Trans-pQTL study identifies immune crosstalk between Parkinson and Alzheimer loci

**ABSTRACT**

**Objective:** Given evidence from genetic studies, we hypothesized that there may be a shared component to the role of myeloid function in Parkinson and Alzheimer disease (PD and AD) and assessed whether PD susceptibility variants influenced protein expression of well-established AD-associated myeloid genes in human monocytes.

**Methods:** We repurposed data in which AD-related myeloid proteins CD33, TREM1, TREM2, TREML2, TYROBP, and PTK2B were measured by flow cytometry in monocytes from 176 participants of the PhenoGenetic Project (PGP) and Harvard Aging Brain Study. Linear regression was used to identify associations between 24 PD risk variants and protein expression. The 2 cohorts were meta-analyzed in a discovery analysis, and the 4 most strongly suggestive results were validated in an independent cohort of 50 PGP participants.

**Results:** We discovered and validated an association between the PD risk allele rs12456492G in the RIT2 locus and increased CD33 expression ($p_{	ext{joint}} = 3.50 \times 10^{-5}$) and found strongly suggestive evidence that rs11060180A in the CCDC62/HIP1R locus decreased PTK2B expression ($p_{	ext{joint}} = 1.12 \times 10^{-4}$). Furthermore, in older individuals, increased CD33 expression on peripheral monocytes was associated with a greater burden of parkinsonism ($p = 0.047$), particularly bradykinesia ($p = 6.64 \times 10^{-3}$).

**Conclusions:** We find that the rs12456492 PD risk variant affects expression of AD-associated protein CD33 in peripheral monocytes, which suggests that genetic factors for these 2 diseases may converge to influence overlapping innate immune-mediated mechanisms that contribute to neurodegeneration. Furthermore, the effect of the rs12456492G PD risk allele on increased CD33 suggests that the inhibition of certain myeloid functions may contribute to PD susceptibility, as is the case for AD. *Neurol Genet* 2016;2:e90; doi: 10.1212/NXG.0000000000000090

**GLOSSARY**

AD = Alzheimer disease; DLPFC = dorsolateral prefrontal cortex; eQTL = expression quantitative trait locus; GWAS = genome-wide association study; HABS = Harvard Aging Brain Study; PD = Parkinson disease; PGP = PhenoGenetic Project; pQTL = protein quantitative trait locus; ROS-MAP = Religious Orders Study and Memory and Aging Project; SNP = single nucleotide polymorphism.

Parkinson disease (PD) and Alzheimer disease (AD) are clinically distinct neurodegenerative diseases; however, their pathologic features (e.g., Lewy bodies and tau tangles) and certain clinical traits (e.g., parkinsonism and dementia) are often found together in older individuals with these syndromic diagnoses.1-3 In addition, microglia and macrophages have been implicated in both PD and AD pathogenesis, and the myeloid-specific gene TREM2 has been implicated in both PD and AD susceptibility,4,5 suggesting a common role for the innate immune system in both diseases.6-8 To underscore further a role for the innate immune system in both PD and AD,
our group recently found that multiple PD and AD susceptibility variants influenced the RNA expression of nearby genes: they were cis-expression quantitative trait loci (eQTLs) primarily in monocytes.9,10 Thus, it appears that the functional consequences of AD and PD risk alleles may converge in influencing innate immune pathways.11

Given the results of our initial eQTL analysis, we hypothesized that PD-associated single nucleotide polymorphisms (SNPs) could have protein QTL effects with innate immune AD susceptibility genes in trans. To test this, we took advantage of a previously generated data set of protein expression levels of AD-related myeloid genes, TREML2, TREM1, TREM2, TYROBP, PTK2B, and CD33 in monocytes from 226 genotyped participants of the PhenoGenetic Project (PGP) and the Harvard Aging Brain Study (HABS).12 In the analyses presented here, we determined whether 24 validated PD susceptibility SNPs (table 1) influenced the expression of these 6 AD-related proteins in a discovery analysis and then validated the top results in an independent set of participants.

**METHODS** We used the same methodology as the one used in a previous study.12 Additional information is included in the e-Methods at Neurology.org/ng.

