{min}}^2 + 1) \), as described in Press et al. (1992).

3.4.2. Transverse Acceleration to Orbit-averaged Drift

As discussed in Section 3.4.1, our orbit-determination software provides the capability to model the magnitude of the instantaneous acceleration imparted on a rotating object due to anisotropic reradiation of absorbed sunlight. However, for the purpose of comparing our results with those extant in the literature, it is useful to convert between this quantity and the orbit-averaged change in semimajor axis, \( \langle \dot{a}/d \rangle \).

We note that because there is an arbitrary scaling factor (\( \xi \)) in our Yarkovsky force model (Equation 3), we can select model parameters that maximize the transverse component of the acceleration without prejudice. Therefore, we set the spin pole orientation parallel to the orbital pole and the phase lag \( \phi \) to \(-90^\circ\). Neither of these choices affect the final estimated value of \( \langle \dot{a}/d \rangle \) (Section 4.5).

To find \( \langle \dot{a}/d \rangle \), we first considered the instantaneous change in semimajor axis due to some small perturbing transverse force, as given by (Burns 1976)

\[
\frac{\dot{a}}{d} = \frac{2}{\sqrt{GM}} \frac{a^2}{1 - e^2} \frac{1}{2} (1 + e \sin \theta_i) T \frac{T}{m},
\]

Figure 1. Echo spectra of 1566 Icarus obtained at Arecibo on 2015 June 17 at 0.25 Hz resolution (top) and June 18 at 0.4 Hz resolution (bottom).
\[ \frac{da}{dt} = \frac{3}{4\pi} \frac{L}{c \sqrt{GM}} \frac{1}{D_B} \frac{1}{\sqrt{a}} \left( \frac{1 + e \sin \theta_f}{1 + e^2} \right)^2 \left( (1 + e \cos \theta_f)^2 - (1 + \frac{\sqrt{a}}{D_B})^2 \right)^{3/2} \]

Averaging Equation (7) over one full orbit yields
\[ \langle \frac{da}{dt} \rangle = \frac{\dot{\alpha}}{\sqrt{a}} \left( \frac{3L\dot{\alpha}}{4\pi c \sqrt{GM}} \frac{1}{D_B} \right) \]

where
\[ \dot{\alpha} = \frac{1}{2\pi} \int_0^{2\pi} \frac{(1 + e \sin \theta_f)(1 + e \cos \theta_f)}{(1 - e^2)^{3/2}} dM \]

is a quantity that depends only on orbital parameters and the true anomaly \( \theta_f \) is a function of the mean anomaly \( M \).

Noting that \( \dot{\alpha} = 1 \) when \( e = 0 \), we can plug nominal values into Equation (8), yielding
\[ \langle \frac{da}{dt} \rangle = 1.45 \times \left( \frac{1 \text{ au}}{a} \right)^{5/2} \frac{\xi}{0.01} \times \left( \frac{1 \text{ km}}{D} \right) \times \left( \frac{1 \text{ g cm}^{-3}}{\rho} \right) \times \frac{10^{-4} \text{ au}}{\text{Myr}} \]

### 3.4.3. Detection Verification

Once a \( \langle da/\rangle \) has been estimated, it is necessary to verify whether the measured Yarkovsky effect signal is sufficiently strong to be considered a true detection. To determine this, we performed an analysis of variance to compare our best-fit Yarkovsky model (\( \xi = \xi_0 \)) to a model in which no Yarkovsky effect was present (\( \xi = 0 \)).

The analysis of variance was designed to compare the goodness-of-fit between two models with different number of model parameters, a task that is otherwise not straightforward. We followed the methods described in Mandel (1964). Specifically, we calculated the test-statistic
\[ F = \frac{\epsilon_\xi}{\epsilon_Y}, \]

where
\[ \epsilon_\xi = \frac{\sum_{i=1}^{N} \left( \frac{E_{0,i} - \sigma_i}{\sigma_i} \right)^2 - \sum_{i=1}^{N} \left( \frac{E_{0,i} - 0}{\sigma_i} \right)^2}{m_Y - m_0} \]

and
\[ \epsilon_Y = \frac{\sum_{i=1}^{N} \left( \frac{E_{0,i} - 0}{\sigma_i} \right)^2}{N - m_Y} \]

Here, \( E_{0,i} \) is the simulated \( i \)th observation assuming gravity only (\( \xi = 0 \)), \( E_{0,i} \xi \) is the simulated \( i \)th observation assuming a Yarkovsky model with \( \xi = \xi_0 \), \( \sigma_i \) is the \( i \)th measurement and \( \sigma_i \) is the measurement uncertainty for that observation, \( N \) is the number of observations, and \( m_Y, m_0 \) are the number of free parameters in the Yarkovsky model (\( m_Y = 7 \)) and gravity-only model (\( m_0 = 6 \)), respectively.

We then calculate the value
\[ p = \int_{X=F}^{X=\infty} f_{m_Y-m_0, N-m_Y}(x) dx \]

where \( f_{m_Y-m_0, N-m_Y} \) is the \( F \)-distribution probability density function with \( m_Y - m_0 \) and \( N - m_Y \) degrees of freedom. The \( p \)-value serves as a metric for testing the null hypothesis that the \( \xi \) variable is superfluous. In other words, a small \( p \)-value indicates that it would be implausible for us to record the astrometry that was actually observed in a gravity-only universe. Small \( p \)-values suggest that a non-gravitational
component to the acceleration is required. For instance, one could choose \( p < 0.003 \) as a threshold to reject the null hypothesis. This criterion approximately corresponds to a 3-standard-deviation detection. We will see that we can reject the null hypothesis for Icarus with much higher confidence than \( p < 0.003 \).
4. Results

4.1. Cross Section and Polarization Properties

The circular polarization ratio \( \mu_C \) is defined as the ratio of the cross section in the same sense circular polarization (SC) as that transmitted to that in the opposite sense circular polarization (OC). \( \mu_C \) serves as a measure of the surface roughness at size scales comparable to the wavelength of the transmitted light. The arithmetic average \( \mu_C \) for Icarus, as calculated from the Arecibo (S-Band) CW observations, was \( \mu_C = 0.18 \) with a standard deviation of 0.05 (Figure 1 and Table 3). Some of the observed variations may be due to non-uniform scattering properties over the asteroid’s surface.

Icarus’s total radar cross section \( (\sigma_T) \), defined as the sum of the OC and SC cross sections, was measured for each day of observations using CW data. The arithmetic average \( \sigma_T \) as calculated from the Arecibo CW observations is 0.030 km\(^2\) with a standard deviation of 0.007 km\(^2\).

The values for circular polarization ratio and total radar cross section, as calculated from the Goldstone (X-Band) CW observations, are \( \mu_C = 0.33 \) (standard deviation 0.05) and \( \sigma_T = 0.069 \text{ km}^2 \) (standard deviation 0.041 km\(^2\)). Mahapatra et al. (1999) previously reported \( \mu_C = 0.48 \pm 0.04 \) at X-band.

There are two possible explanations for the discrepancies in polarization ratios at S-band and X-band. First, the low S/N of the Goldstone observations may affect the determination of the polarization ratios because receiver noise may inadvertently contribute to the SC cross-section estimates, artificially raising the \( \mu_C \) values. For this reason, we believe that the Arecibo values are more accurate due to the much higher S/N (Table 1 or Figure 2). Second, it is also possible that Icarus’s cross sections and polarization ratios have a wavelength dependence. If so, the difference between the Arecibo and Goldstone \( \mu_C \) values would suggest that Icarus’s surface is smoother at S-band wavelength (12.6 cm) size scales than at X-band wavelength (3.5 cm).

4.2. Bandwidth

The observed bandwidth, as measured from the CW data, reached a minimum on the second day of observations, which is consistent with the sub-radar latitude reaching an extremum on that date (Table 4) if the object is approximately spheroidal.

The predicted limb-to-limb bandwidth—which can be calculated from the expression

\[
B_{LL} = \frac{4\pi D \cos \delta}{\lambda P}\]

where \( P \) is the object’s rotational period, \( \delta \) is the latitude of the sub-radar point, and \( \lambda \) is the wavelength of the transmitted signal—does not appear to agree with observations. As we will discuss in detail in Section 5, this object’s high specularity means that under certain observing conditions, the echo signal may contain very little power from surface regions with high incidence angles \( (\theta_{inc} > 45^\circ) \), a fact already alluded to by Pettengill et al. (1969) and Goldstein (1969). As a result, the calculated limb-to-limb bandwidth does not correspond to the observed bandwidth, but the bandwidth measured at a level 1-standard-deviation above the noise does correspond to the bandwidth calculated from the shape model at the same signal strength.

4.3. Shape and Spin Pole Determination

In Figure 3, we report solutions for the spin pole orientations that satisfy \( \Delta \chi_I \leq \frac{1}{3} \) (Section 3.1.2). After determining these solutions, we ran a clustering analysis based on the nearest-neighbor algorithm (Altman 1992) to group solutions with spatially correlated spin pole positions. Figure 3 shows cluster membership with coloring. The mean three-dimensional Cartesian position of these clusters, projected onto the celestial sphere, are indicated with black crosses, and the 1- and 2-standard-deviation uncertainty regions in cluster mean position are indicated with dashed circles. Note that projection effects make these regions appear non-circular.

Table 4 shows the two possible pairs of spin pole positions, labeled by their color (as seen in Figure 3). Each pair’s member clusters (the purple and green clusters, and the red and blue clusters) are approximate antipodes of their partner.

The associated ellipsoid axis diameters and scattering parameters (Section 3.1.1) are also listed in Table 5. The uncertainty given for each parameter was calculated as the standard deviation in said parameter among members of the corresponding cluster. Because the members of each cluster are not strictly independent samples, these standard deviations may be underestimates of true uncertainties and do not account for potential systematic errors.

The parameters listed in Table 5 show the specularity parameter \( C \) (Equation (1)) for the two pairs of spin pole solutions. All solutions are consistent with a Hagfors \( C \) value of 13. The Hagfors formalism assumes that the surface roughness has been smoothed with a wavelength-scale filter. In this formalism, the \( C \) value corresponds to the root-mean-square slope \( (S_0) \) of a gently undulating surface at scales greater than the wavelength. From the expression

\[
S_0 = \frac{1}{\sqrt{C}}\]

we find that the surface of Icarus has rms slopes of \( \sim 16^\circ \). For comparison, Evans & Hagfors (1968) found \( S_0 \) for the lunar
Figure 3. Results of our search for Icarus’s spin-axis orientation, in the ecliptic frame of J2000. We fit ellipsoids to the data with trial values of the spin-axis orientation that were evenly distributed across the celestial sphere (Deserno 2004) with an initial spacing of 15°. The spin pole location was allowed to float during these fits. Solutions with $\Delta \chi < \frac{1}{7}$ (Section 3.1.2) were plotted as circles and colored according to cluster membership. Black “+” symbols indicate a cluster’s mean position, whereas dotted lines show the 1- and 2-standard-deviation uncertainty region in mean cluster position. Black “x” symbols indicate solutions that did not fall within any cluster with more than one member. Triangles show the location of the orbital poles.