**Standard protocol approvals and patient consent.** Experiments, including blood draws, brain autopsies, and data analysis, were done in compliance with protocols approved by either the Partners Human Research Committee or the Rush University Institutional Review Board. Written, informed consent was obtained from all participants.

**PhenoGenetic Project.** For this study, cryopreserved peripheral blood mononuclear cells derived from healthy, genotyped participants of the PGP, a living biobank, from Brigham and Women’s Hospital in Boston, MA, were used. To date, 1,753 self-reported healthy participants, ranging in age from 18 to 50, have been recruited. Of the participants, 71% are Caucasian and 62.7% are female. The genome-wide genotype data to determine ancestry.

**Harvard Aging Brain Study.** Neuroimaging was used to identify cognitively nonimpaired, healthy older individuals with increases in brain amyloid in the longitudinal HABS. Participants range in age from 65 to 90. Currently, 276 participants are enrolled in the study; 81% are Caucasian and 59.4% are female. These individuals undergo clinical and neuroimaging evaluations, as described previously.13 Of the HABS participants, 161 have been genotyped, and the EIGENSTRAT program was used to determine ancestry. All the individuals in the current study are of European ancestry (n = 61).

b Used proxy variant rs115462410.

**Religious Orders Study and Memory and Aging Project.** Similar to HABS, the Memory and Aging Project (MAP) and Religious Orders Study (ROS) are longitudinal aging studies. Participants are recruited while cognitively nonimpaired and undergo annual clinical assessments in addition to agreeing to donate their brains at the time of death under the Anatomic Gift Act. Detailed antemortem clinical and neuropathologic assessments are performed for each participant. Parkinsonism was assessed by trained nurses at study entry and was based on 26 items from a modified version of the motor section of the Unified Parkinson’s Disease Rating Scale.14 Four previously established parkinsonian sign scores (bradykinesia, rigidity, tremor, and gait disturbance) were derived from these 26 items, and a summary global parkinsonian sign score was constructed by averaging these 4 scores, as detailed in prior publications.15–17 The retention rate and autopsy rate of participants exceeds 90% and 80%, respectively. A detailed report of MAP and ROS can be found elsewhere.16–18 All individuals with CD33 monocyte surface protein expression (n = 151) and those with PTK2B RNA expression from the dorsolateral prefrontal cortex (DLPFC) (n = 508) were determined to be of European ancestry by using EIGENSTRAT.
Statistical analysis. In summary, 24 SNPs previously identified in a PD genome-wide association study (GWAS) were selected for the study. Our analysis was limited to 144 SNP:protein pairs (24 SNPs × 6 proteins) in the discovery phase. Four SNP:protein pairs with the lowest, most suggestive p values were selected for follow-up in the validation phase. To identify statistically significant

(1)

\[ Z = \sum_{i=1}^{n} w_i \frac{Z_{i,j}}{\sqrt{n_i}} \]  

(2)

\[ w_i = \sqrt{n_i} \]

\[ n_i = \text{sample size of experiment } i. \]

RESULTS Protein expression of genes thought to be important for AD (TREM1, TREM2, TYROBP, and CD33) was previously measured using flow cytometry in primary human monocytes from 115 younger, healthy participants of PGP and 61 older, cognitively nonimpaired participants from HABS in a quantitative trait study with AD susceptibility variants: PTK2B protein expression was also measured in a subset of 66 PGP participants and in all HABS participants. We repurposed this data set to determine whether the 24 PD susceptibility variants previously identified in GWAS (table 1) were associated with measured protein expression. We meta-analyzed the 2 cohorts (PGP and HABS) in a discovery phase analysis to identify suggestive results and then validated these results in an independent cohort consisting of 50 PGP participants. A joint analysis combining individuals from the discovery and validation phases was also performed to summarize all available data. Together, the 165 PGP participants had a mean age of 33.7 (±10.59) years and were 40.6% male, while HABS participants had a mean age of 76.3 (±6.08) years and were 50.8% male.