Table 5
Possible Spin Poles (Ecliptic Coordinates) and Corresponding Size and Roughness Values

| Cluster color | Spin pole | Roughness | Ellipsoid Axis Diameters | Equiv. Diameter |
|---------------|-----------|-----------|--------------------------|-----------------|
|               | $\lambda$ | $\beta$   | $2a$ (km) | $2b$ (km) | $2c$ (km) | $D_{eq}$ (km) |
| Purple        | 135° ± 10° | 4° ± 10°  | 12.9 ± 2.1 | 1.49 ± 0.15 | 1.53 ± 0.16 | 1.18 ± 0.13 | 1.39 ± 10% |
| Green         | 313° ± 10° | −6° ± 10° | 13.9 ± 0.7 | 1.64 ± 0.12 | 1.59 ± 0.12 | 1.18 ± 0.27 | 1.45 ± 13% |
| Red           | 78° ± 10°  | 82° ± 10°  | 13.3 ± 2.0 | 1.65 ± 0.19 | 1.64 ± 0.19 | 1.38 ± 0.20 | 1.55 ± 13% |
| Blue          | 270° ± 10° | −81° ± 10° | 13.8 ± 1.4 | 1.61 ± 0.15 | 1.60 ± 0.17 | 1.17 ± 0.39 | 1.44 ± 18% |

Note. Our adopted solution (Section 5) is shown in bold and represents a moderately flattened spheroid.

Figure 4 shows a series of delay-Doppler images obtained on the first day of Arecibo observations, the corresponding model images, and the residuals, while Figure 2 shows the observed Doppler spectra compared to those predicted by our adopted model. The simulated observations for this set of figures were generated from the average shape, spin pole, and scattering parameters of our adopted solution (Table 5, blue cluster).

As we will discuss in Section 5, this clusters spin pole is our preferred solution because it is consistent with historical radar measurements and because of the sign of Icarus semimajor axis drift.

4.5. Yarkovsky Drift

We calculated the $\hat{\alpha}$ value for Icarus’s orbit ($e = 0.83$) of $\hat{\alpha} = 3.16$ (Equation (8)). We then identified the best-fit efficiency factor $\xi$ (Section 3.4.1). Assuming a density of $\rho = 2.7 \text{ g cm}^{-3}$ appropriate for Q-type asteroids (DeMeo et al. 2014) and our adopted effective diameter of $D = 1.44 \text{ km}$, the best-fit efficiency factor is $\xi = (4.1 \pm 0.4)\%$.

The best-fit $\xi$ value corresponds to a semimajor axis drift rate of $\langle da/dt \rangle = (−4.62 \pm 0.48) \times 10^{-4} \text{ au My}^{-1}$. This lies within one standard deviation of the value found by Nugent et al. (2012) of $\langle da/dt \rangle = (−3.2 \pm 2.0) \times 10^{-4} \text{ au My}^{-1}$. Farnocchia et al. (2013) found a drift rate of $\langle da/dt \rangle = (−0.86 \pm 1.8) \times 10^{-4} \text{ au My}^{-1}$. Neither of these previous results incorporated the 2015 radar astrometry, nor the more than 300 optical observations taken of 1566 Icarus since 2012.

The $p$-value (Section 3.4.3) for a Yarkovsky drift model with $\langle da/dt \rangle = (−4.62 \pm 0.48) \times 10^{-4} \text{ au My}^{-1}$ and 2312 degrees of freedom is less than $10^{-10}$, leading to a confident rejection of the null hypothesis (Section 3.4.3), which we interpret as a Yarkovsky detection.

In addition to conducting an analysis of variance (Table 8), we performed a variety of analyses to test the rigor of our Yarkovsky result. A description of these tests can be found in Appendix D.
We note that while our analysis of the thermal acceleration acting on Icarus assumed a spin pole aligned with the orbital pole (Section 3.4.1), our final \( \langle da/dt \rangle \) value is insensitive to this assumption. We performed numerical estimates (Figure 5) of the magnitude of the Yarkovsky effect for the four possible spin pole orientations (Section 4.3). The drift was calculated as the change in position between the best-fit Yarkovsky model and the best-fit model with no Yarkovsky effect. The \( \langle da/dt \rangle \) value shown was calculated as the slope of a linear fit through these differences. All spin pole orientations gave consistent semimajor axis drifts. These drift rates are also consistent with the rate of \((-4.62 \pm 0.48) \times 10^{-4} \) au My \(^{-1} \), determined semi-analytically using Equation (8).

We plan on using our MONTE-based orbit-determination software to measure the orbital perturbations affecting other NEOs in Icarus-like orbits (Margot & Giorgini 2010). These measurements can in turn be used to put constraints on the \( \beta \) parameter in the post-Newtonian parameterization of general relativity (GR) and possibly the oblateness of the Sun. The GR and Yarkovsky perturbations are essentially orthogonal.
Table 7
Orbital Elements and Improvements in their Formal Uncertainties After Inclusion of the 2015 Radar Astrometry

| Parameter | Value | Uncertainty | Improvement Factor |
|-----------|-------|-------------|-------------------|
| $a$ (au)  | 1.077926624685 | 6.5e−11 | 2.6e−11 | 2.5 |
| $e$       | 0.82696732129 | 3.0e−08 | 6.9e−09 | 4.3 |
| $i$ (deg) | 22.828097364 | 6.9e−06 | 2.5e−06 | 2.8 |
| $\Omega$ (deg) | 88.020929001 | 1.6e−06 | 6.5e−07 | 2.5 |
| $\omega$ (deg) | 31.363864782 | 3.4e−06 | 1.2e−06 | 2.8 |
| $M$ (deg)  | 34.015936514 | 1.7e−06 | 4.3e−07 | 4.0 |

Note. The elements are semimajor axis $a$, eccentricity $e$, inclination $i$, longitude of the ascending node $\Omega$, argument of pericenter $\omega$, and mean anomaly $M$. These orbital elements are valid at the epoch 2015 June 12 00:00:00 UT with our nominal Yarkovsky drift Solution (Section 4.5).

Table 8
Yarkovsky Measurement Results for 1566 Icarus

| Data Set Used | $N_{opt}$ | $N_{rad}$ | $\langle da/dt \rangle$ [au/My] | $F$ |
|---------------|-----------|-----------|-------------------------------|-----|
| MPC           | 1148      | 23        | $-4.6 \pm 0.5$                | 250 |
|               | 1148      | ...       | $-4.9 \pm 0.5$                | 264 |
| Screened      | 931       | 23        | $-4.0 \pm 0.9$                | 139 |
|               | 931       | ...       | $-3.8 \pm 1.1$                | 107 |
| Screened (J.L.M.) | 931     | ...       | $-3.6 \pm 1.0$                | 98  |

Note. The observational arc for these measurements was 1949–2015. The radar astrometry includes both Arecibo and Goldstone measurements from 2015. $N_{opt}$ and $N_{rad}$ indicate the number of optical (after outlier rejection) and radar measurements, respectively. $F$ indicates the F-score, which serves as a measure of significance for the necessity of a non-gravitational force component in the dynamical model (Section 3.4.3). An F-score of 70 or above corresponds to a $p$-value of less than $10^{-15}$, or a detection at the $\geq 5\sigma$ level. The rows labeled MPC indicate analysis done with the full MPC data, with basic outlier rejection and observational weighting calculated using the methods described in Farnocchia et al. (2015). The rows labeled “screened” indicate analysis done with a smaller data set from which astrometry deemed suspect on the basis of a gravity-only model was eliminated (J. Giorgini 2017, personal communication). A full description of the data and methods used can be found in Appendix D.

because Yarkovsky drift primarily affects the semimajor axis, whereas GR does not affect the semimajor axis but instead causes a precession of the perihelion. The clearest separation between these perturbations will be obtained by solving for the orbits of multiple asteroids simultaneously (Margot & Giorgini 2010).

5. Discussion

5.1. Spin Pole

As noted in Section 4, analysis of our radar data yields four possible sets of spin pole orientations for Icarus, and given their low $\Delta \chi$ values, these solutions are statistically indistinguishable from each other. Icarus’s spin pole has also been measured in the past from light-curve data, which gave three possible spin poles. Light-curve observations of Icarus between 1968 June 14 and June 21 were analyzed by Gehrels et al. (1970) and re-analyzed by De Angelis (1995). Gehrels et al. (1970) reported a spin-axis orientation of $\beta = 0^\circ \pm 3^\circ$, $\lambda = 223^\circ \pm 3^\circ$ or $49^\circ \pm 3^\circ$, whereas De Angelis (1995) found $\beta = 5^\circ \pm 5^\circ$, $\lambda = 214^\circ \pm 5^\circ$. These light-curve-derived spin poles are not consistent with our 2015 radar data, which leaves two possibilities—either the light-curve-derived spin poles are incorrect, or Icarus’s spin pole has changed at some point since the 1968 apparition. We can determine which of these two possibilities is more likely by analyzing historical radar measurements of this object.