In the discovery phase, 4 PD SNP:AD protein pairs with the lowest, most suggestive p values (rs11060180:CD33 [\( p_{\text{disc_meta}} = 7.38 \times 10^{-4} \]), rs12456492:CD33 [\( p_{\text{disc_meta}} = 2.14 \times 10^{-3} \]), rs11060180:PTK2B [\( p_{\text{disc_meta}} = 0.011 \]), and rs12637471:TYROBP [\( p_{\text{disc_meta}} = 0.011 \)] [table 2; table e-1]) were selected for validation in an independent experiment (n = 50). Among the 4 SNP:protein pairs, only the rs12456492:CD33 association was validated after Bonferroni correction (\( p_{\text{cut-off}} = 2.5 \times 10^{-3} \) [\( p = 0.01/4 \)]) [\( p_{\text{val}} = 2.39 \times 10^{-3} \), \( p_{\text{joint}} = 3.50 \times 10^{-3} \); table 2; table e-2] with the direction of effect being consistent in the discovery and validation analyses. Although the influence of rs11060180 on PTK2B expression was only suggestive in the validation phase (\( p_{\text{val}} = 0.028 \); table 2), it was the only other association aside from rs12456492:CD33 in the joint analysis to pass the global Bonferroni threshold (\( p_{\text{joint}} = 1.12 \times 10^{-3} \); table 2; table e-3) and had a consistent direction of effect in both data sets. Furthermore, we applied

### Table 2

a Meta-analysis p value for the discovery phase (discovery PGP and HABS participants combined).

b The 4 associations were tested independently in a validation phase (Bonferroni cutoff is \( p = 2.5 \times 10^{-3} \) [\( p = 0.01/4 \)]).

c Joint p value combining discovery and validation phases.
a permutation-based analysis to all 144 hypotheses tested, in which the false discovery rate (FDR) was derived from 10,000 permutations of the data (genotype was permuted). In this analysis, both the rs11060180:PTK2B and rs12456492:CD33 associations were the only associations to yield FDR = 0.05 (table e-4). Thus, our 2 main results were unlikely to be chance observations.

Consistent with the previously reported rs3865444C:CD33 AD risk allele,13 the PD risk allele rs12456492G in the RIT2 locus was associated with increased CD33 surface expression on monocytes (figure, A) and explained 7.6% of the variance in CD33. Conversely, the suggestive rs11060180A risk allele near CCDC62/HIP1R was associated with decreased PTK2B expression (figure, B) and explained 8.5% of the variance in PTK2B; this result contrasts with the PTK2B and NME8 AD susceptibility variants rs28834970C and rs2718058A, respectively, which we have previously reported to be associated with higher levels of PTK2B expression in this data set.12 To determine whether these trans associations were present at the mRNA level, we analyzed mRNA expression in monocyte ImmVar data13 and in DLPFC tissue from the Religious Orders Study and Memory and Aging Project (ROS-MAP). Brain tissue was analyzed because infiltrating CNS monocytes and brain-resident microglia, cell types that are known to express the measured proteins, are thought to play a critical role in the accumulation of AD pathology. Neither rs12456492 nor rs11060180 had an association with CD33 or PTK2B mRNA, respectively, in either data set.

Intrigued by the evidence suggesting that AD-associated proteins CD33 and PTK2B may play a role in PD, we examined the extent of association of PD-related pathologic (neuronal loss in the substantia nigra, burden of Lewy bodies) and clinical (parkinsonism as well as its component measures of bradykinesia, rigidity, and gait impairment) traits with ROS-MAP monocyte CD33 surface expression (repurposing a previous data set13) and ROS-MAP DLPFC PTK2B mRNA expression (the only PTK2B expression data available from this cohort). We did not observe an association of PTK2B mRNA expression in DLPFC with these traits. However, we did note a nominal association of increasing CD33 monocyte protein surface expression with a greater global measure of parkinsonism (p = 0.047) that appeared to be primarily driven by an effect on bradykinesia (p = 6.64 × 10⁻³).