Table 9 lists Icarus’s reported bandwidths from the three radar apparitions that garnered CW measurements—namely 1968 (Goldstein 1969; Pettengill et al. 1969), 1996 (Mahapatra et al. 1999), and 2015 (this work)—along with the bandwidths that would have been measured at the corresponding dates, if Icarus’s spin pole orientation were constant. We generated predictions for four possible spin poles $-\lambda = 313^\circ \pm 10^\circ$, $\beta = -6^\circ \pm 10^\circ$ (the green cluster), $\lambda = 270^\circ \pm 10^\circ$, $\beta = -81^\circ \pm 10^\circ$ (the blue cluster), $\beta = 0^\circ \pm 3^\circ$, $\lambda = 49^\circ \pm 3^\circ$ (Gehrels et al. 1970), and $\beta = 5^\circ \pm 5^\circ$, $\lambda = 214^\circ \pm 5^\circ$ (De Angelis 1995)—and compared the predicted measurements for these poles to the reported values. A direct comparison suggests that no spin pole is consistent with measurements from more than one apparition. However, this interpretation is slightly misleading, as there were a variety of types of bandwidths reported in these articles. Pettengill et al. (1969) and Goldstein (1969) reported
bandwidths at full-width half-max, while Mahapatra et al. (1999) reported their best estimate of the limb-to-limb bandwidth (Appendix B). In this work, we reported the measured bandwidth at one standard deviation above the noise ($B_{\text{LL}}$), as well as the limb-to-limb bandwidth calculated from our shape models. Therefore, to facilitate comparisons of these bandwidths, we have attempted to convert the historical measurements to limb-to-limb bandwidths by estimating the signal’s zero-crossing point, as well as adjusting for the decrease in apparent bandwidth caused by Icarus’s highly specular surface, which results in an approximate halving of the observed bandwidth as compared to the nominal limb-to-limb bandwidth for very low $S/N$ observations. The estimated $B_{\text{LL}}$ also accounts for the fact that some authors reported the half-max bandwidth, rather than zero-crossing bandwidth. All bandwidth measurements and predictions have been converted to the Arecibo S-band frequency of 2380 MHz for ease of comparison. For observational details, see Appendix B.

However, if the light-curve-derived spin poles are correct, then the spin-axis orientation of Icarus would have had to have changed since the 1968 apparition. A difference in spin orientation may be caused by non-principal axis (NPA) rotation or the effect of torques due to anisotropic mass loss. Mass loss may occur due to thermal fracturing. NPA rotation may remain undetected in light-curve or radar data if one of the fundamental periods is long compared to the span of observations in any given apparition or if the object is approximately spheroidal. NPA rotation requires a mechanism to excite the spin state on a timescale shorter than the NPA damping timescale. The Burns & Safronov (1973) timescale for damping to principal axis rotation assuming silicate rock ($\mu Q = 5 \times 10^{12} \text{Nm}^{-2}$, $\rho = 2.71 \text{g cm}^{-3}$) is $\sim$25 million years, during which Icarus experiences close planetary encounters that may excite its spin. However, if the material properties are closer to those reported by Scheirich et al. (2015) ($\mu Q = 1.3 \times 10^7 \text{Nm}^{-2}$), NPA rotation would require an excitation in the past 100 years, which we consider unlikely.

Three arguments favor the principal axis rotation solution: (1) the light-curve-derived spin poles predict bandwidths that are inconsistent with observations (Table 9); (2) the bandwidths predicted by the blue cluster spin pole solutions can match observations over three separate apparitions, (3) damping to principal axis rotation would likely occur on short timescales. This conclusion suggests that interpreting the evolution of light-curve amplitudes may not be sufficient in determining spin pole orientations accurately. Other considerations, such as knowledge of albedo variations and inhomogeneous scattering behavior, may be necessary to properly interpret light-curve data.

### 5.2. Cross Section and Size

Using the results of our analysis, we have found that 1566 Icarus’s radar scattering behavior is consistent with a Hagfors specularity constant of $C = 13$. This level of specularity is unusual for NEOs (Appendix C) and helps to explain the lower-than-expected image quality. Diffusely scattering surfaces can reflect power from high incidence angles—therefore, surface elements with normal vectors not aligned with the observer’s line of sight can still contribute to the return signal. The surface elements of specular objects, on the other hand, reflect most of their incident power away from the observer unless they lie close to the sub-radar point (for ellipsoidal objects). The result is a very sharp drop-off in $S/N$ for incidence angles greater than $\sim 20^\circ$. This effect can be seen in Figure 4.
Furthermore, the small amount of echo power returning from regions with high incidence angles ($\theta_{\text{inc}} \gtrsim 45^\circ$) helps to resolve the difference between Icarus’s observed bandwidth and the limb-to-limb bandwidth calculated from the object’s shape and spin pole orientation (Table 4). The most highly red and blueshifted signals are reflected from these high-incidence regions, and the large attenuation of these signals reduces the span of the measured bandwidth. This effect may also explain a discrepancy noticed by Mahapatra et al. (1999), who measured Icarus’s bandwidth during its previous radar apparition nearly two decades ago and pointed out that the measured bandwidth corresponds to a diameter around half of the value found radiometrically by Harris (1998).

The results presented within this work suggest Icarus’s surface and sub-surface properties are unusual among the known population of NEOs. The radar albedo $\delta_T$ (defined as the radar cross section divided by the object’s geometric cross section) for an object with a diameter of $\sim 1.44$ km and a measured radar cross section of 0.03 km$^2$ is less than 2% (see Table 3), which we believe to be the lowest radar albedo ever measured (e.g., Magri et al. 1999, 2001, 2007a).

The radar albedo for a specular reflector provides an approximation to the Fresnel reflectivity, which is related to the dielectric constant (Evans & Hagfors 1968). Our radar albedo measurement yields the surprising low dielectric constant of 1.8. Most non-volcanic rocks have dielectric constants above 5, unless they are in a powdered form with high porosity (Campbell & Ulrichs 1969), in which case their dielectric constants are about 2. Our measurements suggest that Icarus may have a low surface density or, equivalently, a high surface porosity.

Furthermore, a radar specularity of $C = 13$ is unusually high compared to most radar-imaged NEOs. This high specularity and low radar albedo suggest an unusual surface structure. Due to its highly eccentric orbit ($e = 0.82$) and low semimajor axis ($a = 1.08$ au), Icarus approaches within 0.19 au of the Sun. At that distance, the equilibrium sub-solar point temperature is expected to lie between 600 and 900 K. Jewitt & Li (2010) found that at temperatures within this range, certain mineral compounds undergo extensive structural changes, possibly through the mechanism of thermal fatigue (Delbo et al. 2014). It is possible that a combination of cratering history, spin evolution, and repeated close approaches to the Sun have modified the surface of Icarus in such a way as to substantially lower its radar albedo.

Finally, we point out that the equivalent diameter determined herein adds to the list of conflicting sizes estimates for Icarus in the literature. Using various thermal models, Harris (1998) found a diameter of anywhere between 0.88 and 1.27 km. Mainzer et al. (2012) determined a diameter of 1.36 $\pm 0.43$ km using NEOWISE data at 3.4, 4.6, and 12 $\mu$m and the Near-Earth Asteroid Model (NEATM; Harris 1998). Following their 1999 CW measurements of Icarus, Mahapatra et al. (1999) calculated a diameter between 0.6 and 0.8 km, assuming the spin pole reported by De Angelis (1995). Finally, a diameter can be calculated from the expression (Fowler & Chillemi 1992)

$$D = \frac{10^{-0.4M_\odot} 1329}{\sqrt{p_V}},$$

which, coupled with the measured H-magnitude of 16.3 (Harris 1998) and geometric albedo $p_V$ of 0.14 (Thomas et al. 2011), yields a diameter of 1.95 km. More recent light-curve measurements obtained at large phase angles yield $H = 15.5$ (Warner 2015), which corresponds to a diameter of 2.80 km. We found an equivalent diameter of 1.44 km with 18% uncertainties.

6. Conclusions

In this work, we analyzed Arecibo and Goldstone radar observations of 1566 Icarus to estimate its size, shape, scattering properties, orbital parameters, and Yarkovsky drift. These results suggest that this object has unusual surface properties and resolves long-standing questions about the object’s size.

We presented the first use of our orbit-determination software and demonstrated its ability to generate accurate radar ephemerides and to determine the magnitude of subtle accelerations such as the Yarkovsky effect.

A.H.G., J.L.M., and A.K.V. were funded in part by NASA Near-Earth Object Observations Program grant NNX14AM95G and NSF Planetary Astronomy Program grant AST-1109772. Part of the work done here was conducted at Arecibo Observatory, which is operated by SRI International under a cooperative agreement with the National Science Foundation (AST-1100968) and in alliance with Ana G. Mendez-Universidad Metropolitana (UMET), and the Universities Space Research Association (USRA). The Arecibo Planetary Radar Program is supported by the National Aeronautics and Space Administration under grant Nos. NNX12AF24G and NNX13AQ46G issued through the Near-Earth Object Observations program. Some of this work was performed at the Jet Propulsion Laboratory, which is operated by Caltech under contract with NASA. This work was enabled in part by the Mission Operations and Navigation Toolkit Environment (MONTE). MONTE is developed at the Jet Propulsion Laboratory. The material presented in this article represents work supported in part by NASA under the Science Mission Directorate Research and Analysis Programs.

Appendix A

Yarkovsky Acceleration

For an object with diameter $D$, at a distance from the Sun at time $t$ of $r$, the energy absorbed per second is

$$E = \frac{L_\odot}{4\pi r^2} \frac{\pi}{2} \left(\frac{D}{2}\right)^2,$$

assuming perfect absorption.

The acceleration $\ddot{r}$ is equal to the photon momentum absorbed, $\dot{p}_r$, over the mass of the object, $m$.

$$\ddot{r} = \frac{\dot{p}_r}{m} = \frac{E}{c} \frac{1}{m} = \frac{L_\odot}{4\pi r^2} \frac{\pi}{2} \left(\frac{D}{2}\right)^2 \frac{1}{c} \frac{1}{m}.$$
Expressing the object mass in terms of density, $\rho$, and $D$, yields
\[
\dot{r} = \frac{L_\odot}{4\pi r_i^2} \pi \left(\frac{D}{2}\right)^2 \frac{1}{c} \frac{1}{4\pi} \left(\frac{D}{2}\right)^3 \rho
\]
\[
= \frac{3}{8\pi} \frac{L_\odot}{c} \frac{1}{r_i^2} \frac{1}{D\rho} \dot{r}.
\]
This acceleration is applied in the positive radial direction (in heliocentric coordinates).
\[
\dot{r} = \frac{3}{8\pi} \frac{1}{D\rho} \frac{L_\odot}{c} \frac{1}{r_i} \dot{r}.
\]
Because it is purely radial, this acceleration will not cause a measurable change in the orbit.

However, the absorbed photons will eventually be re-radiated and induce an acceleration upon emission as well. Since the object is rotating about some spin axis $\hat{\rho}$, this secondary acceleration will not (necessarily) occur along a radial direction. Furthermore, given that all the absorbed photons must eventually be re-radiated, we can express the magnitude of this secondary acceleration in the same manner as its radial counterpart. Here we define a phase lag, $\phi$, to describe at what rotational phase (relative to the sub-solar longitude) the majority of the photons are re-emitted, and an efficiency factor, $\xi$, which is tied to the effective acceleration if one assumes that all photons are re-emitted with phase lag $\phi$. $X_\hat{\rho}(\phi)$ is the rotation matrix of angle $\phi$ about $\hat{\rho}$.
\[
\dot{r} = \frac{\xi}{8\pi} \frac{1}{D\rho} \frac{L_\odot}{c} \frac{1}{r_i} X_\hat{\rho}(\phi) \dot{r}.
\]

The Yarkovsky effect is caused by this *non-radial* secondary acceleration.