**DISCUSSION** We conducted a trans-pQTL study in human ex vivo monocytes examining the relationship between PD risk variants and expression of AD-related proteins TREM1, TREM2, TREML2, TYROBP, PTK2B, and CD33 to detect whether AD and PD pathophysiology share common innate immune mechanisms. We discovered that the PD risk allele rs12456492 in the RIT2 locus was associated with increased CD33 surface expression and found highly suggestive evidence that the rs11060180 PD risk allele in the CCDC62/HIP1R locus was associated with lower PTK2B expression. Of interest, these trans associations were not observed at the mRNA level, highlighting the importance of protein-level QTL studies, which can capture effects of posttranslational regulation.22

PTK2B, a member of the focal adhesion kinase family, is a protein tyrosine kinase that is rapidly activated by a number of mediators including lipopolysaccharide, cytokines, and cell adhesion23,24 and is thought to play an important role in the phagocytosis and migration of monocytes and macrophages through its involvement in cytoskeletal signaling pathways.25 In a GWAS, rs28834970 in the PTK2B locus was identified as having a significant association with AD susceptibility,26 and we have been able to confirm that rs28834970 has both a cis-eQTL and cis-pQTL effect on PTK2B expression in monocytes.9,16 Although the effect of the CCDC62/HIP1R rs11060180 PD risk allele on decreasing PTK2B is opposite of that in AD
(in which risk variants are associated with increased PTK2B), the effect of rs11060180 was consistent across our discovery and validation studies. Thus, while certain immune molecular pathways may be implicated in both PD and AD, they may not have the same role in the 2 diseases. This is not unlike a number of susceptibility alleles that are associated with different inflammatory diseases but have effects in opposite directions (being risk-associated for one disease and protective for another).12,27 In addition, we did not detect an association between PTK2B mRNA cortical expression and PD-related traits in the ROS-MAP cohort; however, an analysis of a PD-specific cohort would provide a complementary analysis that would be more relevant for the context of PD.

The AD-associated protein CD33 is a sialylated siglec expressed on the surface of myeloid cells and contains putative immunoreceptor tyrosine–based inhibitory motifs that are known to suppress cellular activity such as proinflammatory cytokine secretion and amyloid beta uptake.13,28 Not only has such an effect been implicated in AD through GWAS,26,29–31 but the effect of the CD33 rs38654442 risk allele on increased CD33 protein expression31,32 as well as CD33’s effect on amyloid accumulation in humans and mouse models of AD has been reported. In our study, we found that the rs12456492 Parkinson risk allele in the RIT2 locus was associated with increased CD33 expression, consistent with the CD33 AD risk allele, which suggests that myeloid suppression is associated with PD susceptibility, as is the case for AD. Of note, we found that CD33 protein surface expression on monocytes of older individuals was modestly associated with bradykinesia, implicating CD33 in PD pathogenesis in addition to AD. These intriguing results will be important in guiding future studies examining the role of CD33 in both diseases.

Growing evidence indicates that the innate immune system plays an important role in PD and AD pathophysiology, but it remains unclear whether overlapping signaling pathways are involved. Our pQTL study revealing that the AD-associated protein CD33 is modulated by a PD susceptibility locus and that increased CD33 monocyte surface expression is correlated with both PD and AD clinical traits suggests that, although PD and AD causal variants are distinct, some of them may converge on the same signaling pathways. Furthermore, the association of increased CD33 with PD risk provides the insight that myeloid suppression is a risk factor for PD. It is also not clear whether the effects we report in peripheral monocytes contribute to PD directly by influencing the behavior of infiltrating cells that differentiate into macrophages or whether these associations reflect shared effects with resident microglia. While we report some overlap between the effects of AD and PD variants in monocytes, it is important to note that the bulk of the monocyte molecular pathways implicated in each disease appears to be unique (as evidenced by opposing relationships in PTK2B expression between PD and AD risk alleles), which suggests that therapeutic approaches to target immune pathways in PD and AD may have to be considered carefully to avoid provoking another neurodegenerative process as an adverse event. Although more work will be needed to verify these associations in macrophages and microglial at the sites of pathology, our findings begin to shed light onto common immune mechanisms contributing to both PD and AD, which may aid in the development of therapeutic strategies used to target each disease.