### Appendix B

**Historical Data Concerning 1566 Icarus’s Spin Pole Orientation**

For the purpose of facilitating bandwidth comparisons, we normalize all bandwidths to the Arecibo S-band frequency of 2380 MHz and label the corresponding unit S-Hz. Except where otherwise noted, the bandwidths discussed here are relayed as they were reported in the corresponding articles—i.e., without any corrections applied for specularity. We also note the distinction between reported half-power bandwidths and zero-crossing bandwidths.

#### B.1. Pettengill et al. 1968 Radar Observations

The radar detection of Icarus by Pettengill et al. (1969) on 1968 June 13 marked the first detection of an asteroid with radar. These observations were conducted at the Haystack Observatory at a frequency of 7840 MHz. A second set of observations took place on 1968 June 15. Pettengill et al. (1969) observed half-power Doppler extents of 70 Hz on June 13 and 13 Hz on June 15. Because both sets of observations spanned multiple rotations of Icarus, the change in bandwidth cannot be attributed to the shape of the object.

The bandwidth reported on June 13 is overestimated for two reasons. First, the authors reported a drift of their data-taking ephemeris by 8 Hz over the data-taking period, indicating that the echo was at most 62 Hz. Second, the authors applied a variety of smoothing windows (8, 16, 32, and 64 Hz) and reported only the spectrum with the maximum S/N, which they obtained with the 64 Hz smoothing window. Because the convolution operation broadened the echo, we estimate that the original intrinsic echo was between 32 and 62 Hz.

Thus, the June 13 Pettengill et al. (1969) half-power bandwidth correspond to a value between 9.7 S-Hz and 19 S-Hz, and the June 15 bandwidth corresponds to 4.0 S-Hz.

#### B.2. Goldstein 1968 Radar Observations

Goldstein (1969) detected Icarus between 1968 June 14 and 16 with a bistatic configuration at Goldstone. The frequency was 2388 MHz and the reported half-power bandwidth for observations between June 15 04:30 UT and June 16 10:00 UT is about 7 Hz (or 7 S-Hz).

#### B.3. Gehrels et al. 1968 Light-curve Observations

Light-curve observations of Icarus between 1968 June 14 and June 21 were analyzed by Gehrels et al. (1970) and re-analyzed by De Angelis (1995). Gehrels et al. (1970) reported a spin-axis orientation of $\beta = 0^\circ \pm 3^\circ$, $\lambda = 223^\circ \pm 3^\circ$ or $49^\circ \pm 3^\circ$, whereas De Angelis (1995) found $\beta = 5^\circ \pm 5^\circ$, $\lambda = 214^\circ \pm 5^\circ$. These spin poles do not appear to be consistent with most of the radar CW bandwidths observed during the 1968, 1996, or 2015 apparitions (Table 9).

#### B.4. Mahapatra et al. 1996 Radar Observations

Mahapatra et al. (1999) used Goldstone and observed a zero-crossing Doppler bandwidth of 35 Hz at 8510 MHz. Because they used a 10 Hz smoothing window, the intrinsic bandwidth could be 35–45 Hz, or a value between 9.8 and 12.6 S-Hz.

### Appendix C

**Attempts to Fit a Lower Specularity**

The specularity reported in this work for 1566 Icarus is unusually high. When originally fitting the shape and scattering properties for this object, we initially forced a lower specularity on our models. After many such attempts, we came to the conclusion that a diffusely scattering surface did not match the data we observed.

Figure 6 demonstrates what an attempted fit to Icarus’s CW spectra and delay-Doppler images looks like when the specularity is fixed to a lower value of $C = 2$ and a “cos” scattering law is utilized. This scattering behavior can be defined with respect to the differential radar cross section per surface element area (Section 3.1.1), via

\[
\frac{d\sigma}{dA} = R(C+1)\cos^2C \theta.
\]

These fits are the result of allowing all other model parameters (ellipsoid axis ratios, signal scaling parameters, etc.) to float and performing a full fit on the same data set used for the results reported in this article. The best-fit model has an equivalent diameter of 1.05 km and, as the figure demonstrates, results in a poor fit to the data. Note in particular that while the bounds of the model spectrum are approximately equal to the bounds of the data spectrum, the shape of the spectra do not match. In addition, the signal in the delay-Doppler image does not drop off fast enough as range from the observer increases. The fast drop-off noted in the data necessitates a specular
model. Such a model can be realized with either a two-component “cos” scattering law or a “hagfors” scattering law.

Appendix D
Additional Evidence of Yarkovsky Detection

We performed a variety of analyses to test the rigor of our Yarkovsky result (Section 4.5).

D.1. Screening Test

We re-ran our Yarkovsky analysis with an independently curated set of optical and radar astrometry (Jon Giorgini, pers. comm.). This data set has been screened for potential outliers and faulty measurements using a gravity-only model, with around 20% of the original astrometric data being discarded. Our analysis of these data (931 optical astrometric points and 23 radar astrometric points from 1949 to 2015) yielded a drift in semimajor axis of 

\[ \frac{da}{dt} = -4.0 \pm 0.9 \times 10^{-4} \text{ au My}^{-1} \]

when including both radar and optical astrometry and

\[ \frac{da}{dt} = -3.8 \pm 1.1 \times 10^{-4} \text{ au My}^{-1} \]

when including optical astrometry only (Table 8).

As a further verification, one of us (J.L.M.) used the software he developed in previous work (Nugent et al. 2012) with this independently screened data set and found 

\[ \frac{da}{dt} = (-3.6 \pm 1.0) \times 10^{-4} \text{ au My}^{-1} \] (Table 8).

D.2. Prediction Test

One way to analyze the accuracy of a Yarkovsky result is to check its predictive power when compared to a gravity-only dynamical model. Instead of collecting additional astrometry, which is not straightforward, we can simulate a prediction by re-analyzing a subset of the data before some fiducial point in time, \( t_f \), and then checking how the resulting trajectory fares at predicting observations that were taken after \( t_f \).

The first range measurement of Icarus was obtained from Goldstone on 2015 June 14 (Table 2). We therefore chose 2015 June 13 23:50 UT as \( t_f \). We fit a Yarkovsky model to the data taken before \( t_f \) (936 optical observations and 11 radar observations, from which 55 optical observations were discarded as outliers), and found a semimajor axis drift rate

\[ \frac{da}{dt} = -3.8 \pm 1.1 \times 10^{-4} \text{ au My}^{-1} \] (Table 8).

\[ \frac{da}{dt} = -3.6 \pm 1.0 \times 10^{-4} \text{ au My}^{-1} \] (Table 8).

\[ \frac{da}{dt} = -4.0 \pm 0.9 \times 10^{-4} \text{ au My}^{-1} \] (Table 8).

\[ \frac{da}{dt} = -3.8 \pm 1.1 \times 10^{-4} \text{ au My}^{-1} \] (Table 8).
of \( \langle \dot{a} / dt \rangle = (-3.7 \pm 0.7) \times 10^{-4} \text{ au My}^{-1} \). This fit yielded a goodness-of-fit of \( \chi^2 = 634 \). We also fit a gravity-only model to the same set of data, which resulted in a goodness-of-fit of \( \chi^2 = 662 \). We then compared how well these best-fit trajectories could predict the first Icarus range measurement on 2015 June 14. The best-fit Yarkovsky model residual for this prediction was 97 km, while the best-fit gravity-only model residual was 267 km. This demonstrates that the Yarkovsky model more accurately predicted a future measurement than the gravity-only model.

### D.3. Incorporation Test

Another test of rigor is an incorporation test. After performing the prediction test described above, we then added the first Doppler and range measurements of 2015 and fit both a gravity-only model and a Yarkovsky model once again. No additional outlier rejection was allowed. With these new Doppler and range measurements, the best-fit semimajor axis drift rate for the Yarkovsky model is \( \langle \dot{a} / dt \rangle = (-4.7 \pm 0.5) \times 10^{-4} \text{ au My}^{-1} \). The goodness-of-fit for the Yarkovsky model is \( \chi^2 = 638 \), or a <1% increase as compared to the Yarkovsky fit prior to including the new radar measurements. The best-fit gravity-only model yielded a goodness-of-fit of \( \chi^2 = 719 \), or a 9% increase as compared to the gravity-only fit prior to including the new radar measurements. These results suggest that incorporating the first Icarus radar measurements into a gravity-only model results in a general degradation in the quality of the fit to optical observations. However, these same radar measurements can be included in a Yarkovsky model with no appreciable effect on the goodness-of-fit.

### D.4. Combined Test

Finally, we re-ran both the prediction test and the incorporation test described above on the curated data set. The best-fit Yarkovsky model fit to data taken before \( t_f \) yielded a drift in semimajor axis of \( \langle \dot{a} / dt \rangle = (-3.53 \pm 1.11) \times 10^{-4} \text{ au My}^{-1} \) and a goodness-of-fit of \( \chi^2 = 172 \), while the gravity-only model had a goodness-of-fit of \( \chi^2 = 182 \). The Yarkovsky model predicted the first Goldstone range measurement with a residual of 43 km, while the gravity-only model predicted residual for that data point was 128 km. For the incorporation test, we again added the first Goldstone Doppler and range measurements to the data set. For the Yarkovsky model, the best-fit drift in semimajor axis was \( \langle \dot{a} / dt \rangle = (-3.95 \pm 0.97) \times 10^{-4} \text{ au My}^{-1} \), with a goodness-of-fit of \( \chi^2 = 173 \), or an increase of <1% as compared to the Yarkovsky fit prior to adding the new radar measurements. The best-fit gravity-only model had a goodness-of-fit of \( \chi^2 = 189 \), or a 4% increase as compared to the gravity-only model fit prior to adding the new radar measurements. Note that these fits were performed on a data set for which outlier rejection had been performed assuming a gravity-only model—even so, a gravity-only model still required a marked decrease in fit quality in order to incorporate the first radar measurements, while the Yarkovsky model saw no appreciable change in goodness-of-fit.

### D.5. Summary

The tests that we performed are summarized in Table 10 and Table 11 and confirm the robustness of the Yarkovsky detection.
